HARMSWORTH SELF-EDUCATOR

1906

Vol. III. Pages 1777—2640

A KEY TO THE HARMSWORTH SELF-EDUCATOR

At the heading of each article in the Self-Educator is the number of the group to which the article belongs, and a reference to this key indicates precisely the place of the article in the scheme of the book. This key, therefore, enables the student at any time to understand what has preceded and what is to follow any part of the work to which he may happen to turn.

Group 1.

Agriculture. Beekeeping. Gardening.

Farming. In all its Branches. Dairying. Poultry.
Beekeeping. A Practical and Commercial Course.
Gardening. How to Get the Most out of a Minimum of Land. Gardening for Pleasure and Profit. Market Gardening.

Group 2.

Art. Architecture. Glass. Earthenware. Carving.

Art (Theory and Training). Painting. Sculpture. Architecture (Theory. Styles. Practical Training). History of Art.
Glass and Earthenware. Including Pottery.
Carving. Wood. Bone. Ivory. Horn. Tortoiseshell.

Group 3.

Biology. Psychology. Sociology. Logic. Philosophy. Religion.

Biology. Including Evolution. Palæontology. Heredity. Anthropo[illegible]
[illegible]
Sociology. Including Politi[illegible]
Logic and Philosophy. The Science of Reasoning and Philosophical Systems.
Religion. History and Systems. Christianity.

Group 4.

Building. Cabinet Making. Upholstering. Fire.

Building. Excavating. Drainage. Manufacture of Bricks, Limes, and Cements. Bricklaying. Clay Wares. Reinforced Concrete. Masonry. Carpentry. Slates and Tiles. Plumbing. Joinery. Foundry and Smiths' Work. Painting, Paper Hanging and Glazing. Heating, Lighting, and Ventilation. Building Regulations. Building Abroad. In Business as a Builder.
Cabinet Making and Upholstering.
Fire. Fireproof Materials. Fire Prevention. Fire Extinction.

Group 5.

Chemistry and Applied Chemistry.

Chemistry. Inorganic and Organic. Chemistry of the Stars.
Applied Chemistry. Acids and Alkalies. Oils (Fixed Oils and Fats; Waxes; Essential Oils and Perfumes; Paints and Polishes). Candles. Soaps. Glycerine. Glues and Adhesives. Starches. Inks. Tar and [illegible] Uses of Paper). Photography.

Group 6.

Civil Service. Army and Navy.

Civil Service. Municipal. National. Imperial.
Army and Navy. How to Enter Them.

Group 7.

Clerkship and the Professions.

Clerkship and Accountancy. Complete Training. Bookkeeping.
Banking. The Whole Practice of Banking.
Insurance. Life, Fire, Accident, Marine.
Auctioneering and Valuing. Practical Training.
Estate Agency. Departments and Officials of a Great Estate. Training a Land Agent.
Medicine. Training of a Doctor. Specialists. Veterinary Surgeons. Chemists and Druggists. Dentistry: The Dental Mechanic. Home and Professional Nursing.
Church. How to Enter the Ministry of all Denominations.
Scholastic. Teachers. Professorships. Governesses. Coaches. Tutors.
Secretaries, etc. Institution Officials. Political Organisations. Lecturers.
Law. Solicitors and Barristers. Personal and Commercial Law.

Group 8.

Drawing and Design.

Drawing. Freehand. Object. Geometrical. Brush. Memory. Light and Shade.
Technical Drawing. For Engineers; Coppersmiths, Tinmen, Boilermakers; Architects; Stonemasons; Carpenters and Joiners; Plumbers.
Design. Book Decoration. Textiles. Wall Papers. Metal Work.

Group 9.

Dress.

Dress. Dressmaking. Underclothing. Children's Clothing. Tailoring. Millinery. Men's Hats. Furs and Furriers. Feathers. Shirts and Collars.

Group 10.

Electricity.

Electricity. Electrical Engineering. Telegraphs and Telephones (including operation of). Cables and Insulated Wire. In Business as an Electrical Engineer.

Group 11.

Civil Engineering.

Civil Engineering. Surveying. Varieties of Construction. Machines Employed. Roads. Bridges. Tramways. Railways. Water Supply. Sewerage. Refuse. Hydraulics. Pumps. Harbours. Docks. Lighthouses. Foreign Work. In Business as a Civil Engineer.

Group 12.

Mechanical Engineering. Military Engineering. Arms & Ammunition.

Mechanical Engineering. Applied Mechanics. Workshop Practice. Tools (Hand and Miscellaneous. Machine Tools. Portable Machine Tools). Machines and Appliances (A General Guide to Construction. Clocks and Watches. Scientific Instruments).
Military Engineering. Pontoons. Bridges. Fortifications. Rafts. Trenches. Passing Rivers. Conditions in Peace and War.
Arms and Ammunition. Manufacture of Arms and Explosives.

Group 13.

Geography. Astronomy.

Geography. Physical. Political. Human. Commercial.
Astronomy. A Survey of the Solar System.

Group 14.

Geology. Mining. Metals and Minerals. Gas.

Geology. A Course in Geology.
Mining. The Practice of Mining: Coal, Gold, Diamonds, Tin, etc.
Metals. Metallurgy. Iron and Steel. Iron and Steel Manufactures. Metal Work. Cutlery.
Minerals. Mineralogy. Properties of Minerals.
Gas. Manufacture of Gas.

Group 15.

History

History. A Short History of the World.

Group 16.

Housekeeping and Food Supply.

Servants. Qualifications and Duties of Every Kind of Servant.
Cookery. A Practical Course.
Laundry Work. Washing. The Laundry as a Business.
Foods and Beverages. Milling. Bread-making. Biscuits and Confectionery. Sugar. Condiments. Fruit. Fisheries. Food Preserva[illegible]

Group 17.

Ideas. Patents. Applied Education.

Ideas. The Power of Ideas in Life. Brains in Business.
Patents and Inventions. How to Protect an Idea.
Applied Education. Application of Education in Every Walk of Life.

Group 18.

Languages.

Latin. English. French. German. Spanish. Italian. Esperanto.

Group 19.

Literature. Journalism. Printing. Publishing. Libraries.

Literature. A Survey of the World's Great Books and their Writers. Poetry. Classics. Fiction. Miscellaneous. How to Read and Write.
Journalism. A Guide to Newspaper Work, with Practical Training.
Printing. Composing by Hand and Machine. Type Cutting and Founding. Engraving and Blocks. Bookbinding and Publishing
Libraries. Officials and Management of Libraries.

Group 20

Materials and Structures. Leather. Wood Working.

[illegible] h of Materials.
Structures. The Stability of Structures.
Leather. Leather Industry. Leather Belts. Boots and Shoes. Saddlery and Harness. Gloves. Sundry Leather Goods.
Wood Working. Design and Operation of Wood Working Machinery. Wood Turning. Miscellaneous Woodwork.

Group 21.

Mathematics.

Mathematics. Arithmetic. Algebra. Geometry. Plane Trigonometry. Conic Sections.

Group 22.

Music. Singing. Amusement.

Music. Musical Theory. Tonic Solfa. Tuition in all Instruments. Orchestration. Conducting. Bell Ringing. Manufacture of Musical Instruments
Singing. The Voice and Its Treatment.
Amusement. Drama and Stage. Business side of Amusement. Sports Officials.

Group 23.

Natural History. Applied Botany. Bacteriology. Natural Products.

Natural History. Kingdom of Nature. Its Marvels, Mechanism, and Romance. Animal Life. Flowers. Plants. Seeds, Trees, Ferns, Mosses, etc.
Applied Botany. Tobacco & Tobacco Pipes. Forestry. Rubber and Gutta Percha. Basket and Brush Making. Cane Work. Barks (Cork, Wattle).
Bacteriology. Pathological and Economic.
Natural Products. Sources. Values. Cultivation.

Group 24.

Physics. Power. Prime Movers.

Physics. A Complete Course in the Science of Matter and Motion.
Power. A General Survey of Power. Natural Sources. Liquid and Compressed Air.
Prime Movers. Engines. Steam. Gas. Heat. Turbines. Windmills.

Group 25.

Physiology. Health. Ill-health.

Physiology. Plan of the Body. Digestive, Circulatory. Respiratory, Locomotor and Nervous Systems. The Senses.
Health. The Five Laws of Health. Personal Hygiene. Environment. State Medicine and the Public Health.
Ill-health. General Ill-health. Its Special Forms. Common Ailments and Domestic Remedies.

Group 26.

Shopkeeping. Business Management. Publicity.

Shopkeeping. A Practical Guide to the Keeping of all Kinds of Shops
Business Management. The Application of System in Business.
Publicity. Advertising from all Points of View As a Business.

THE STATE LADDER OF LEARNING

II. Opportunities for Boys in the British Isles .. 1777

THE STATE LADDER OF LEARNING

II.* OPPORTUNITIES FOR BOYS IN THE BRITISH ISLES

By W. H. Stuart Garnett

"WHOSO has sixpence," said the Sage of Chelsea, "is monarch, to the extent of sixpence, over all men; he commands cooks to feed him, philosophers to teach him, kings to mount guard over him—to the extent of sixpence." But we have changed a good many things since Carlyle's day, and the student of the present commands philosophers to teach him even if the sixpence be wanting. Under the Customs and Excise Act of 1890, and the Education Acts of 1902 and 1903, the various local authorities have certain sums to administer, a part of which they are bound to devote to the purposes of higher education; and, as a matter of fact, most of the county and borough councils devote a large part of these sums to the provision of scholarships for the support of students of moderate means at the secondary schools and technical and university colleges throughout the kingdom.

Scotland's Ladder. The sums awarded by the local authorities in Scotland for the direct encouragement of education in this sense compare very unfavourably with those granted in the sister kingdom. Lanark—the county which has been most liberal in the allocation of bursaries to technical education—expended, in 1904, £1,572 in bursaries for the promotion of technical education, and £187 in bursaries for the promotion of secondary education; Kincardine also granted the large sum of £1,207 in bursaries, but this, on the other hand, was devoted entirely to the promotion of secondary education. For the most part, however, the sums granted in scholarships by the Scottish authorities are small, amounting for the whole of Scotland to £7,309 17s. granted to secondary, and £4,319 7s. 8d. granted to technical students.

On the other hand, Scotland has done better than England in the provision of schools and colleges. Since 1872 Scotland has had the advantage of a system of educational administration substantially the same as that introduced in England by the Education Acts of 1902-3, under which primary and secondary education are co-ordinated and controlled by a single authority. The result is that in all the larger towns excellent secondary schools are provided by the school boards, to which elementary school children are admitted by examination up to the age of 12 years, and in which a free education is given until the pupils are of age to enter the universities.

There is little, if any, social distinction between the secondary schools (whether they have free places or not) provided by the school boards and those which are not under the same control; and the most historic school in the country, the Royal High School, Edinburgh, the school of Walter Scott, which derives its title from a patent of James VI., is now managed by the Edinburgh School Board.

Ireland's Educational Institutions. In Ireland scholarships are divided into three classes, open to candidates below the ages of 16, 17, and 18 respectively, and are awarded to those students who attain a satisfactory standard at the examinations of the Irish Intermediate Board. In 1905, 225 scholarships were so awarded, the boys taking 159 and the girls 66. At first sight both the number and value of these scholarships compare rather unfavourably with the corresponding figures for the English counties, but the lower cost of all kinds of education in Ireland, and the extensive provision of free schools by the different religious societies, entirely prevent any grievance in this connection.

Unquestionably the real hardship under which the Irish student labours is the difficulty of obtaining a university education, if, like the majority of his countrymen, he hold the Catholic faith. The four university colleges of Ireland set out in one of the subjoined tables are all of a distinctly Protestant type, so that Catholic parents are, not unreasonably, unwilling to send their sons to institutions which they hold to be subversive of faith. Maynooth, on the other hand, is distinctly a clerical seminary, and does not lay itself out to provide the Catholic laity with a university education on broad lines.

There are certain Catholic colleges in the country, of which University College, Dublin, is the best and largest; but, on the whole, these are not equal to the larger and wealthier Protestant institutions, and the provision of means of education for the Irish Catholic must be regarded as sadly inadequate.

Wales. The provision of scholarships in Wales is in many districts unsatisfactory. The county of Glamorgan gives a large number, and Carnarvon is nearly as liberal; in the other counties, however, very few scholarships are given, and these are chiefly agricultural.

The first and second of this series of tables are an attempt to represent in a small compass the facilities for secondary education afforded to a boy resident in any part of the British Isles. The other tables show in the same way the means of university and technical education.

As far as primary education is concerned, the uniformity which prevails over the country makes it unnecessary to provide such a table. We shall only remark that in England and Wales primary education is provided by the local education authorities constituted by the Education Acts of 1902 and 1903; in Scotland the provision is made by the school boards under the Act of 1872; while in Ireland there are no public elementary schools, but the greater part of the burden of elementary education is borne by voluntary schools deriving the greater part of their maintenance directly from the State, but subject to parochial control.

There are also a large number of elementary and other schools in Ireland, some of them of a

very high order of merit, provided by various religious societies, of which the largest is the Society of Christian Brothers. The elementary schools of these societies, and many of their secondary schools, are entirely free, or else charge only a nominal fee; and, further, the ablest boys in the lower grade schools are frequently offered the opportunity of passing without cost through the higher and intermediate schools of the societies.

In the first table of First Grade Secondary Schools the first column shows the county or district under consideration. The second column shows the total sum awarded by the English and Welsh counties, and the boroughs within their geographical limits, in scholarships of any kind during the year 1903. Since that time many counties have raised their awards, but a complete statement on the subject is not yet obtainable.

In the third column of the first Secondary Schools table are shown the leading secondary schools situated in the different counties. The standard is not quite uniform; many schools have been omitted in the London district, and in some of the large provincial centres, that would have deserved mention had they been situated in Northumberland or Cornwall. A child is not, of course, confined to the schools of his, or her, own county. A boy living in Huntingdonshire, for instance, has numerous and excellent schools accessible in Bedford and Cambridge.

FIRST GRADE SECONDARY SCHOOLS OF SCOTLAND, IRELAND AND WALES

Total Grants: Scotland, £11,630. Ireland (Exhibits awarded in 1905), £6,160. Wales, £5,590

N.B. It must not be supposed that the descriptions "Protestant" and "Catholic" imply that the schools in question are closed to boys of other faiths. The Scholarships in Irish schools last generally for one year only.

Fees and Allowances. The fourth column of the first Seconday Schools table shows the fees for day boys and boarders in the different schools. In many cases these increase with the age of the boys. Where the second fee is not given, no provision is made for boarders, and in a few cases no day pupils are admitted. These fees are the inclusive charges made by the schools themselves. It does not necessarily follow that a boarder can live at the school at a cost to his parents of the fee mentioned. It would be absurd to suppose that it is possible to send a boy to Eton at a

cost of £162 a year. It will be advisable, generally, to make an allowance of 50 per cent. of the fees stated for clothes, pocket-money, etc.

The fifth and sixth columns show the entrance and leaving scholarships given by the schools. The leaving scholarships given by certain of the schools in any one year depend upon the vacancies occurring, so that it is only possible to indicate the limits within which they vary.

LEADING HIGHER TECHNICAL COLLEGES OF THE UNITED KINGDOM

Institution.	Fees.	Remarks.
LONDON.		
Battersea Polytechnic	According to course	Chemical and motor departments strong
Chelsea: South-Western Polytechnic	£12 10—£21	
Regent Street Polytechnic	5—12gs.	Fees very low. Linguistic department good
Stepney: East London College	10gs.	Evening class fees, up to 5gs. Chemistry good
Clerkenwell: Northampton Institute	About £15	Evening class fees, from 2s. 6d. upwards. Unique department of technical optics
Holborn: Birkbeck Institute	According to course	Chemical and commercial departments strong
West Ham: Municipal Technical Institute	8—12gs.	Evening class fees very low
PROVINCES.		
Redruth: School of Mines	Up to 6gs.	No evening classes
Derby: Municipal Technical College	10gs.	Evening class fees, 5s.—1 guinea
Plymouth: Municipal Technical College	8—12gs.	Evening class fees, 5s.—1 guinea
Sunderland: Municipal Technical College	Up to £8	Evening class fees, 5s.—£8
Wigan and District Mining	20—30gs.	Evening class fees low
Chelmsford: County Laboratories	£1 a week; county students free	No evening classes
Bristol: Merchant Venturers Technical College	10gs.	Evening class fees very low
Manchester: Municipal School of Technology	15—20gs.	Evening class fees, 2s. 6d.—3gs. A very fine college
Preston: Harris Institute	1 guinea—5gs.	Evening class fees, 2s. 6d.—10s.
Salford: Royal Technical Institute	5—6gs.	Evening class fees, 2s. 6d.—£1 5s.
Leicester: Municipal Technical School	£3—£9	Evening class fees, 3s. 6d. to 12s. 6d. Leather trades
Brighton: Municipal School of Science and Technology	15s.—15gs.	No evening classes
Birmingham: Municipal Technical School	From £1 10 upwards	From 2s. 6d. upwards
Swindon and N. Wilts. Technical Institution	2gs.	Evening class fees, up to £8
Coventry: Municipal Technical Institute	Up to 2gs.	Evening class fees, 5s.—10s. Watchmaking department good
Portsmouth: Municipal Technical Institute	£6 6	Evening class fees from 5s. upwards
Hull: Municipal Technical School	Up to 15gs.	Evening class fees from 2s. 6d. upwards
Bradford: Technical College	Up to 15gs.	Fees low. Mechanical engineering and textile departments good
Halifax: Municipal Technical School	From 4gs. upwards	Evening class fees, from 2s. 6d. upwards
Huddersfield: Technical College	5—9gs.	Fees low
Sheffield: Technical School	Up to 18gs.	Unique metallurgical department
Swansea: Technical College	Up to 15gs.	
Camborne: Mining College	Up to £10	Evening class fees, 3s. 6d. to 8s. 6d. The premier practical mining school
SCOTLAND.		
Glasgow and West of Scotland Technical College	10gs. Numerous Bursaries of £25. Students are eligible for the Carnegie Trust Bursaries	3 leaving scholarships £30—£100. Probably the finest technical college in Great Britain
Edinburgh: Heriot Watt College	Fees low	Several free places
Glasgow: The Athenæum	According to course	Literary and commercial
Aberdeen: Robert Gordon's College	£7	Low fees

Neither can we in every case assign a definite value to the entrance scholarships, as the emolument is sometimes made up by reduction or remission of fees and the like. Many of these scholarships provide simply free education. These are described in the table as "free."

The values assigned to the scholarships are in every case annual ones, and the duration of the emoluments is, in the case of entrance scholarships, generally for the term of the school career, and in the case of leaving exhibitions, for three or four years.

Universities and Technical Institutions. Other tables show the university and technical institutions of the British Isles. The technical colleges not infrequently give literary courses, and nearly all of the universities provide a technical training, so that the distinction

Dewsbury: Technical School ..	2s. 6d.—7s. 6d.
Leeds: Institute of Science and Art	5s.—10s. 6d.

is often nothing more than the powers possessed by the universities of granting degrees. Where no special fees are stated it may generally be assumed that a university course costs from £25 to £35 a year, and a day course at a technical college from £8 to £15 per annum. Evening classes cost from 2s. 6d. to 25s. the course, according to the number of hours' work done and the apparatus used. The charge generally works out at about 1d. per hour.

These colleges draw their students from a much wider area than do the secondary schools, and many of them have some particular department of peculiar excellence, attended by students from all parts of England and beyond. Thus, while a Tyneside boy would naturally seek a technical training at the Armstrong College, or a Sheffield boy at the University College, Sheffield, yet a student might well go from Sheffield to Newcastle to study coal-mining or marine engineering, or from Newcastle to Sheffield to seek a training in metallurgy and the manufacture of tools. Of all such departments we have endeavoured to give some account in the last column of the table.

loyers and Technical Educa-

A question of growing importance to r in the selection of a technical college is the relations subsisting between the college authorities and the local employers of labour. These relations vary widely. It was, for instance, at one time, the general habit of engineering firms, now happily abandoned, to regard men trained in the Cambridge engineering school as "theoretical men"—a crushing condemnation—while the leaving certificate of certain other institutions was accepted at something more than its face value.

There is a growing tendency at present among practical men to esteem highly the value of a theoretical training, and the American system of half-time training is being slowly adopted in this country. Among London technical schools, the Northampton Institute in particular deserves credit for an arrangement, made possible by the great interest in technical education taken by Messrs. Yarrow, under which students may spend six months in each year of a four years' course under instruction, and six months in the workshops.

Efforts are being made to create a similar good understanding in some of the provincial centres, and there is reason to hope that the next few years may see a great advance in the scientific training of experts in every technical department and in that of engineering in particular.

THE RACES OF THE WORLD

Relation of Anthropology to Other Sciences. Typical Skulls. Cranial and Facial Measurements. Stature Ethnology, the Science of Races. Books on Biology

Group 3
BIOLOGY
13

Concluded from page 1707

By Dr. GERALD LEIGHTON

UP to this point we have been tracing the means by which animals and plant species arose and became what they are, the whole process of organic evolution culminating in the production of man. We have finally in this course of Biology to look for a little at man, as a species, and observe how the species is divided into a number of very different varieties, inhabiting various parts of the world, each with habits of body and mind peculiar to themselves. This is the study of Anthropology, the science of man.

Such a science, it will be seen at once, is related to almost all other sciences. It is closely connected with Zoology and Physiology on the one hand, and, of course, is bound up with the study of History and Theology on the other. It also touches the study of comparative anatomy, the comparison of the structure of man with that of the higher animals, which in this work will be dealt with in NATURAL HISTORY. Other points that are raised come into the realm of PSYCHOLOGY, and will be found in that section. Here we shall consider man chiefly from the aspect of Ethnology, taking for our study the typical examples of the principal races of mankind.

Physical Characters. In comparing the characteristics of living races of mankind, the points which are usually taken for comparison and contrast are the colour of the skin, the hair, the eyes, the size of the body and its proportions, the features of the face, and, above all, the detailed measurements of various parts of the skeleton. From the last source are compiled what are termed the "anthropometric tables."

Of all the body measurements, those of the skull are of greatest importance in Anthropology. This is accounted for in part by the fact that the skull contains the brain, and it is largely in brain quantity and quality that races of men differ. It must be remembered, however, that a large skull does not necessarily mean a brain of corresponding size or quality. The two parts of the skull, from this point of view, are the *cranium*, or brain-box, and the *face*. The cranium is estimated by taking the measurements of its capacity, its circumference in various directions, and the segments of the circumference. The dimensions of the face are also measured as to its total size and the size of different parts in relation to each other.

The skull may be judged in two ways—by a simple inspection, and by exact measurements. The former method, or cranioscopy, gives us certain views of the skull—*viz.*, from above, from the side, giving the profile, from behind, and from below. Each of these views shows its own special points for comparison with other skulls. Actual measurements of the skull are termed those of craniometry. The degree of brain development is estimated by the capacity of the cranium, a certain deduction of space being made for other structures which are also present in that cavity. Various methods are adopted for estimating this capacity, such as filling the cranium with No. 8 chilled shot, and then pouring the shot into a graduated measure. In this way it is found that a normal human cranium has a capacity varying from 1,000 to 1,800 cubic centimetres. Something depends upon the sex, so that skulls of the same sex must be taken for comparison, the mean capacity of the female skull being about ten per cent. less than that of the male cranium.

The Groups of Skulls. Taking the capacity of the cranium as a basis of classification, skulls have been divided into three groups—the smallest, or Microcephalic (below 1,350 cub. cent.); the medium, or Mesocephalic (between 1,350 and 1,450 cub. cent.); and the largest, or Megacephalic (all above 1,450 cub. cent.). The distribution of these may be shortly indicated in a table, thus:

Microcephalic Races.	Mesocephalic Races.	Megacephalic Races.
Veddahs and hillmen of India	American Indians	Europeans
Andamanese	Chinese	Japanese
Australian aborigines	African negroes	Eskimos
Extinct Tasmanians	Malays	Mongolians
Bushmen	Polynesians	Burmese

The average cranial capacity in the European races is about 1,500 cub. cent. Sir William Turner, of Edinburgh University, who has made a special study of the skulls of the world, has recorded a male Scotch cranium of almost 1,800 cub. cent., as contrasted with a female Australian aboriginal cranium of only 900 cub. cent. The enormous difference between these two figures gives some idea of the evolution of the brain which has taken place since the first appearance of truly man-like animals. In the anthropoid apes the greatest capacity is about 500 cub. cent.

Length, Breadth, and Height of Skulls. By taking measurements of the length, breadth, and height of skulls, another method of classification is obtained, the chief point in which is the comparison of one of these measurements with the other. Thus, the length is compared with the width by assuming that the length equals 100, and then representing the width as so much per cent. The result of this is termed an "index," and the so-called "cephalic index" is arrived at thus:

$$\frac{\text{Greatest width} \times 100}{\text{Length}} = \text{The Cephalic Index.}$$

This is the most important method of classifying skulls. It gives five groups of skulls, the technical names of which sound somewhat formidable, but are quite expressive of their meaning. By working out the above formula, it is found that skulls of different races fall into the following groups: Those below 70, hyperdolichocephalic; from 70 to 75, dolichocephalic; from 75 to 80, mesaticephalic; from 80 to 85, brachycephalic; and from 85 upwards, hyperbrachycephalic. Extreme variations beyond these figures are probably not normal skulls. The value of this method of classifying skulls is shown when it is applied to a number of skulls of the same race of men; thus, it is found that the skulls of Australian aborigines are remarkably dolichocephalic, while those of the Andamanese are brachycephalic, both of these representing very primitive types. Stated generally, America tends to have brachycephalic skulls, Africa dolichocephalic, whilst Asia exhibits all types. The following table from Professor Cunningham shows the distribution among the races:

Dolichocephalic.	Mesaticephalic.	Brachycephalic.
AMERICA. Eskimos Fuegians		American Indians Eskimos of N. Alaska
AFRICA. African negroes Zulus Kaffirs	Bushmen Akkas Egyptian seaboard	
ASIA. Veddahs Certain hill tribes of India	Japanese Chinese	Malays, East Indian Islanders Andamanese Burmese Tartars Mongols
POLYNESIA. Melanesians	Mixed Races.	Polynesians
EUROPE. Mediterranean seaboard Isles of Italian Seas Sweden Norway	Greeks Turks French Germans Danes British	Lapps, Finns, North Swedes North Norwegians Poles Russians Hungarians Bohemians Austrians

Facial Measurements. Just as the cranium is taken as a basis of measurements, which enable us to group skulls together, so the face region is also utilised. It is, of course, obvious to all that the faces of different races are very characteristic. The forehead, the eyes, the nose, all are of great interest from this aspect. And just as certain skull measurements give a cranial index, so others give a "facial index." This is arrived at by a percentage comparison of the length and width of the face, according to which "high faces" are above 90, and "low faces" below 90. Most Europeans have high, or narrow faces; but Mongols and Eskimos have low, or broad faces. The lower jaw is also a very characteristic part of the face. Faces in which the jaw projects in a marked manner are termed "prognathous," but this appearance depends to a great extent upon the nose also. Calculations of the height and width of the nose give a "nasal index," according to which a skull exhibits narrow nostrils (leptorhine), as the English; medium nostrils (mesorhine), as the Chinese; or broad nostrils (platyrhine), as the aboriginal Australian.

Similarly, the measurements of the orbit give an "orbital index," and those of the palate a "palatal index."

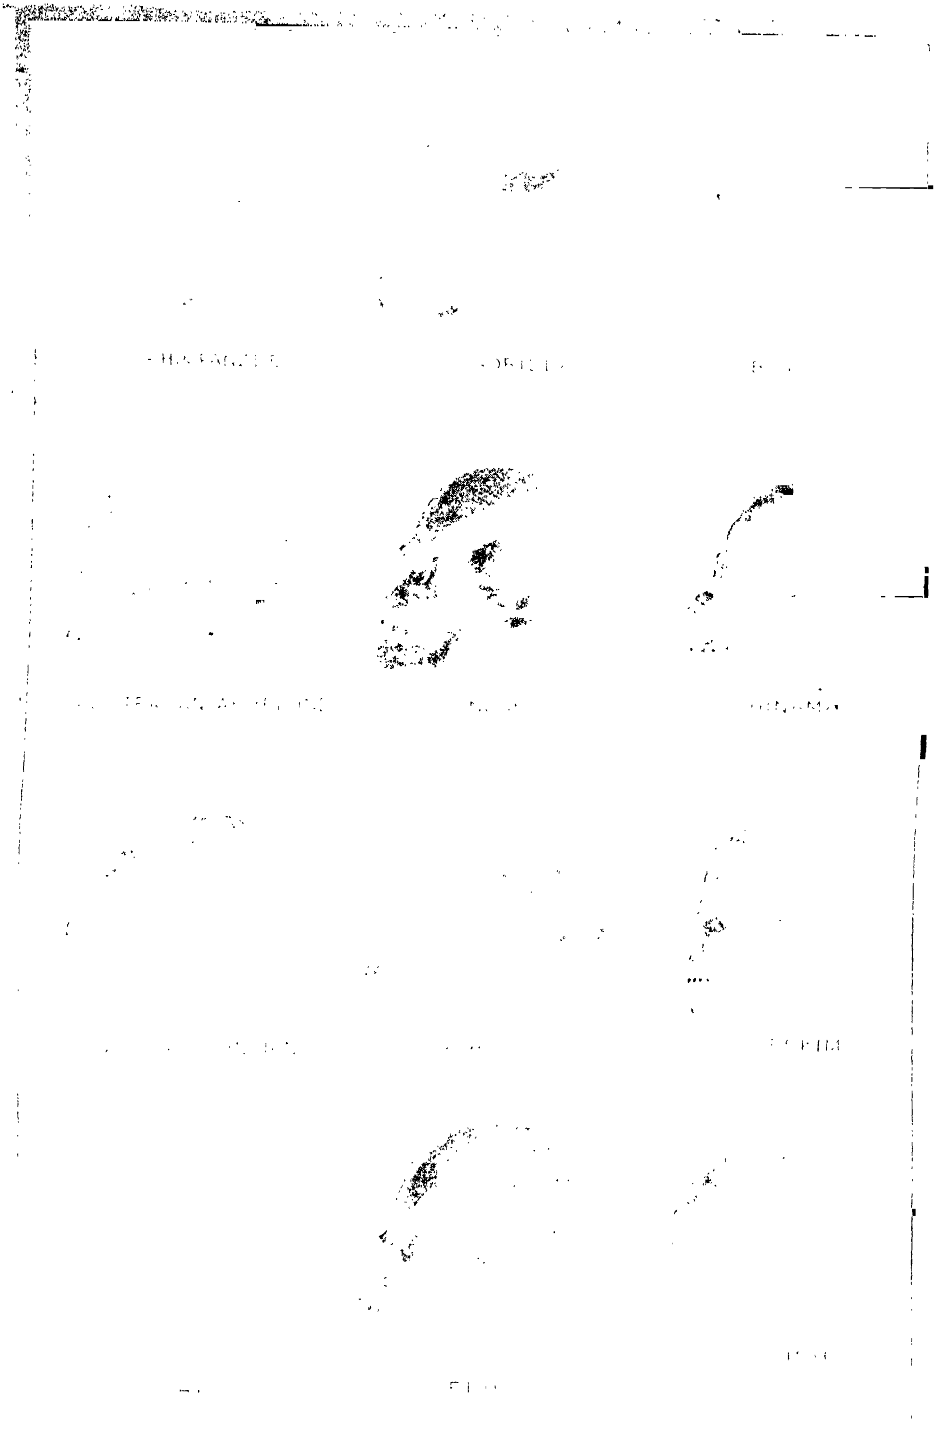
The Face and Cranium Together. If the measurements and shapes of the face be now considered together with those of the cranium, instead of separately, as above, we obtain an expression of the relative projection of the face in front of the cranium, which is what gives a skull its general appearance when simply judged by looking at it. In many animals the face projects very prominently, as in the ape and horse. They have "prognathous" skulls. This is also characteristic of the lower races of mankind, such as negroes and Australian aborigines. When the projection is only slightly seen, as in the case of Europeans, the skull is said to be "orthognathous"; where the projection is between these two extremes, it is termed "mesognathous." This "gnathic index," so important in describing a skull, is arrived at by measuring the distance between the basion to the base of the incisor teeth, multiplying this by 100, and dividing the product by the distance from the basion to the root of the nose. Below 98, skulls are orthognathous; from 98 to 103, mesognathous; above 103, prognathous.

The following tables exemplify the arangement of skulls in the groups just described:

Leptorhine (Narrow nostrils).	Mesorhine. (Medium).	Platyrhine (Broad).
English Scotch Parisians Basques (French)	Chinese Lapps Peruvians Mongols Javanese Polynesians	Hottentots Tasmanians Negroes Australian aborigines New Caledonians (The black races)

Orthognathous.	Mesognathous.	Prognathous.
Europeans Bushmen	Chinese Japanese Malays Maories Polynesians Andamanese	Hottentots Australian aborigines Tasmanians Melanesians Kaffirs Negroes

The Stature of Races. In addition to the racial differences already indicated, there is the question of stature, a character in which races exhibit most marked variations. The Akkas of equatorial Africa are the smallest, and



TYPICAL SKULLS

in them the height of both males and females is below 4 ft. The Bushmen, Lapps, Eskimos, and Veddahs all fall below the average height of 5 ft. The differences in stature are very largely due to differences in the length of the bones of the legs, hence, when a number of people of different heights sit down, their heads appear to be almost at the same level; standing up the varying heights are at once obvious. Various methods are used to determine and compare statures. The length of the shin-bone added to that of the thigh-bone, the result multiplied by two, and to this result one inch added, gives a fairly accurate estimate.

The tallest races are the Norwegian, Scottish, Irish, English, German, French, Swedish and Russian.

Many other measurements of various bones are used for making racial comparisons ; but as it is unnecessary to enter into them here, we may proceed to glance now at the races themselves and some of their predominating characteristics.

ETHNOLOGY

The science of races deals with the external features by which races are distinguished, some of which we have described above, and also with their intellectual and moral capacities and peculiarities, as well as with their manners and customs, their language, origin, social organisations, relationships, and distribution. It is sometimes far from easy to draw a hard-and-fast line between two races, the characters of the one frequently exhibiting gradations into that of the other, the result being that various classifications of mankind have been proposed. As any classification is merely a matter of convenience, and depends upon the particular method adopted, we need not restrict ourselves here to any special arrangement.

The study is naturally one of great antiquity, the term anthropology being used first by Aristotle, chiefly in a philosophical sense. He discusses man as an animal in his " History of Animals," and deals with his psychical as well as his physical nature. The modern study of the subject dates from the publication of Darwin's " Origin of Species," and especially from the time of the discovery of proof of the great antiquity of man. The physical aspect of Anthropology is that of the relation of man structurally to other animals, and the relation structurally of various races. Ethnology, while including this to a certain extent, also studies the mental side of human nature.

As regards the position of man in the animal kingdom, it may be noted that Linnæus placed him among the *Primates*, while Cuvier gave him an order (Bimana) to himself. The majority of Zoologists at the present time place man in the order Primates, along with the monkeys and lemurs. The comparison between man and these animals is dealt with in another part of this course, which should be studied in connection with this subject. [See NATURAL HISTORY].

The Australian Aborigines. The aboriginal inhabitants of the continent of Australia as well as those of Tasmania (now extinct) exhibit a very primitive and rude sta of civilisation. They dwell largely in the open building no permanent dwellings, and occup themselves in the pleasures of hunting and warlike pursuits. They practise no form agriculture, and their weapons and implement are few. Among the former is the well-know boomerang. Their clothing is of the scantiest and their food includes fruit, fish, roots, an products of the chase, also such out of the wa articles of diet as lizards, ants, caterpillars an worms.

Physically, the skulls are of the dolicho-cephalic type, and the face prognathous, th jaws protruding. The nose, which is narro at the root, widens out below, ending in wid nostrils of the platyrhine type, and the mout is wide also. There is a thick covering of hai on the body, that on the head being frizzly The skin varies a good deal in colour, from blac to coppery red. Many of the customs of thi race are very interesting, especially those relating to marriage. Wife-stealing is commor owing to the fact that a man must not marry within his own tribe. The language is highl complicated.

Intellectually, the Australian aborigina devotes most of his energies to the procuring o food, and in that sphere, where the success depends upon the actueness of the senses, he is extremely clever. As a tracker of prey he is unrivalled, and is by no means a bad cook.

Indications of an elementary artistic faculty are seen in the rude sketches of sharks and lizards on the walls of caves and on the surface of rocks.

There is no government except family and tribal law, and the code of morality is limited to the ideas of property. The religious ideas of the people appear to be mainly a dread of demons, but it is extremely difficult to find out what they really think. They are unable to calculate in abstract numbers beyond five. The aborigines are disappearing before the advance of the white man, being driven more and more from the best land into the deserts and bush of the interior, while those who remain in touch with civilisation acquire with rapidity the least desirable of its products.

The Papuans. This race, which inhabits New Guinea and other islands, is regarded by some as the most nearly allied to the Australian aborigines. Their characteristics are described by Mr. Alfred Wallace in his " Malay Archipelago." They are well made physically, with regular features, intelligent black eyes, curly hair, thick lips, large mouth, nose flat beneath, with large nostrils, and a dark brown, or almost black skin. The colour depends on the exact locality inhabited, being darkest in New Caledonia, dark brown in New Guinea, blue-black in Fiji. Mr. Wallace says that " they are superior in stature to average Europeans, but have long and thin legs, and the splay foot of the negro. They are copper-coloured, of a light, active build, often with very good features, which they paint ; but the men's teeth and mouths are much disfigured by constant use of betel-nut. The hair is usually worn frizzled out into a huge mop. The women's hair is always cut short. Their weapons appear to be spears, swords, clubs, and stone hatchets, but no bows and arrows were seen amongst them. Occasionally human jaws and spinal bones are worn as bracelets and ornaments. They appeared to take pleasure in making us understand that they had eaten the original owners of the bones; but these bones, as well as the few skulls exhibited in their villages, appeared to be of ancient date. The houses are built after the Malay fashion, on poles raised five or six feet above the ground, and consist of one large apartment."

The skull is high and narrow, the jaws protruding, the lips large. Agriculture is followed to a certain extent, fields and gardens being fenced in. Intellectually and morally the Papuans are able to attain to a fairly high standard, and both sexes, as a rule, wear some clothing round the loins. Little is known of their religious ideas, which, however, include a belief in a future state. Cannibalism is their greatest reproach. The inhabitants of Fiji are the most civilised. They have some capacity in artistic work, and make pottery. Captain Moresby concluded from his experiences that the Papuans are a promising race, and, under the influence of civilisation, have a good future before them.

The Mongoloid Races. A number of races are grouped under this general heading, including the Polynesians, Asiatics, Malays, Chinese, Japanese, Turks, American aborigines, and many other allied races.

The Malay Race. The Malays are divided into Asiatic and Polynesian. None of them are absolutely black, the Asiatics being yellowish. All of them have straight hair, which is scanty on the body, and prominent cheek-bones.

The Polynesian Malays. These include the Maories of New Zealand—a fine race of men, who, though diminishing in numbers on the first contact with civilisation, now appear to be slightly on the increase again. They were originally cannibals, and extremely warlike. Indeed, as fighters, they were unsurpassed. So well have they adapted themselves to English methods that they send their own representatives to the Parliament of the colony, and generally have proved themselves a highly intellectual race. The language, like all Polynesian languages, is most agreeable in sound, being rich in vowels and poor in consonants. It is polysyllabic.

Southern Asiatics. In this group are the Chinese, Burmese, Siamese, Annamese, Tibetans, and others. Their common characteristics are a yellow skin, oblique eyes, and straight black hair, which is slight in amount on the face and body. Many of them have attained a high degree of civilisation, and have the inventive faculty well developed. Their language is monosyllabic. They do not readily adopt Western methods, being in this respect markedly different from the Japanese.

Japanese and Koreans. The languages of these peoples show considerable structural differences from the Chinese, from whom, however, they received their earlier civilisation though they are now rapidly adopting European methods in both civil and military life.

Northern Old World Mongoloids. In this group are the Tungus (to which belong the Manchus, the conquerors of China and the establishers of the dynasty), the true Mongols, or Tartars, the Turks (including the Osmanlis of European Turkey), the Finns, and Samoyedes. All of them somewhat resemble the Indo-Chinese physically, but they live more by fishing, hunting, and cattle-breeding. Classed with the Finns are the Lapps, the Hungarians, and the Bulgarians.

Amongst Northern races whose origin is doubtful are the inhabitants of Saghalien, and the Ainos, the oldest inhabitants of Japan. They are characterised by general hairiness, which is the more remarkable in that they are in the midst of smooth-skinned races.

Inhabiting the shores of Behring's Straits are a number of North Asiatic and American tribes, of which the Eskimos are most important. They are intelligent, of low stature, with oblique eyes, and broad, flat faces.

The American aborigines appear to be allied to the Mongol race, and probably crossed over originally from Asia. Reddish-copper colour predominates, with a more prominent nose. Most of them are hunting peoples, now rapidly disappearing. Among them are the famous Apaches and Sioux, and the Caribs of Central America.

The Aborigines of India, or Dravidians. The tribes included here have, as a rule, a very dark skin approaching to quite black, long, black, curly hair, abundant hair on the body, lips like those of negroes, but not a prominent jaw.

Bushmen and Hottentots. In these South African tribes the hair is matted, and there is very little on the body; the jaws are somewhat prominent; the lips rather less prominent than those of negroes; the nose snub-shaped, the build slim, and the stature low, particularly in the Bushmen. The colour is yellowish-brown. The peculiarity of the languages is the clicking sounds. These people are by no means unintelligent. Cattle-breeding has long been their occupation, and before Europeans went to South Africa they used to smelt iron and work in metals. They used poisoned arrows for hunting.

The Negroes. It is a great mistake to consider the negro as identical with the African, the southern limit of the negro being the south margin of the Sahara, south of which is the country of the Hottentot and Bushmen. The typical negro is too well known to need detailed description, but, at the same time, the type is not often seen. The skin is black, the hair woolly, the lips thick, the lower part of the face protruding or prognathous, the forehead low and receding, and the skull bones are thick. But various negro races differ greatly in external characters, the colour passing through every shade, from ebony black to yellow. The nose is usually broad and flat, and there is but little hair on the body or face. Amongst them are the Kaffirs of the south-east, a brave, intelligent, and warlike race, who are also cattle-breeders; the Bechuanas, who dwell more inland; and the Ashantees of the Soudan, a cruel race, but intelligent, exhibiting considerable skill in the manufacture of sword-blades and cotton cloths. It is in the Soudan that the typical negro is found.

The religion of negro tribes, in the absence of introduced Mohammedanism, is practically a low form of fetish worship, with idols of wood and stone, there being, however, under it all the idea of a Supreme Being. Their religion is entirely one of fear of good and evil spirits, human sacrifices being offered up to propitiate their deities. They are polygamous. Many tribes were reduced to the lowest state of degradation by the iniquities of the slave-trade.

The Highest Human Races. Amongst what are termed "the Mediterranean Nations," which include all the Europeans who are not Mongols, is found the highest type of living men. In the Northern nations the skin and complexion are very fair, in the Southern races the skin is darker; whilst in North Africa and Eastern Asia it is yellowish, brown, or red. The bridge of the nose is always high, the jaws are never prominent in a typical case, and the whole contour of the face is regarded as expressing the highest nobility of character to be found in mankind. Included in these Mediterranean nations are the *Hamites* of North and East Africa, amongst which are the Berbers, the ancient Egyptians, and their modern representatives, the Copts, and the Nubians and Abyssinians. They were the first of the Mediterranean nations to attain to high civilisation, and the degree of this can be estimated by what we know of the ancient Egyptians and their monuments. Then there are the *Semites*, including the Jews, Arabs, Abyssinians proper, and the ancient Phœnicians, Assyrians, Canaanites, and Babylonians. The skin varied from slight darkness to deep brown, with high aquiline nose. Their civilisation was of a high order from an early age, and has contributed much to that of modern Europe.

The Aryan Race. Of deepest interest and importance to us, as being that to which we ourselves belong, is the *Aryan*, or *Indo-European* family. Two branches have long been recognised, the European and the Asiatic. The European includes the Germanic, or Teutonic nations, such as the English, German, Dutch, Danes, Norwegians, Swedes, etc.; the Romance nations, or French, Italians, Spaniards, and Portuguese; the Slavonians, or Russians, Bohemians, Servians, etc.; the Greeks; and the Celts of Brittany, Wales, the Scottish Highlands, and Ireland. The Asiatic section of the family is represented by the Hindoos, the Afghans, the Beloochis, the Persians, the Armenians, and the Kurds. "The Indo-Europeans have the physical characteristics of the Mediterranean races in the fullest purity, while among the inhabitants of Europe the remarkable peculiarities of fair hair and blue eyes are frequent. The New World is now largely occupied by European Aryans, and probably the aboriginal races will, in time, entirely disappear. Among the Greeks, ancient and modern, the highest type of physical beauty is common. We meet with fair, ruddy, and dark complexions, with golden, auburn, and dark hair, with blue and dark eyes. The Spaniards, Italians, and natives of the South of Europe generally, have dark complexions, eyes, and hair, with frames less robust than the members of the Teutonic stock. The Germans were anciently described as tall and robust, with fair complexion, light or red hair, and blue eyes, and to some extent this description still holds good of the Germanic peoples. The physical characters of the Slavonians present little that is peculiar. The Russians, especially in the north, are fair, with light brown, flaxen, or red hair. The Persians, among Asiatic Aryans, are well known as a remarkably handsome people, with regular features, long, oval faces, and large black eyes. The Mahrattas of Central India have proved themselves a warlike and vigorous race. Physically, they are said to be undersized, and not well formed."

Odd Races in Europe. Probably the oldest inhabitants of Europe are the Basques of the North-east of Spain and South-west of France. The physical characters of these peoples, together with those of some Caucasian tribes, are similar to those of other races in the Mediterranean group, but their language sets them in a group apart. Their origin is doubtful.

In our general outline of the living races of mankind it has been impossible to do more than merely indicate how man has become differentiated into the number of races and varieties mentioned. Almost every race has a book to itself; some, indeed, have very many, and to these we must go for a detailed study of races and nations. Here we merely wish to emphasise the great variety which exists, and the profound variations which occur in physical characteristics, and no less in mental and moral qualities. All these are the product of organic evolution and natural selection of some form; each is adapted to some special environment to which it has attained by the survival of the fittest, and in the ultimate struggle for existence among the nations some are dying out, whilst others are becoming supreme.

And here we must leave man as the animal, and turn our attention to him as a moral and intellectual being, endowed with capacities and hopes far transcending those of his ancestors, embracing a destiny to be wrought out by

Exultations, agonies
And love, and man's unconquerable mind.

What to Read on Biology. It may be hoped that the course of BIOLOGY, which at this point comes to an end, may have aroused in the minds of at least some readers sufficient interest in the great problems of life to make them desirous of carrying their studies further. Such, indeed, has been the object constantly before the mind of the writer. No course of this kind can pretend to do more than point the way; it requires a library to follow out the side roads and the bypaths. Some of the main roads are dealt with in other portions of the SELF-EDUCATOR—*e.g.*, NATURAL HISTORY, GEOLOGY, etc.—but others must be left for each individual student to follow up in accordance with the special aspect of the subject which appeals to him most. It may, therefore, be of service to conclude by giving a short bibliography, selected from the many excellent works on various aspects of biology, which the reader who wishes to trace out the great principles already discussed into more detailed branches can study to the best advantage. We may divide these under some of the headings which have guided us in the former parts of this course.

Books on the Great Problems of Biology. Charles Darwin's name at once suggests itself, and every student of the subject should make himself familiar with the following works of Darwin: "Origin of Species" (new edition, 1902); "Descent of Man" (new edition, 1901); "Variation of Plants and Animals under Domestication" (1868). In addition the student should read some of the works of Alfred Russell Wallace, Herbert Spencer, and Haeckel. For example: Wallace's "Darwinism" (1889); Spencer's "Principles of Biology"; Haeckel's "Generelle Morphologie." Among other works and writers the following may be suggested: Karl Pearson's "Grammar of Science" (1900); Weismann's "The Evolution Theory" (translated 1904); J. A. Thomson's "The Science of Life" (1899); Mivart's "The Genesis of Species" (1871).

Textbooks on Zoology. The student who turns his attention to the forms of animal life, their distribution, and habits, will find a large number of textbooks on zoology, from which he may select: Huxley's "Anatomy of the Invertebrated Animals" (1877); Huxley's "Anatomy of the Vertebrated Animals" (1871); Parker & Haswell's "Textbook of Zoology"; J. A. Thomson's "Outlines of Zoology"; Nicholson's "Textbook of Zoology"; Mudge's "Textbook of Zoology"; Ray Lankester's "Treatise on Zoology" (being issued in 10 vols.), and many others. The more modern ideas, facts and speculations concerning the problems now interesting the biological world will be found discussed in recent works on Variation and Heredity, two aspects upon which we have laid great stress in this course. It is to these works that the student must go to bring himself up to date in biological thought, because great conceptions have been elaborated in the last few years, and the trend of thought is changing rapidly in various directions, due to the actual facts which have been collected upon Variation and the actual experiments which have been and are being made upon Heredity.

Books upon Variation. Two books upon Variation may be suggested: W. Bateson's "Materials for the Study of Variation," Vernon's "Variation in Animals and Plants."

Books on Heredity. The following are the authoritative books on Heredity: Archdall Reid's "Principles of Heredity" (2nd. ed. 1906); J. A. Thomson's "Heredity" (1904); Weismann's "Essays on Heredity"; Weismann's "The Germ Plasm"; Cossar Ewart's "The Pennycuik Experiments." Much of the most recent work is to be found only in papers contributed to the various scientific societies, such as the Royal Society and the British Association; indeed, there is no one book which gives a general survey of every aspect of the question, nor could any one book be up to date at present, because of the vast amount of experimental work now in progress. For this reason the publications of the various scientific societies must be consulted from time to time. Reference to special articles in the "Encyclopædia Britannica" will give information on some recent points.

Miscellaneous Books. Lastly, we may append a list of works, the titles of which are a sufficient indication of their contents, and from which the reader may choose. E. B. Wilson's "The Cell in Development and Inheritance" (2nd ed. 1902); Geddes & Thomson's "The Evolution of Sex"; Francis Galton's "Natural Inheritance" (1889); C. Lloyd Morgan's "Animal Life and Intelligence"; G. J. Romanes' "Mental Evolution in Animals" (1883); F. E. Beddard's "Textbook of Zoo-Geography"; H. F. Osborn's "From the Greeks to Darwin" (1894); Nicholson and Lydekker's "Manual of Palæontology"; Herbert Spencer's "Principles of Biology" (1864-6).

This is merely a selection from a vast number of works which might be cited if space permitted, but it covers most of the ground which will be required by the reader who wishes to pursue this course further. It need hardly be said that every group of animals has its own library as well, and the reader will have no difficulty in finding a book upon a special part of the animal kingdom in which he may be specially interested. The student of biology is earnestly advised to read first the old masters—especially Darwin—but not to rest content with learning what they thought and said, but to continue his researches into the work of present-day biologists, many of whom are engaged in throwing absolutely new light upon many problems which a few years ago were dim and obscure. The student who does this may rest assured that he will reap an intellectual harvest which will more than repay the effort involved, and which will give him an interest in Life such as can be obtained in no other way.

SOME GRADUATED EXAMPLES OF DRAWING IN INDIAN INK OR SEPIA

Continued from page 1749

LIGHT AND SHADE

Drawing in Monochrome with Sepia or Indian Ink. Preparing and Stretching the Paper. Flat Washes. Gradations. Simple Objects and Groups

By WILLIAM R. COPE

Drawing with Sepia or Indian Ink. This kind of shading may be begun when the student has had a fair amount of practice with stumping chalk, for he will then have gained considerable experience in judging tone values, etc., and so will be able to lay on a wash of colour which will require little or no alteration, thus ensuring freshness and cleanliness, and avoiding a muddy and sloppy kind of work.

Stretching the Paper. Before beginning to draw, in order to avoid cockling of the paper, the latter should be wetted thoroughly with clean water, stretched upon a drawing-board, and the edges only of the paper pasted down about an inch or an inch and a half wide all round. While it is drying, it should be placed *in a horizontal position*, or one or more edges may not stick down firmly, and the paper would thus have an undulating surface, quite useless for good work. Drawing-boards specially made for stretching paper without pasting down may be obtained. Or, again, the student may purchase paper already stretched on cardboard, and although rather more expensive, it is, nevertheless, admirable for almost any work in water-colour. The paper should be Whatman's or O. W. S. "not" surface.

Laying on a Flat Wash. This gives much trouble to most beginners, and yet it is a very easy matter if done in the right way.

Have two good sable-hair brushes (Nos. 5 and 8), and a "wash" brush about an inch wide; also two jars of clean water, one of which should be kept as clean as possible, and the other used for rinsing the brushes. Damp the surface of the paper all over with clean water before putting on a wash of colour, which should not be done until the "shine" of the water has passed away. Experiment will teach more than words when the paper is in the right state. Mix plenty of colour to the required tone; use as large a brush as possible, full of colour; begin with horizontal strokes at the top of the drawing, which should be tilted at a suitable angle (about 35°), so that the colour runs down, and makes a pool all along the bottom edge of each wash across [see **440**]; continue this process until the whole surface is covered. Stir up the colour in the dish thoroughly each time a fresh brushful is taken up. Squeeze out the remaining colour in the brush on a sponge or rag, and absorb the final pool at the bottom by applying the point of the brush lightly to the superfluous colour to be soaked up. Fig. **439** shows how the wash ought to appear when finished, while **436** indicates what will happen if the wash is put on as shown in **437**.

A Gradated Tone. Fig. **438** shows a good and useful exercise in gradation of tones, which merge into one another without any definite line of demarcation. Such gradation is often required—in fact, more so than a flat wash—when objects having curved surfaces are being studied, and even flat surfaces frequently require gradation of tone, as explained previously. The student must, therefore, practise carefully and many times, until he is able to produce an appearance in his work similar to that shown in **438**.

Several different values of tones should be mixed ready in separate dishes. Then wash the paper all over with clean water, and when the "shine" has disappeared lay on the darkest tone of colour along the upper portion of the paper; keep a good pool of colour along the edge of each wash across, and also be sure to have the drawing tilted at the requisite angle. When two or three washes across have been made, take up some of the next lighter tone of colour, and put on two or three horizontal washes of that value. Then proceed with the other values in a similar manner. If the colour should be uneven—that is, streaky or blotchy—do not try to patch it up while it is wet, or it will make a bad matter worse. Wait until it is dry to make corrections, although none should be required if the foregoing instructions are implicitly obeyed.

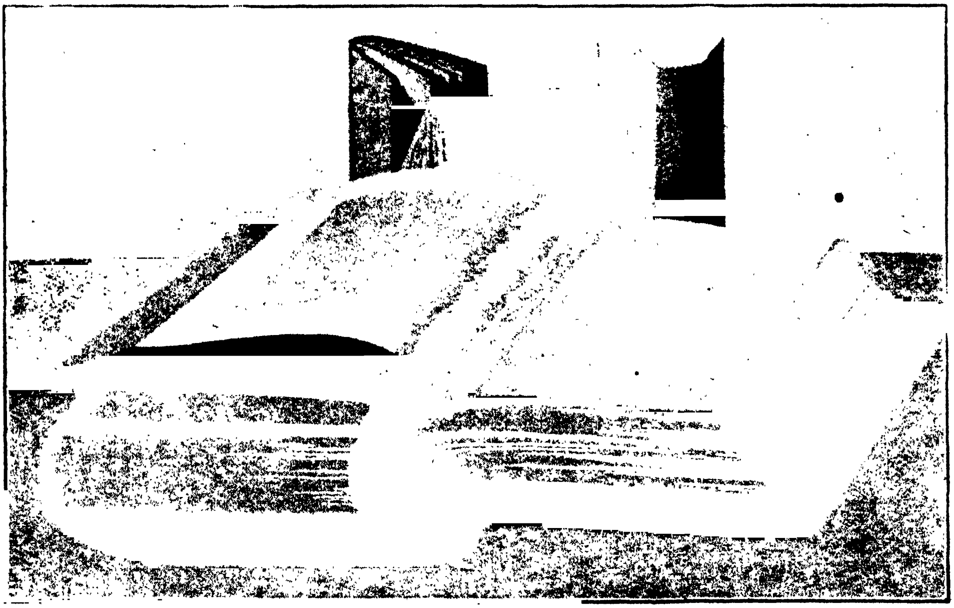
Sepia Drawing of Simple Objects. Having learnt how to manipulate such values of tones, the student should take a rectangular block or box, make a careful drawing of it in pencil, then lay on a moderately light tone all over the drawing of the object and its cast shadow [see **441**]. This light tone should be equal in value to the apparent lightest tone of the object. It is generally best to put on light tones first. Do not make a study of a glazed or polished object yet, as there would be too many difficulties to contend with, owing to the many reflections on the surface.

Fig. **442** shows how the next stage should be executed, by putting on the next darker tone equal in value to that seen on the top surface of the block. The third stage [**443**] has a darker tone still only on the right-hand vertical surface and the cast shadow. Finally, the cast shadow is made darkest of all, as shown in **444**. The student should keep in mind the advice given previously about values of edges, etc., and endeavour to express them truthfully. The edges should be softened with a brush that has been dipped in the water and partially dried upon the sponge or rag, and one should be careful not to lose the correct shape of a surface or shadow.

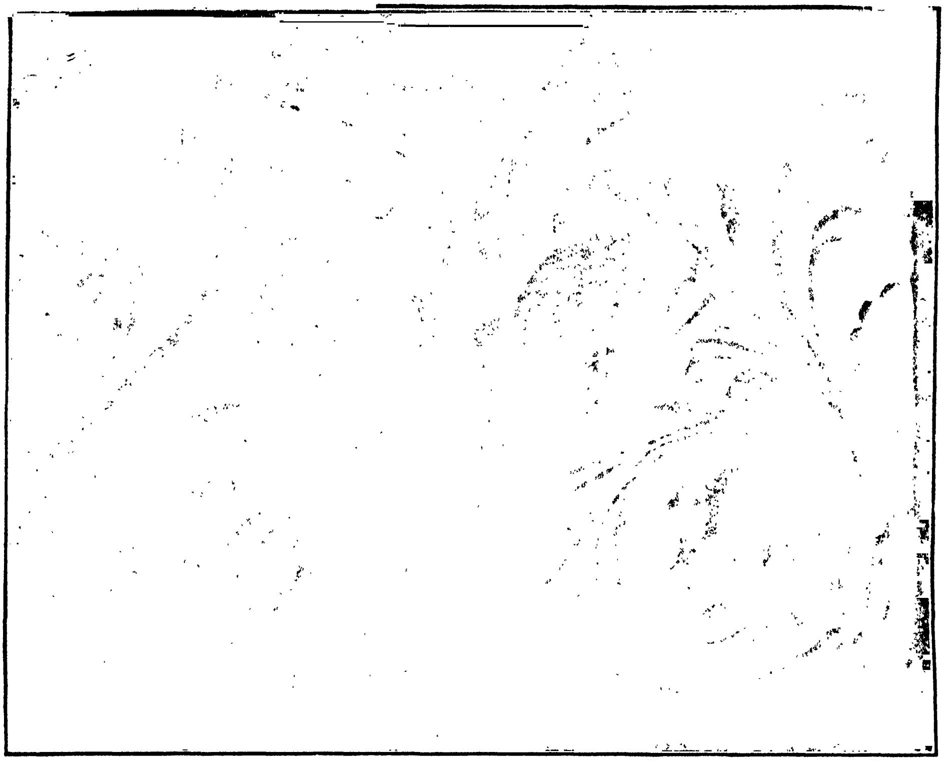
449. WASH DRAWING (INDIAN INK) OF WINE-GLASS AND BANANAS

A Law for Shadows. As many beginners in drawing make errors when sketching the outline for shadows, it would be well for them to remember the following law. "*When a shadow falls on a plane which is parallel to the edge of the object which causes the shadow, the edge and its shadow will vanish to the same point.*"

Objects with Flat Surfaces. Now study a group such as is indicated in **446**. First make a correct drawing of the objects and their shadows, then spend a few minutes in ascertaining which is the lightest and which the darkest tone, what order the intermediate ones should take, and their relative values, whether there are any reflected lights, any gradations of tone, the varying values of edges, etc. Start shading by laying on the lightest tone all over the drawing, and next, the



450. WASH DRAWING (INDIAN INK) OF GROUP OF BOOKS



451. STUDY IN SEPIA OF ROMANESQUE ORNAMENT

second darker value, as shown in **445**. Proceed with each darker tone as in the preceding exercise. Note the subtle gradation on the vertical surface of the rectangular block where the pyramid causes a darker shade to appear.

Objects with Curved Surfaces. The next study introduces objects having curved surfaces [**448**], and here very great care is needed, and application made of the facts learnt when executing the exercise shown in **438**. Again most searching observation must be made concerning the drawing and tone values, etc. Do not be misled about the position of the lightest part of the cone and cylinder. It must be noticed that it is not quite on the extreme left-hand boundary of the cone, nor quite on the top boundary of the cylinder, but a little way inside each. The delicate and subtle tone on these light boundaries helps considerably to give the roundness of the objects as well as to suggest a space behind them.

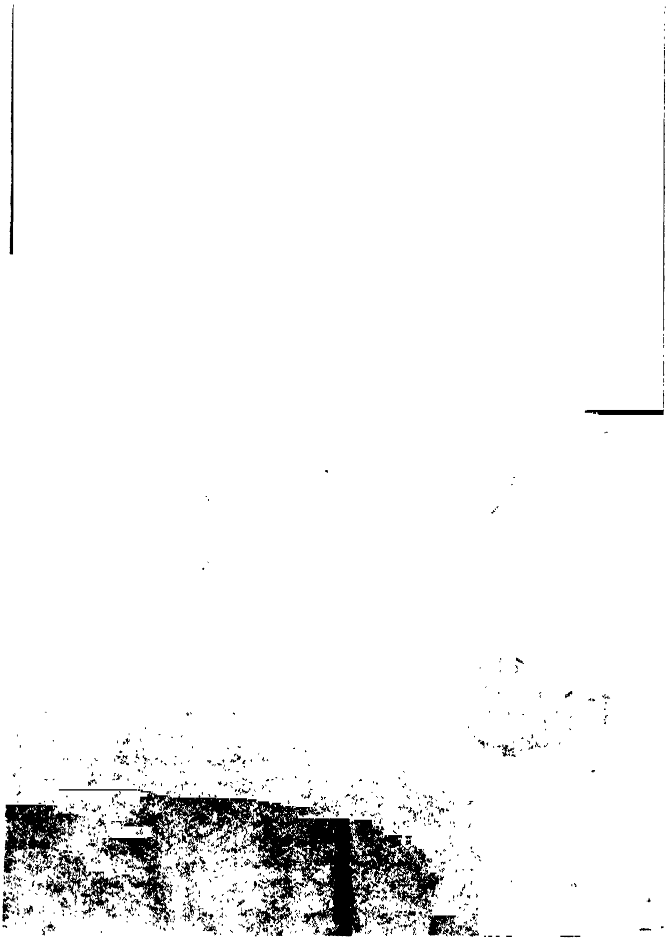
Notice, too, the reflected light on the right-hand boundary of the cone, and the lower part of the cylinder, the peculiar shape of the shadow of the cone on the cylinder, and that the straight-edged part of the shadow of the latter vanishes in the same direction as the straight boundaries of the cylinder.

Begin shading with the lightest tone, as before, and afterwards with darker shades, blending them somewhat with one another as required, so as to obtain an appearance like that in **447**. With further washes, blending and softening them as needed, finish the drawing as shown in **448**.

Of course, it is not intended that the student should merely copy the drawings here given. He must study from objects, for that is the only true way of training one's self satisfactorily.

More Difficult Groups. In **449** we have a more interesting study, which, nevertheless, will demand still more observation and very great care in execution. The change from one tone to another is so subtle that only keen perceptive powers will see what ought to be seen. There is, too, the glazed surface of the wine-glass to be represented, with the strong high light and the other many various values of reflected light tones, all of which require special care in drawing and in giving the values of edges, etc. Notice the peculiar shape of the shadow of the wine-glass on itself, on the adjoining banana, and on the horizontal surface of the table. See how soft is the shadow's edge on the table. Be careful of the drawing and the tones of the dark markings on the skins of the fruit. There are many other facts which must be diligently sought, before a satisfactory representation can be made.

Start with the lightest tones again, and proceed with the others in proper sequence. Keep the colour fresh and clean. Do not scrub it about, or the work will soon have a muddy appearance. Some reflected lights may be



452. A WATER-COLOUR STUDY OF STILL LIFE

taken out with a partially dry brush while the colour is somewhat damp; this will avoid hardness of edges to such reflected lights. Once more, *study from the objects.*

A Group of Books. The group of books shown in **450** will make a capital exercise, and give scope for further training of the perceptive faculties, and skill in manipulating the brush and colour. When drawing such a group, great attention must be given to the law of apparent convergence of parallel receding edges, as well as to the tone values, etc. The brushwork must be as direct as possible, and this can only be so when the student has a clear idea in his mind of what he is about to represent. The work in this exercise should be done in a similar order to that of the preceding ones.

Sepia Study from a Cast. Fig. **451** shows a study in sepia from a cast of ornament which will make an admirable test of the student's ability to judge proportion and tone. The original drawing was 21 by 18 in. in size. The high lights in this reproduction, as in **449**, **450**, and **452**, are rather too dark.

A More Difficult Group. In **452** we have a much more ambitious and more difficult group, but still very interesting, and one which will give the student some idea of composition when arranging objects. It will be noticed that a background has been introduced which is rather low in tone, and many objects apparently lose their edges in places. The original drawing was 24 by 18 in. in size, again indicating how large the student's drawing should be. When a monochrome study as difficult as **452** can be executed satisfactorily, the student is well prepared to start ordinary colour work.

MOTION AND LOCOMOTION

The Three Orders of Levers in the Body. How the Erect Position is Maintained. Walking, Running, and Jumping

By Dr. A. T. SCHOFIELD

MOTION in itself is no more a proof of life in a man than in a steam-engine; it is the method by which it is produced in man that differentiates him from a machine. Motion and locomotion are not the same. Motion is movement only, but locomotion is movement from one place to another; in walking we get both.

A great deal of motion takes place in the body apart from locomotion, although, in fact, the body as a whole does not change its place.

For motion or locomotion four structures at least are necessary as regards the mechanism. Something to be moved—the bones; a place where they move—the joints; machinery that moves them—the muscles; and a force that drives the machinery—the nerves; and all movements involving these structures take place according to mechanical laws. These, then, we will briefly consider.

A System of Levers. The principle with which we are most concerned is that of *leverage*, or movement by means of levers. A lever is simply a bar that lifts (French *lever*—to lift), which may be either straight or crooked, and made of any rigid substance, such as wood, iron, or bone. All our bones are used as levers or bars.

Now, as a rule, we can do so much more work with levers than we can do without them that Archimedes, who discovered their use, said that if he had a lever long enough, and a fulcrum to rest it on, he could move the world. If you see lying on the ground a piece of rock or a large chest that you cannot lift or move, get an iron crowbar—which acts as a lever—put a little block of wood on the ground, and rest the crowbar on this block of wood, and the tip of the crowbar under the rock or chest. By then pressing down the long end you can prise up the chest or rock, and perhaps turn it right over. The block of wood that supports your crowbar is the *fulcrum*. If you stir the fire with a poker between the bars, they form the fulcrum on which the poker, which acts as a lever, moves. In a see-saw the support on which the see-saw rocks is the fulcrum. In a pair of scales the beam acts as a lever, and the pivot in the middle on which it works, the fulcrum. In a lever there are two other things we must consider besides the fulcrum—the *power and the weight*.

The power *is the force that moves the lever;* the weight is the *object that is moved*. If you stir the fire, it is very easy to see that your *arm is the power*, the *grate-bar the fulcrum*, and the *coal the weight*. When you lift a chest or rock with a crowbar, in the same way your *arm again is the power, the stone the weight, and the ground or block the fulcrum*. In a pair of scales, again, whichever is the *heavier side* contains the power, because it moves the lighter one, and the *lighter one* contains *the weight*. In a see-saw the *heavier child is the power*, and the lighter one is the *weight*, or the one that is moved. The parts, then, in a lever are three in number. They are the *fulcrum* (F), or the fixed point on which the lever moves, which in the body is invariably a joint; the power (P), or the force that moves the lever; and the weight (W), or the object that is moved.

Orders of Levers. The orders of levers vary according to their relative position, thus:

WFP. is the first order—*i.e.*, when the fulcrum is in the middle.

PWF. is the second order—*i.e.*, when the weight is in the middle.

WPF. is the third order—*i.e.*, when the power is in the middle.

A pump is a capital example of the first order. Nut-crackers are in the second order; pushing open a door, or lifting a spadeful of earth, are in the third order.

Levers of the Body. Now, all three orders of levers are used in the body, although the third is undoubtedly the favourite, for a reason that will be evident.

Tapping the foot on the ground [101], raising the head off the chest, and straightening the arm, are examples of the first order, thus:

W.	F.	P.
foot	ankle-joint	muscles of calf
head	joint with spine	muscles of spine
hand	elbow-joint	triceps muscle

Standing on tiptoe is an instance of the second order. Thus:

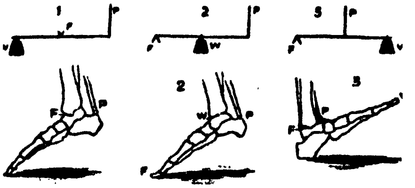
P.	W.	F.
calf muscle	body	toes resting on ground and acting as a joint

Bending the arm, closing the jaw, are examples of the third order, thus:

W.	P.	F.
hand	biceps	elbow-joint
jaw	jaw muscles	jaw joint

Respecting this third order, observe that the power, or the muscle, is attached between the fulcrum in the joint at one end and the weight to be lifted at the other.

The nearer the muscle is attached to the weight to be lifted the more it has to be contracted to lift the weight, whereas the nearer it is attached to the fulcrum the less it has to contract, but greater force is needed. For instance, consider the attachment of the muscles of the arm and leg. You will have noticed how all the body-levers have the fulcrum close to the power at the end of the bar. Thus, the elbow-joint is close to the point of the elbow behind, and the ankle is close to the heel; and you will also have noticed in the same way that in every case the muscles are attached as near to the fulcrum, or joint, as possible. Those that lift the arm are fixed just below the shoulder [102]; those that lift the forearm are fixed just in front of the elbow; those that move the thigh just below the hip; and those that move the leg just below the knee.



101. THE THREE ORDERS OF LEVERS

1. Tapping the ground with the foot. 2. Raising the body on the toes. 3. Raising the toes from the ground

Why a Muscle is Attached near the Fulcrum. The object is to give the greatest movement of the limb with the least contraction of the muscles. If you take two bits of firewood [103] a foot long, and join them together at one end with a tack, open them at right angles, and tie a string from one end to the other, it will be 17 in. long. To bring the ends of the two pieces together by pulling on the string, you must use up all the 17 in.; but if you tie one end of the string close in front of the joint in the way our muscles are fixed, you will find that, though you have to pull harder to bring the pieces of wood together, you only use up about 1 in. in length of the string to move the ends of the firewood 17 in.

By this contrivance, therefore, the slight contraction of the muscles can move the limbs a great distance. When you kick a football, your foot goes through a great space, but the muscle that moves it only contracts an inch or two.

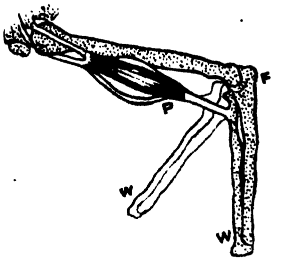
Shoulder and Hip Contrasted. Some special joints in the body call for a brief consideration. Let us first contrast the shoulder and the hip. The shoulder is not a fixed joint, but can be moved backwards and forwards to a certain extent. It is supported behind by the shoulder-blade, and in front by the collar-bone. This latter bone has a double curve; all shocks received at the shoulder, therefore, as in falls, or in striking, etc., are broken by the spring allowed in the shoulder itself, and by the spring in the collar-bone. If the shock, however, is very violent, the jar breaks the collar-bone about the middle. The shoulder is not a universal joint—that is, it cannot move in all directions, but it practically does so, as it is not stopped by the pressure of flesh against flesh in any direction, excepting inwards, when the arm is brought against the side. In an upward direction, however, we cannot raise the arm above the level of the shoulder, because the end of the collar-bone and the arm-bone then come together. If we wish to raise the arm higher, the shoulder itself, being movable, is tilted up. The joint has muscles on all four sides, which pull the arm upwards, downwards, inwards, and outwards.

Now the hip, though a universal, or ball-and-socket joint, differs from this in nearly every particular. While the chief peculiarity of the shoulder is its elasticity and its free mobility, the hip is noted for its great strength and firmness, and limited power of movement.

The hip-joint is perfectly rigid, and never moves itself, the socket being part of the strong bony pelvis. Although the thigh can move in every direction to a slight extent, it cannot move very far in any. Its forward movement, which is the greatest, is checked by the meeting of all the fleshy part of the thigh with the abdomen. Its backward movement beyond a straight line with the pelvis is checked by the strong fibrous band [104] that stretches across the front of the joint. The movement inwards is checked by the other leg, and outwards by other bands, and by a strong cord that fastens the ball of the head of the femur to the bottom of the socket of the hip-bone of the pelvis. It is surrounded with powerful muscles, except on the inner side, where they are weak.

How we Stand Upright. Some other joints may be considered as we look at the phenomenon of the erect position in man. At first sight it appears that nothing could be more natural than the erect attitude. It is only when we look at the means by which it is attained that we see what a feat it is to stand upright. The attitude itself is peculiar to man, and is not natural even to the anthropoid apes.

Let us consider how this position is maintained. We will begin at the foundation and go upwards. This tall column, 6 ft. high, more or less, called the body, is balanced on the front of the feet (about 3 in. square), and upon the two heels (about 2 in. square). The toes are in front of the body, and if the latter tends to fall forwards, press firmly against the ground to prevent it; the heels, too, are behind to prevent the body from falling backwards. If the body tends to fall sideways, the foot on the side towards which it leans, pressing firmly on the ground, restores the balance.



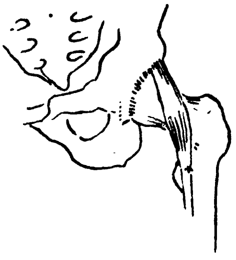
102. DIAGRAM OF ARM-LEVER OF THIRD ORDER

Showing how near the muscle is to fulcrum, and its thickening as forearm is raised

These experiments can be readily tried, and then they will be better understood. In standing on one leg, of course, there is very little to prevent our falling sideways.

Having the two feet, then, firmly planted, the two legs come next. They are hinged at the knee, and would naturally fold up backwards if not forcibly kept straight. The muscle that does this is the powerful extensor of the leg, which, passing down in front of the thigh, crosses the front of the knee, is fixed into the knee-cap, and continued down to the top of the shin, or the tibia, where it ends, and so braces the leg straight. The leg cannot fold forwards because of the crucial ligament in the knee-joint, neither can it twist to one side or the other.

Necessity for Standing Erect. Now we have the two legs upright, how are we to balance the body on the two balls of the hip-joints without falling over?—for it would naturally appear that we should topple forward or backward unless incessantly braced up by muscles before and behind. Here, however, we come across a beautiful contrivance for saving the dreadful fatigue a muscle would undergo by such a continued effort. There is no danger of the hip-joint folding up forwards in the erect position, as the body is heavier behind the joints, and the strain is rather to prevent the body from falling backwards From the front on each side of the pelvis, therefore, passing across the front of each joint, and fixed just below in the front of each femur, is a band of fibres, not muscle, so strong that nothing can break or stretch it. If we stand quite erect the whole strain is thrown off the muscles on to these powerful bands, which, when put to the full stretch, just allow the legs and body to extend in a straight line, but not more; so that the body by this means is balanced on the legs without fatigue. Those who have not learned to stand in this way soon get tired. The spine, being firmly fixed into the hip-bones, is first bent forward, to throw the weight of the heaviest part to the front, and then, as the weight gets lighter, it bends backwards between the shoulders, and forwards again in the neck, there being no joint that can double up between the hip and the neck. At the neck a good deal of the strain of keeping the head erect is taken off by an elastic ligament like a strong indiarubber band, which passes from the occiput to the spine, and so keeps the head erect without effort.

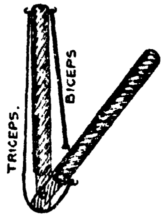


104. ILIO-FEMORAL BAND IN FRONT OF HIP JOINT

Horses which have a long neck, and a heavy head to hold up at the end of it, have a similar band of immense thickness running from the head along under the mane to the shoulder.

The human body, then, tends to fall backwards below, and forwards above; that is, there is less support for it behind at the heels than forwards at the toes; so the ankle, knee, and hip would all fold backwards if they could, while the head would drop forwards on to the chest, as we see it does in sleep, when the muscles are relaxed.

Arrangement to Preserve the Brain from Shock. Before leaving this subject the contrivances to preserve the brain from shock are worth noticing. Passing from above downwards, we notice *first* that the brain itself is saved from all jars by not touching the base of the skull, but floating on a sort of water-bed. The next two provisions are in the spinal column. In the *second* place it is a double curve, forming a double spring, thus breaking shocks; and, *thirdly*, the pad of cartilage inserted between each pair of vertebræ breaks all jars travelling up the bones. *Fourthly*, at the fourth pair the base of the spine is wedged into the pelvic arch. In this case the keystone is inserted between the two side bones, upside down, so that the broadest part of the sacrum looks downwards and forwards, and the narrow end points backwards and upwards. It is thus slung between the bones in such a way, like a carriage hung on "C" springs, that every jar upwards or pressure downwards tends to separate the keystone from the arch instead of jamming the bones together, and so reduce the shock.



103. DIAGRAM OF ELASTIC & WOOD
Showing action of biceps and triceps, and value of the third order of levers

The *fifth* contrivance is that the head of the femur is at right angles to the shaft, which alone reduces the force of shock one half.

The *sixth* is the slant of the femur to the middle line; and the *seventh* is at the knee, where we have between the bones two strong pads of cartilage to prevent all jarring.

The *eighth* is the keystone which forms the instep of the foot. In this case it is set in the usual way, with the broad end uppermost, and the narrow end below resting on a *stout* band of fibres, which breaks all jar.

The *ninth* and last is in the foot, where the hinder pier of the arch comes straight down to the ground, and is formed of one bone, called the heel; but the front pier slopes very gradually, like a spring, and is composed of twenty-four bones. Thus, we get in the foot-arch solidity behind and elasticity in front [6, page 101].

If you stand on a form and jump on to the floor, first on your toes, or the front pier, you will see how beautifully this elastic pier breaks all shock; and then on the heel, you will feel what a jar you get. When we walk, run or jump, therefore, the shock is prevented from reaching the brain:

1. By the water-bed on which the brain rests
2. By the double curve of the spine
3. By the pads between each of the vertebræ
4. By the inverted keystone in the pelvic arch
5. By the neck of the femur
6. By the slant of the thigh-bone

7. By the pads in the knee-joint
8. By the keystone of the foot arch
9. By the spring of the front of the foot

Walking. The movement of the body from place to place is the result of combined action of many muscles. In the act of walking the muscles of the arm should be entirely relaxed, as they are not required in any way, and the arms should be left to hang naturally. Many of the other muscles are used either in maintaining the position of the trunk or in moving the legs.

In starting to walk, say, with the right leg, the muscles of the calf raise the heel from the ground, while the muscles in front of the abdomen pull the body a little forward, still further raising the right heel. When the body is inclined forward to a certain extent, it would fall over were it not for the next act, which consists in allowing the left leg to move forwards to support it. This is done partly by a pendulum-like swing and partly by a forward pull of the muscles in front of the thigh. The left leg is now in front of the body, and the balance is restored; but the right leg has not ceased to act yet. It continues to push the body still further forwards while the muscles in front of the trunk still pull it over, until it is in advance of the left leg, thus raising the right leg off the ground and allowing it to swing forwards in its turn. Walking thus depends on pushing upwards with the leg and pulling forwards with the front of the trunk. As the body is supported alternately on each leg, it is inclined a little from side to side, so as to throw the weight fully on it, and prevent falling over sideways. Thus the body in walking is continually rising and falling, and swaying slightly from side and side.

Jumping, Running, and Hopping. Jumping consists in a spring off the ground, caused by the sudden contraction of both calves forcing the toes so violently against the ground that the body is jerked into the air.

Running is a series of short jumps with each leg alternately, so that both feet are constantly off the ground at the same time. The body is inclined still more forward than in walking, as is seen in soldiers when they change into the "double" from "quick march."

Hopping consists in a jumping on one leg, caused by the most violent contraction of the muscles of the calf of which they are capable.

We may, in conclusion, note that movement is by no means a necessary sign of strength. Babies move all their muscles a great deal, and often without much reason, because their minds have not yet got much control to quiet their movements, but the older and stronger a person gets, the less he moves excepting when he wants to do so, because he has all his muscles under control. To keep constantly moving, therefore, does not show that we are strong, but may indicate that the brain power is weak.

In the locomotor, as in all other systems of the body, there are control centres that prevent unnecessary action, check its being excessive, and tend to promote a steady healthy condition. Such control presides over the action of the heart, the temperature of the body, and the details of the digestion as well as over all muscular effort.

PNEUMATICS

Air: its Pressure, Weight, and Mechanical Value. Boyle's and Dalton's Laws. Pneumatic Drills, Hammers, and Hoists. Fans and Blowers

By JOSEPH G. HORNER

It is rather surprising that the laws and truths which we intend to consider now were unknown until within comparatively recent times. Three hundred odd years before the time of Christ, Aristotle brought his great mind to bear on the subject, but came to the alarming conclusion that air had no weight. Thenceforward, for close on nineteen hundred years, things were seen as through a glass darkly. The eagerness with which gases and liquids rushed in to fill a vacuum was glibly "explained" by the phrase, "Nature abhors a vacuum." In the seventeenth century that galaxy of great minds—Galileo, Guericke, Torricelli, and Pascal wrested from Nature the great truths that underlie the questions of pressure and elasticity of gases.

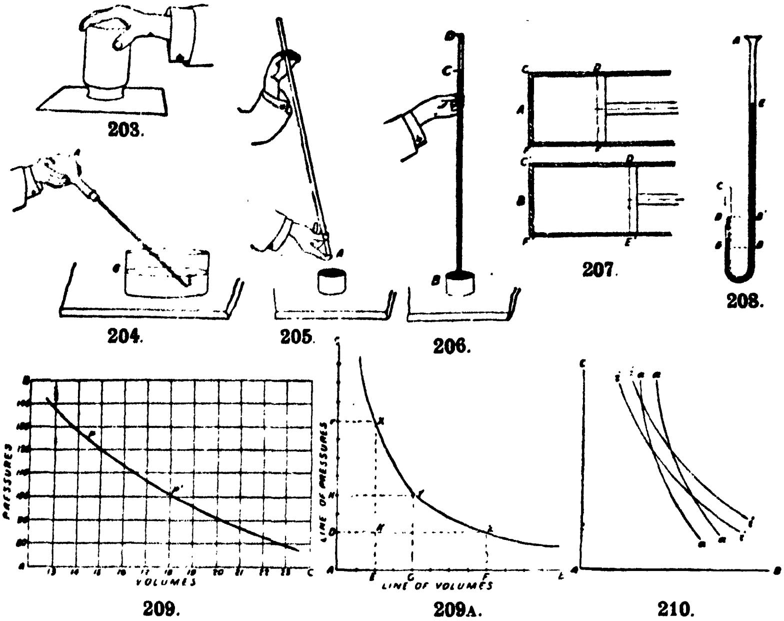
The pressure and elasticity of air (which may be taken as a typical gas) may be clearly and visibly demonstrated by simple experiments which can be easily performed by the student. If, for example, a tumbler or beaker be entirely filled with water, and a sheet of paper pressed over the mouth and the tumbler inverted as in **203**, the paper remains in position, and the water in the glass. One might think that both paper and water would fall to the ground immediately the glass were inverted. This does not happen because, great though the pressure of the water may be, the pressure of the atmosphere against the paper is still greater. If, however, the vessel be not completely filled—that is, if air be present inside, the exterior pressure is neutralised and overcome.

Expansibility of Air. The expansibility as well as the pressure of the atmosphere is illustrated in **204**. The empty flask A is fitted with a cork, through which a long piece of glass tubing passes. The end of the tube is placed beneath the surface of the water in the trough B. (If the water be coloured with a little red or black ink its movement will be more readily seen.) The two hands are then placed round the flask, as shown in the illustration, and the heat they impart to the air contained in the flask causes it to expand and escape, as will be seen by the stream of bubbles which rise through the water. When the hands are removed, and the flask and its contained air resume the ordinary temperature, water will rise from the trough and up the tubing towards the flask. The liquid rises against the force of gravity because the pressure of the atmosphere acts on the water surface, is transmitted upwards through the tubing, and so causes the liquid to fill the space which was occupied by the expelled air. If the flask were gently heated with a Bunsen flame, the results would, of course, be still more pronounced.

The Schoolboy's Sucker. The schoolboy's sucker is another and a striking illustration of air pressure. A piece of leather attached to a string is well soaked, and then pressed firmly with the foot against a smooth surface, so as to exclude all air between the leather and the surface. It is then found difficult or even impossible to pull the leather away from it; if the leather be in contact with a slate or a loose slab of marble these things may be easily lifted into the air. This is not due to any "suction," but to the great pressure of the atmosphere outside the leather, and the absence of any air between the sucker and the substance to which it holds.

Measuring Air Pressure. The experiments just described prove that the atmosphere has weight, but give us no idea of its amount. A means of measuring that weight is shown in an experiment first performed by Galileo's pupil Torricelli, and since repeated millions of times in the schools, colleges, and laboratories of the world. A pump had been sunk at Florence, but the water obstinately refused to rise above 33 ft. Galileo was consulted, and he concluded that the air had weight, and that a column of water 33 ft. in height was as much as the weight of the atmosphere could balance. Afterwards his disciple Torricelli studied the question. Taking a glass tube about 3 ft. long and closed at one end, he filled it with mercury. The tube was inverted, the open end being temporarily closed with the finger [**205** A], and placed below the surface of mercury in a vessel (B) [**206**]. Immediately the mercury in the tube dropped to a height of 30 in. above the level of the mercury in the vessel. A vacuum (called the Torricellian vacuum) was produced (CD). The only possible conclusion was that this 30-in. column of mercury was balanced by the atmospheric pressure. This was verified by Pascal, who repeated the experiment on the summit of the Puy de Dome, in Auvergne. Two tubes were filled with mercury, and at the foot of the mountain the liquid stood at 28 in. in both tubes. One of them was then taken to the top of the mountain. As they ascended the observers found that the mercury fell to 24·7 in., and as they descended it rose again to 28 in. Pascal's expectations were fulfilled, for he had reasoned that as the pressure of the atmosphere on a mountain-top was less than on the earth's surface, it would only support a correspondingly shorter column of mercury. And as this proved to be the case, it was clear that the mercury was really supported by the weight of the atmosphere.

A cubic inch of mercury weighs ·49 lb., and 30 × ·49 = 14·7 lb. Therefore, as the atmosphere supports a column of mercury whose weight is 14·7 lb., and whose base measures a



ILLUSTRATIONS OF AIR PRESSURE

square inch, we are driven to the conclusion that the pressure of the atmosphere amounts to 14·7 lb. on every square inch. And this pressure, as in the case of water, acts equally in all directions. Mercury being 13·6 times heavier than water, the atmosphere would support a column of water equal in height to 30 × 13·6 in., or $\frac{30 \times 13 \cdot 6}{12}$ ft. = 34 ft. This explains why water refuses to rise to a greater height than this (in practice not more than 25 ft.) in a common lift-pump; hence also the need of a liquid of high specific gravity for use in a barometer.

To this pressure of the atmosphere, then, we are indebted not only for the action of the barometer but also for the action of the various types of water-pumps [see page 1080]. It has, however, been thought fit to deal with pumps under HYDROSTATICS, for the reasons stated in that lesson.

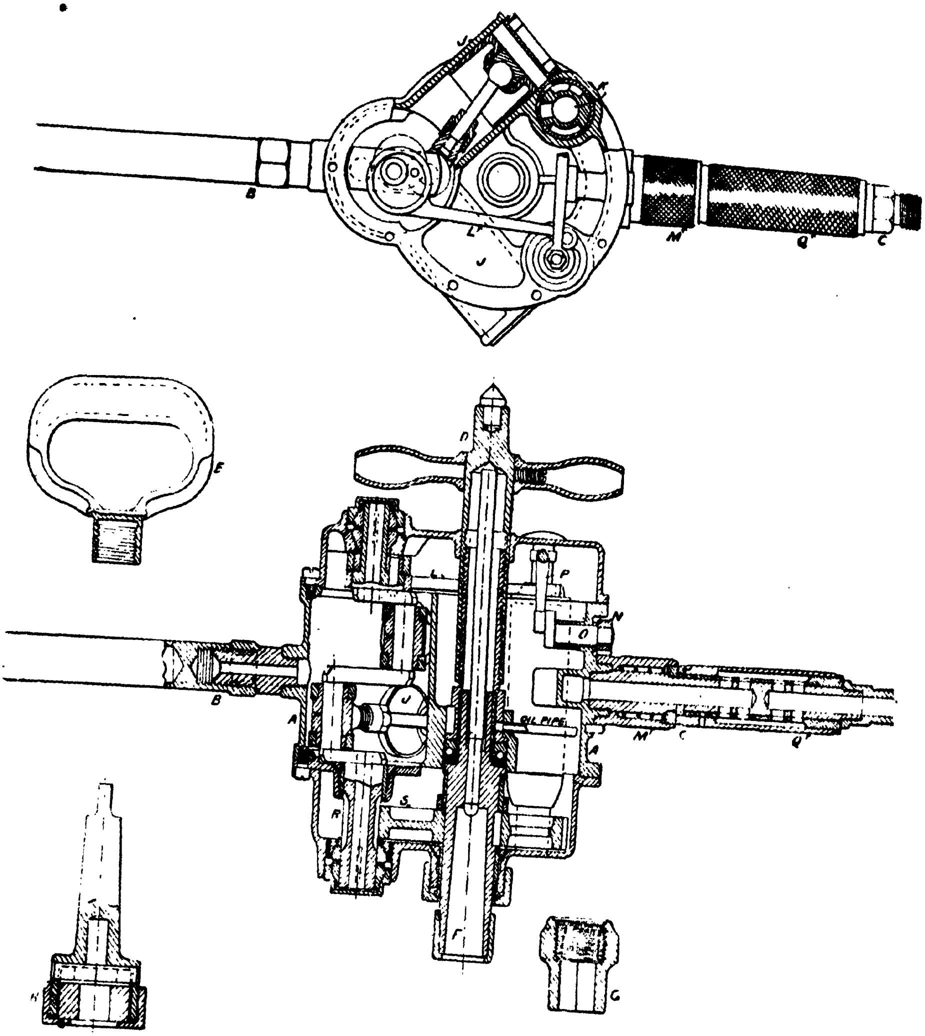
Boyle's Great Discovery. Mention has been made in the course on IDEAS of remarkable cases of simultaneity in discovery. An example of this occurs in the subject now under consideration. In the latter half of the seventeenth century, Robert Boyle, in England, and Edme Mariotte, in France, were both studying the effect of pressure applied to a gas. Their investigations led each to arrive independently at the same great truth, and so nearly simultaneous was the discovery of the law, that in England it is known as Boyle's Law, on the Continent as Mariotte's Law, and sometimes as Boyle and Mariotte's Law. There seems, however, no doubt that the great English, or rather Irish, physicist was first. Boyle's Law may be stated: *The volume of a gas varies inversely as the pressure, temperature remaining unaltered.* Thus, if at a pressure P the volume of a given quantity of a gas be V, and the volume changes to V′ at a pressure P′, then P : P′ : : V′ : V. The product of the extremes being equal to that of the means, PV = P′V′, or

$$\frac{P}{P'} = \frac{V'}{V}.$$

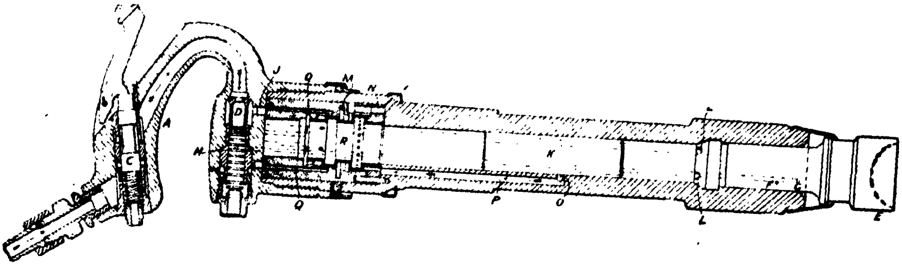
If in **207** A and B represent the same cylinder with the piston in the two positions shown, then the pressure when the piston is at DE is to the pressure when at D′E′, as the space C′D′E′F′ is to the space CDEF. The reader will now see how highly important this law is in engineering, for, translated into technical parlance, it tells us that in the steam in an engine cylinder, the gas in a gas-engine, and the air in an air-engine, as long as temperature is unchanged, the pressure, or elastic force, varies inversely as the volume occupied by the gas.

Verification of Boyle's Law. The law may be verified by means of a long bent tube, as in **208**. Mercury is poured in at A (or at C, and this opening then closed) until it stands at the same level B—B in both branches. Then the air in the closed portion (BC) is at the pressure of the atmosphere. By pouring more mercury into the tube at A, the air in BC gradually becomes more and more compressed, owing to the increased pressure in the long branch. Both the decreasing volume of the air and the increasing pressure of mercury producing it may be measured, and the results tabulated. In a uniform tube such as this the volume is proportional to height, so that a finely-divided scale is all that is necessary for measuring volume and pressure. For the total pressure in each case, the height of the mercury in the long branch above the level of that in the short one must be added to the pressure of the atmosphere, as indicated by the barometer at this particular time, for the pressure of the air in BC is evidently equal to the sum of these two. If for example the air be compressed to occupy the space B′C the height B′E would be added to the barometer height.

The table given shows a series of readings so taken. The first column gives the level



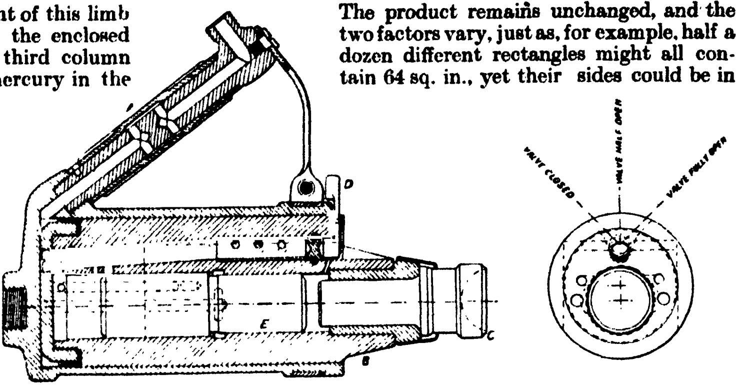
211. DETAILS OF PNEUMATIC DRILL



212. SECTION OF PNEUMATIC RIVETER

REPRESENTATIVE PNEUMATIC TOOLS

(in centimetres) of the mercury in the short branch, and this, subtracted from 26 centimetres—the total height of this limb—gives the height of the enclosed column of air. The third column shows the height of mercury in the long limb, and the difference between this and the level in the short one gives the pressure stated in column four. But the enclosed air is subjected not only to this pressure, but also to the additional pressure of the atmosphere, in this case 76·57 centimetres. Thus the total pressure is that in the fifth column.



213. THE "HOLDER-ON"

Air.		Mercury.			
Level of mercury A	Height of air in short limb, 26 cms. − A = V	Height of mercury C	Difference in level of mercury, C − A = D	Total pressure, 76·57 + D = P	Constant, V × P = K
2·2	23·8	2·2	—	76·57	1822
2·8	23·2	4·75	1·95	78·52	1822

			Average ..	..	1816

Pressure and Volume. On comparing the tabulated results the truth of the law will be evident. A glance shows that as the pressure (P) increases, the volume (V) decreases, and the ratio in which this occurs is seen by taking any two pressures and corresponding volumes. Thus the pressure 125·67 is roughly one and a half, or $\frac{3}{2}$ times 83·17. But the volume corresponding with the first-named pressure is approximately $\frac{2}{3}$ of that at the second pressure. Similarly, with more extended investigations it would be found that with twice the pressure the volume is halved; with 3, 9, 12, 50, or n times the pressure, the volume is reduced to $\frac{1}{3}, \frac{1}{9}, \frac{1}{12}, \frac{1}{50},$ or $\frac{1}{n}$ of the original volume. Moreover, the number (K), obtained by multiplying together the volume and the pressure in each case varies but little from the same product in the other lines. This slight variation is explained by trifling errors of experiment. This fixed value of V × P enables us to state the law thus: *Temperature being constant, the product of the pressure and volume of a gas is a constant.* If one be known, the other is easily found by reducing the law to the formula: *Pressure* × *volume* = *constant.* The product remains unchanged, and the two factors vary, just as, for example, half a dozen different rectangles might all contain 64 sq. in., yet their sides could be in inches: 64 × 1, 32 × 2, 16 × 4, 8 × 8, 12·8 × 5, 6·4 × 10.

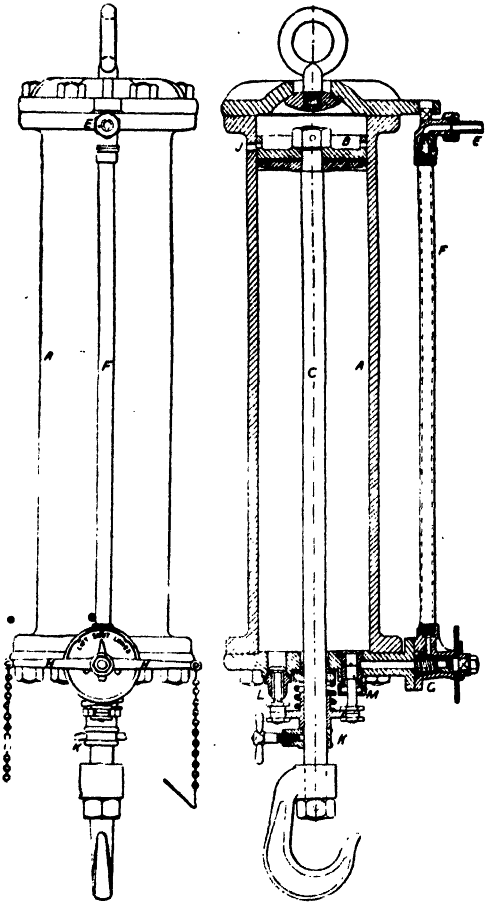
Investigations with pressures less than that of the atmosphere also verify the law.

Behaviour of a Gas. The story of the behaviour of a gas under varying pressures may be told in a more attractive manner by means of graphic representation. The pressures and volumes in the table may be plotted as in **209**, where the bottom (AC) is figured for horizontal line volumes, and the vertical line (AB) for pressures. Then the story is told by the curve. As it extends in the direction C—that is, as the volume increases, the curve sweeps downwards—in other words, the pressure falls; or, as the curve rises the volume decreases and pressure increases. At the point P the volume is about 14, and the pressure 125 centimetres; at the point P′ the volume is 18, and the pressure 100 centimetres. With a wide range of pressures and volumes [**209**A], it will be seen that the curve, though it approaches nearer and nearer to the lines of volumes and pressures, never touches either. The reason for this is clear when we consider that no increase of pressure can bring the volume to zero, and no increase of volume can reduce the pressure of a gas to the vanishing point. It would thus be impossible for this line to be straight, for then it would eventually cut both the line of volumes and of pressures.

Curve of Volume and Pressure. Since the product of the volume and pressure of a gas is constant, this curve exhibits another useful property. If we take any three points, as X, Y, Z [**209**A], then at X the pressure is represented by XE, and the volume XI; at Y, pressure = YG, and volume = YH; at Z, pressure = ZF, and volume = ZD. Therefore, the areas XIAE, YHAG, ZDAF, are all equal; and this would be the case with a point taken at any position on the curve. Because of this property the curve is known as a rectangular hyperbola. Thus the position of any point indicates the two factors volume and pressure, and if one be known the other is immediately found. For if we are given a volume which, according to the scale adopted, equals AF, then by laying this distance along the line of volumes AB, and erecting a perpendicular at F, the pressure is seen to be equal to FZ, or, by referring to the scale chosen, AD.

Referring again to the diagram, if Z marks the first and X the final condition of the gas, then the actual diminution in volume is represented by ZK, and the increase of pressure by KX. The work done by the pressure in changing the volume from AF to AE is represented by the area of the figure ZXEF.

The Law of Dalton. When two or more gases of different kinds are mixed together—and this sometimes occurs, as in the case of air and water vapour in the air-pump of a condensing engine—*the total pressure exerted by the mixture is equal to the sum of the pressures exerted by the different gases.* In other words, each gas exerts its own pressure just as though no other gas were present. This is, in reality, a general law, of which Boyle's Law is a particular case—a fact which will be readily seen on comparing the statement above with that of Boyle's Law as simplified by Professor Rankine: "If we take a closed and exhausted vessel, and introduce into it one grain of air, this air will, as we know, exert a certain pressure on every square inch of the surface of the vessel. If we now introduce a second grain of air, then this second grain will exert exactly the same pressure on the sides of the vessel that it would have exerted if the first grain had not been there before it, so that the pressure will now be doubled. Hence we may state, as the property of a perfect gas, that any portion of it exerts the same pressure against the sides of a vessel as if the other portions had not been there."



214. AIR HOIST

The Question of Temperature. The general effect of heat on solids, liquids, and gases is to cause expansion, and, as a rule, gases expand more than liquids, and liquids more than solids. And it is a well-known fact—a matter of common observation—that if equal increments of temperature be applied to a number of solids (say, rods of copper, iron, zinc), or to a number of liquids (water, alcohol, mercury), there is a considerable difference between their relative expansion, whereas with all gases and vapours expansion proceeds at the same rate when heated through the same interval of temperature. Thus the second great law of gases runs: *The volume of a gas under constant pressure expands, when heated, by the same fraction of itself,* whatever be the nature of the gas (the Law of Charles). What is this fraction?

Experiment has shown that 1,000 volumes of air at 0° C. become 1,366·5 volumes at 100°—*i.e.*, 1 volume at 0° increases to 1·003665 at 1°. The amount of increase in volume for 1°, ·003665, approximately equals $\frac{1}{273}$, and so this fraction is called the coefficient of expansion for air. Thus, for every increase of 1° C., the volume of the gas is increased $\frac{1}{273}$ of its volume. Therefore, 1 cub. in. of a gas at 0° C., when raised to

$$1^\circ = 1 + \frac{1}{273} \text{ cub. in.}$$

$$2^\circ = 1 + \frac{2}{273} \text{ ,, ,,}$$

$$30^\circ = 1 + \frac{30}{273} \text{ ,, ,,}$$

$$n^\circ = 1 + \frac{n}{273} \text{ ,, ,,}$$

Therefore, 273 volumes at 0° are changed to 274 volumes at 1°, 275 volumes at 2°, and so on.

Volume Reduced by Lower Temperature. Now, as a gas expands uniformly with uniform increments of temperature, it follows that with uniform *reduction* of temperature the gas should decrease in volume by uniform fractions of itself—that is, for every degree through which the gas is cooled below 0° C., it should lose $\frac{1}{273}$ of its volume. Then it follows that if cooled through 273 degrees below zero, the gas would theoretically occupy no volume whatever. Such a temperature has never yet been reached, but it is pretty certain that a gas would cease to exist as such at this low temperature. This theoretical point, − 273° C., is therefore called the absolute zero of temperature, and when reference is made to "absolute temperature" it means that the temperature is reckoned from this absolute zero. Absolute temperatures are obtained by adding 273° to the C. reading. If it be the temperature on the C. scale, then absolute temperature = t + 273°. This conception of absolute temperature enables us to connect the two great laws which govern the behaviour of gases: *In a gas the volume (at constant pressure) or the pressure (at constant volume), is proportional to the absolute temperature.* Or, the product of the pressure and volume is proportional to the absolute temperature. If V equals the volume of a gas; P the pressure; and T the absolute temperature, then the ratio $\frac{VP}{T}$ is constant for that gas for all values of V, P, and T.

Practical Importance of Temperature. In making the observations on which the table verifying Boyle's Law was constructed, and from which the curve in **209** was plotted, pressure and volume only were considered, temperature remaining constant. But as far as engineering is concerned, temperature *does* invariably enter into the question, so that when we come to consider the behaviour of steam in the engine cylinder, or air in an air compressor, for example, the problem becomes more complicated. When a gas suffers compression, heat is produced, and unless the pressure is gradual and long continued, the heat produced will be unable to pass away by conduction. It is then evident that the curve traced to show the relations between pressure and volume *when temperature is constant* will not coincide with the curve produced when the heat caused by compression is not allowed to escape. For any gas a number of curves may be traced, each at a different but constant temperature, and these are called *isothermal* lines (Gr. *isos*, equal; *thermē*, heat). So far, we have considered only changes in volume and pressure which have taken place isothermally, and the curves in **209** and **209A** are isothermal curves.

When, however, a gas is compressed, and expands under conditions which prevent any heat passing in or out of the chamber containing it, its behaviour would be represented by a line which would pass from one isotherm to another. Such lines are called *adiabatic* (Gr. *a*, privative prefix; *dia*, through; *baino*, I go). In **210** *i*, *i* are isothermal lines, *a*, *a* are adiabatic lines. The most striking feature about these curves, as compared with the isothermal lines, is the relatively greater angle which they make with the horizontal line AB. This means that a much greater increase of pressure is necessary to diminish the volume of a gas when under adiabatic conditions than when acting isothermally; for a definite increase in pressure the volume will be greater when no heat enters or escapes than when the case is otherwise—a fact which is shown by the diagram.

Compressed Air. Though free air—that is, at atmospheric pressure—is utilised by engineers, air when compressed also becomes a motive power of very great value. Its applications have grown enormously in recent years. To name only a few, miners' rock-drills are actuated thus; mine locomotives and coal cutters also are driven by air. Sunken vessels are raised; hammering, chipping, caulking, riveting, tapping, etc., are effected; parcels are transmitted through tubes, and loads are lifted by cranes.

When air is compressed this is done by the movement of a piston in a cylinder, the average amount of pressure for ordinary purposes being usually 60 to 80 lb. per square inch. When higher ones are required, the work is done in two or three stages, and for some purposes pressures of 500 lb. and more are employed. When air is compressed thus, and made to do work, it does so by virtue of its expansion, by which a portion of the power expended in compression is returned; for convenience, it is stored in a receiver, resembling a steam boiler externally, either vertical or horizontal. There are considerable losses due to friction and the generation of heat, so that an efficiency ranging only from about 30 to 60 per cent. in different cases is available. The use of compressed air has given rise to an immense number of machines, both for its generation and utilisation. With the first we cannot deal here, and a few selections only from the second can be offered.

Pneumatic Drill. The production of rotary motion by means of compressed air is most economically effected by using cylinders and cranks, as in steam-driven reciprocating engines. An example of a pneumatic drill is shown in **211**, used for boring holes in wood and metal, as well as for reaming and tapping, etc. The main body, or casing (A), has two handles (BC), screwed in, providing a means for holding the machine steadily, and also of controlling its action. The counter-pressure is taken by the point centre at the top, fitted in a screw-sleeve (D), which is employed for feeding the drill into its work as cutting proceeds, D being revolved slightly at intervals to force the entire casing downwards, using the hollow handle seen near the top for turning D. Alternatively, a grip-handle (E) (shown detached) is used, where the work permits, such as when wood boring, tapping screw-holes, etc. The tools are held in the taper hole of the spindle F, and can be forced out by screwing down the handle and sleeve D, which action pushes the internal ejector-rod down upon the drill. For square-shank drills another socket (G) is provided, and another (H) for tapping.

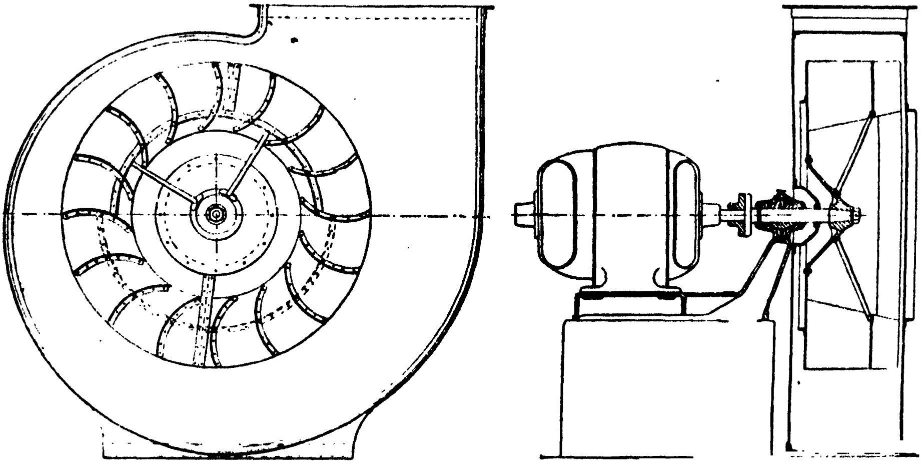
The driving mechanism comprises four single-acting cylinders (J), arranged in pairs at right angles to each other, having the pistons connected with rods to a crank shaft, the pins of which stand at 180° to each other, forming a balanced set. Each pair of pistons is controlled by a balanced "Corliss" valve K (seen in plan) actuated by eccentric rods (L). The valves K are made with a duplex set of ports, so that, by raising or lowering them, the action of the drill can be reversed. The motion is effected by rotation of the knurled sleeve M on the handle C, turning a small pinion on the crankshaft O, this raising or lowering a connecting rod P, fitted with cross-arms, bolted to the ends of the valves K. The handle C has also a throttle mechanism, to turn the air supply on or off, the sleeve Q being rotated to allow the series of holes seen to communicate with each other when starting, so that the air passes from the flexible hose attached to the end of C, right throught the handle, and by passages into the valves and cylinders. The drive from the double-throw crank-shaft to the spindle is seen to be through spur-gears R and S. Oiling is effected by removing the handle B, and also through the pipe seen leading to the spindle, whence the lubricant then spreads to all parts of the mechanism. These tools can be used by divers under water when necessary.

Pneumatic Riveting. The application of compressed air to riveting is shown by the sectional drawing of a "Boyer" long-stroke hammer [212], which is held in the operator's hand, and supplied by a flexible pipe, led through the coupling at the base of handle A. On pressing the thumb-trigger B, the valve C allows the air to pass through the hollow chamber in the hand into the automatic valve D, whence, if the snap E at the extreme end is not pressed on the work, escape occurs through the passage F and hole G. This constitutes a safety device to prevent danger to the workman through the snap being driven violently against the rivet from a distance.

But, on commencing to rivet, the pressure on E forces it backwards, so closing the orifice G. The air in D then presses on the annular shoulder at H, forcing down the valve D, and allowing air to get past the coned seating at the top into passage J, when it gets to the rear of the piston and drives the latter forward against the snap end. The air at atmospheric pressure in front of K has to be got rid of, and this is effected by providing orifices LL, leading through passages (seen dotted) back into the annular chamber recess M, communicating with the atmosphere by channel N. The return of the piston K is accomplished thus: As its rear end passes the port O the air escapes into P, and thence reaches the "constant pressure" ports Q, which, leading into chamber M, allow the air to get along the holes LL, in front of the piston, to drive the latter back. The remaining air at the back of the piston rushes through the ring of holes (shown black) in the valve R, the latter being then in its backward position, so that the holes exhaust into N. The return stroke continues until the piston blocks the (black) holes in R, and the little remaining air is forced back (forming a cushion device, meanwhile) into other orifices at the rear portion of R, communicating with a shoulder on the latter, and causing the air to move R forward ready for another stroke. Other types of these tools are constructed for chipping and caulking, the action being similar, proportions varying, however, to suit the work.

The "Holder-on." An appliance used in conjunction with the riveting hammer is the "holder-on" [213], used on the head of the rivet which is being closed instead of the usual "dolly." The tool is brought up to the work, a bar being screwed into the back end for support, and the throttle formed by the revolvable hand-grip A opened, thus forcing the large cylinder B outwards, and pressing the snap C on the rivet head. The valve D is then opened, causing the piston E to reciprocate, and beat the rivet well into its hole, at the same time the riveting hammerman, on the other side of the plate, begins to turn over the tail. The holder-on valve is then shut off, stopping the piston E, but still keeping the snap pressed up; the elasticity of the air behind the cylinder B forms a cushion or spring, which allows the tool to yield slightly at each riveting blow. When closing is finished, the throttle A is opened to exhaust, and the holder-on removed. The air-passages are seen in full and in dotted lines in sectional and end views. These tools are from the practice of the Consolidated Pneumatic Tool Co., Ltd., of London.

Air Hoist. Hoisting is done either by the application of cylinders imparting a rotary motion (the mechanism being very similar to



215. VENTILATING FAN AS USED IN THE LONDON UNDERGROUND ELECTRIC RAILWAYS

that in 211) to a drum, upon which the lifting chain or rope is wound, or by direct action, as in the hoist [214] (Alley and Maclellan, Ltd.). Here a long cylinder (A) carries a piston (B) and rod (C) to the bottom end of which the hook is attached. Air is admitted from a hose through the pipe at E, passing into the vertical pipe F through a check-valve, which instantly closes should the supply fail, retaining the air already in, and so keeping the load from dropping.

Admission to the cylinder at the bottom is controlled by the throttle G, opened and closed by the levers H H, moved by hanging chains in either direction. As the piston B rises, the air above it escapes through the orifice J, but when near the top of the stroke this is closed by the piston, the little air left forming a cushion, which prevents the piston banging against the cylinder head. An automatic balancing device is fitted to the bottom cover, so that a load may be kept suspended at a uniform height for a while, even though its weight varies, which is the case in building up a mechanism, or emptying a ladle of molten metal. A ring (K) is clamped to the rod C at any desired position, so that, should the load lighten, and the piston consequently rise a little, K opens an escape valve at L, allowing some air to pass out; if, on the other hand, the weight hangs for a long time and air gradually leaks out, a valve at M opens and admits sufficient to compensate for the loss. The eyebolt at the top of the cylinder is suspended from any suitable anchorage, either a beam, or a trolley running upon girders, or a crane-jib. Hoists of this type are made in other patterns, usually of longer stroke than the example shown, and also placed horizontally, operating lifting ropes, passing over pulleys to the ground.

Fans and Blowers. In our study of hydraulics mention was made of the centrifugal pump. There is a machine which differs in no essentials from this pump, which is utilised for the discharge of air, and is termed, according to its method of operation, a *fan*, or a *blower*.

Free air is drawn in at the sides of the fan by the creation of an induced draught, produced by the revolution of the fan, from any source of power. It is then discharged at the outlet, just as the water is discharged from the centrifugal pump, at a rate and pressure depending on the size of the fan and its number of revolutions. It is obvious, therefore, that this machine can be used to exhaust air by drawing it through the vanes, or to force it under pressure into pipes connected with the outlet; and the two may be used in combination—that is, induced and pressure operations combined.

Fans are used for a large number of purposes, the chief of which are the ventilation of mines, public buildings, and factories. In connection with the last two a growing practice is to connect the fans with apparatus for heating the air in winter, and by a system of pipes to discharge it at intervals throughout the building. This is more satisfactory than utilising the natural draught from open windows. Both methods are employed, the induced draught and the pressure system, termed respectively the iteus and the item, concerning the merits of which much controversy has arisen. Another purpose for which the fan is used is in supplying blast to the cupola furnaces of iron-founders and to smiths' forges. The only rival to the fan is the pressure-blower of the Root's and similar types, illustrated in the last article. The fan is a rival to the tall chimney for creating draught in the furnaces of steam boilers; its expense is much less, and it is generally capable of better regulation.

There are three methods of employing fans in connection with steam boilers. Induced draught fans may be used in the main flues of one or more boilers, where of course the fan deals with the gases at a very high temperature. On the other hand, fans are installed to deliver the air at normal temperature directly into a closed ashpit, or closed stokehole, with or without passing through an auxiliary heater, heated by the waste gases from the furnaces. In marine work the practical impossibility of having high chimneys makes it absolutely necessary to employ forced draught, which is most satisfactorily and economically obtained by means of centrifugal fans.

Science of Fans. The mathematics of the fan are rather troublesome, and actual experiment, as in centrifugal pumps, is the only safe basis on which to guarantee results. The subject is too wide for discussion here. The principal factors are the size of the fan and the speed at which it is driven. The volume of air delivered practically varies directly with the speed; the air pressure generated varies as the square of the number of revolutions, and the horse-power required to drive varies as the cube of the velocity. Doubling the speed of a fan, therefore, doubles the volume of air delivered, and increases the pressure produced by four times that originally existing, while the power required is eight times greater. But, in selecting a fan, more than this is required because of the great losses due to friction, leakages, and the effects of bends, long pipes, and, when the air is heated, losses due to resistance of the heater-pipes. A safe rule is to select a large rather than a small fan, one with ample capacity running at moderate speed rather than a smaller one running at high speed. Like many other matters connected with engineering, it is one in which expert advice should be sought.

Fig. 215 is a good example of a ventilating fan, of which thirty-nine were supplied to the Underground Electric Railways Co., Ltd., of London, by Messrs. Heenan and Froude, Ltd., of Worcester. The vanes, or blades, mounted on the 5 ft. 6 in. revolver, are of $\frac{1}{8}$th in. steel plate, riveted to the $\frac{3}{16}$th in. and $\frac{1}{8}$th in. circular plates. The body of the fan is also made of $\frac{1}{8}$th in. plate, combining lightness with a strength sufficient for the purpose. The drive is by electric motor, as seen to the left.

ORGANISED TRAVEL

Organisation of Travel Parties. Duties of the Leader. Special Tourist Reductions in Fares. Cost of a Typical Tour. Necessary Baggage

Continued from page 1650

By Rev. A. L. FILLINGHAM

IT is becoming common for a few friends to co-operate in a holiday arrangement, especially for Continental excursions. The vast possibilities that lie behind this kind of enterprise are scarcely realised. In all such cases it is essential that one, or two at the most, should arrange for the whole excursion.

The Leader of the Party. The supreme difficulty is in securing the right leader. A lady or gentleman of very even temper must be found, who can at the same time be very firm. Combined with a fund of patience there must be some amount of liveliness and good spirits if the party is to go its way with the constant pleasure they naturally desire. There must also be a very clear head for business and some acquaintance with the foreign languages that may be encountered. When the right leader has been found, the very first thing to determine, either mutually or by the leader's choice, is the country that is to be visited, and then more particularly the route by which it will be reached and the district that will be traversed. It will also be necessary to determine whether completely independent arrangements shall be made or whether some of the facilities offered by touring agencies shall be utilised. For instance, it may often serve the purpose of a party to take one of the very cheap week's arrangements offered by nearly all touring agencies, and then continue in the country paddling their own canoe. If they agree to take the whole of the tour under the control of an agency, they will find that a reduction of about 10 per cent. will be granted for a party that includes a reasonably large number.

The scope of this article, however, is specially to explain how a party of this kind can be arranged as a private company which intends to make all its own arrangements under a conductor of its own selection. In making details clear it will be well to treat first of those things which must be done before leaving home, then of those things which will need attention on the holiday itself, and, finally, to give a few samples of cost, etc.

Before Starting. Letters should be sent to the railway or steamboat companies that are most likely to offer travelling facilities to the country that has been selected. The lowest rate for the smallest party, that would be counted as a party, must be ascertained. It will generally be found that substantial reductions of about 30 per cent. can be secured for a party of at least 30 travelling together on the outward journey, but having the right in most cases to return home independently. It is no use wasting correspondence as to independent travel on the outward journey or a smaller minimum than the one which will be stated by the company granting any concessions. These conditions are essential and fixed.

It will be desirable to get the best guide-book to the country selected, and the most modern edition, and to trace out a reasonable itinerary. If a large number in the party are going to the country for the first time they will naturally—though foolishly—desire to see as many places as possible If that desire can be restrained, or if a large number in the party have been to the country previously, it will be desirable to limit the number of stopping-places to one per week. In any case, if a place is worth visiting at all it is worth at least three or four days. If shorter stays than this are made, the labour of packing and unpacking becomes tedious to the party and the process of settling and unsettling his company becomes very trying to the conductor. In a four-night stay three days are secured in which the more vigorous may explore the vicinity more or less widely.

Preliminary Correspondence. Having fixed upon the places to be visited and the time to be spent at each one, it will be desirable to communicate with the foreign railway companies or their agents in England—*e.g.*, Swiss Federal Railway Office, Shaftesbury Avenue, London, W.C.—and find what is the cheapest "rundreise" ticket inside the country which would cover the tour projected. In Belgium, Switzerland, and a few of the more frequented countries very special tickets are often issued which will cover *all* the railways on the national system. In Switzerland a ticket for 15 days bearing the photograph of the person to whom it is issued, to prevent double use, can be procured for about 30s., and is valid on all the ordinary railways and steamboats of the country. When there is a desire to see many things instead of much, these tickets are great economy. When one is staying near a railway line or steamboat course it may save money and provide much enjoyment to have such a ticket in daily use, even though it is not taken outside the district.

Hotel Arrangements. The return "party" fare to the country and the probable railway expenses in the country having been thus ascertained, it is necessary to select from the guide-book two or three likely hotels in each centre where the party proposes to settle. A penny postcard to the respective proprietors will soon bring in quotations for rooms, light, and attendance, breakfast, and evening dinner, if the probable date of the visit, length of stay, and number of persons in the party is stated on the inquiry.

We append a form of postcard inquiry which is found to answer the purpose well:

DEAR SIR,

We hope to bring a party of........persons to................on..........for....days. Will you please send by RETURN POST your price per person per day for hotel accommodation. We should require about two rooms for every three persons, light and attendance; café complet (lunch ?) and table d'hôte; also free carriage for hand baggage to and from station; all included. Please say what you would charge per person each way for those who use the 'bus to and from station. Also please state what you would deduct from pension terms when notice is given before 9 a.m. that déjeuner will NOT be required?

If you could kindly send a map showing where your hotel is placed and a picture of the hotel itself, these will help me to decide.

If you can name any other English party that has stayed with you—giving name and address of conductor—it would oblige. We will reply to your offer a week (or month) before arrival if it is accepted.

As lunch is usually a difficult meal to arrange beforehand when sight-seeing, it is well to make special mention of this, and to ask for terms "with and without luncheon."

The Programme. When all these financial points have been approximately settled, it will be necessary to draw up a programme to submit to all the friends likely to join such a company. This programme should give the station and time for meeting in London, with the exact date; the route chosen and length of sea passage; the condition of united travel on the outward journey; the places to be visited, and, if already settled, the names of hotels; the cost of tour, preferably including a due allowance for extras, or with extras clearly stated; the class of travel at different points should be indicated, the cost of excursions if not included in the main booking; the number of days that the ticket is valid for independent return; the number of days' hotel accommodation included in the cost specified; the possible personal extras such as midday meals, refreshments on the journey, carriage drives, gratuities, and anything that may come in over and above the general cost specified.

If the response to this programme from one's own friends is not sufficient to secure the minimum number required, it will generally be easy to secure likely inquirers by advertising in newspapers that commend themselves to the promoter.

We imagine now that all preliminary arrangements are made and the required minimum have definitely booked. We may add also the hope that they have paid a goodly portion of the money at least a few days before starting. This saves the conductor any risk of bad debts and the member any risk of losing large sums on the journey. The conductor can pay all hotel bills on the route by cheque. We come, therefore, to the second part of our subject.

On the Tour. First of all the conductor must be early at the meeting-place to introduce himself to all the members, and then to introduce them, to some extent, to one another. A great help in this will be found if all luggage is labelled with distinctive tags, such as all one colour, or the patent ones imprinted with one large initial in common, but each a different number and tear-off counterfoil. These are supplied by Messrs. Perry & Perry, 26, Duke Street, St. James Street, London.

Having collected all baggage under one porter, and ascertained that all members are present, it is now time to register. Here a small economy is at once effected. Generally, so many pounds per person is allowed free, or a minimum charge per person is made. By weighing together the baggage of, say, thirty persons, it may be found that only the weight allowed to ten persons is there, and so twenty minimum charges are saved. That is, if little baggage has been taken by each member. This is an essential condition throughout. Much baggage is a burden to those who go for holiday, and a great worry to the one who is arranging its details. Its conveyance to and from Continental hotels should be included in the specified requirements for which prices are sought. Everybody should be told in advance that more than an average of, say, 28 lb. each must be registered, and attended to by the individual member. They should also be reminded that baggage registered cannot be touched till it is delivered up at the destination. A small handbag, with things required en route, should, therefore, be kept from registration.

The Inner Man. On the outward journey reserved carriages will be found, if proper notice has been given and the time-table submitted has been adhered to. Meals en route are generally best left to the members. Some can take very little while travelling, and others prefer to take a little of the food to which they are accustomed, and thereby save the change of diet till they arrive. It is, therefore, hardly just to include these items in the inclusive charge. But it is helpful if the conductor has ascertained price of breakfast here and dinner there, so that he can wire forward the number of seats to be reserved at a certain buffet. In chatting about such details he will get to know the party better, and also secure introductions between different "sets," which might otherwise develop into undesirable cliques.

Of course each hotel will be advised as to the exact hour of arrival, the first meal desired, the total number of beds required, and the number of rooms in which these must be arranged. Nearly all beds are single. The average party requires two rooms for three persons. On arriving at the hotel the proprietor should hand to the conductor a copy of the party-list sent him in advance, with the room number opposite each name, or set of names where friends' names are bracketed. A good wash, a change of dress, and a hearty meal, and, above all, a good night's rest, will put everybody at once into a state of forgetfulness about the tedium of the journey.

The Duties of the Leader. It has now become a question whether the conductor will be at liberty during the day to enjoy himself like other people, or whether he will be the constant leader of an almost uniformly large party. He should have a definite understanding about this at the beginning, whether the excursions are covered by a season ticket, or whether each member has a "rundreise" ticket covering only the absolutely necessary travel of the tour. Of course the season ticket favours people conducting themselves, and in any case that method is greatly to be encouraged. The members get more interest and instruction out of the holiday that way, and the conductor more relief. When it has been arranged to stay for a whole week at each of two centres the tendency becomes very strong for small groups to make their own arrangements day by day.

This is the ideal thing for everybody concerned. It is a great help, however, if the conductor can sketch out one or two possible excursions for each succeeding day, and indicate times of departure and return; also fares, where they will be involved.

Underneath each excursion so sketched friends can sign who would like to join in that particular excursion. Another column can be left for those to sign who will be away from the hotel all day. Then, where the midday meal has been included in the hotel accommodation, proper notice can be given for those who would like lunch packed.

The Wet Day Programme. The conductor will find the duty naturally devolve upon him of providing something for the evenings and on wet days. He need not arrange concerts or start games; but if he does not, he must inspire someone else to do so. Then on Sundays he must be able to announce where English services are held, and of what kind. He must, moreover, in lonely places, arrange for voluntary services if the party desire it and there are members willing to conduct the same. To many who join such companies Sunday may become the most pleasant or the most disappointing memory of the whole tour.

All dealings with the hotel proprietor should be concentrated in the conductor, and all tipping of the servants should be done by him. As a rule, twopence per day per person in the party, wisely distributed according to the proprietor's suggestion, will give satisfaction. Some part of this is well distributed at first and also during the tour. If the conductor seizes occasions that arise, such as late return from excursion, or extra help in interpretation, and bestows occasional gratuities instead of saving all to the end of sojourn, he can do much to make his party welcome at the hotel.

Grumbling. It should also be an honourable understanding, constantly insisted upon, that all complaints must be made to the conductor, and to him alone. It may be that none will occur; but if some small cause of disappointment does arise it is not fair that it should be discussed in the party until the conductor has had fair chance to put it right.

Attention to details such as these, and to others which will readily suggest themselves in the course of the holiday, do much to secure the pleasure of all concerned. Whilst the conductor thus inevitably has more trouble than any other, he has also a great satisfaction in seeing so many thoroughly enjoy what might be an impossible pleasure if he had not undertaken for them.

Sample of Cost. We shall now make a calculation of the cost of a Swiss tour on the lines indicated above. Very exact figures are not given, as they may vary in different years and will vary in any one year according to the route which may be selected; but the following may be safely trusted as an average guide, and are quite the outside figures for a moderately conducted tour extending over 18 days:

Ret. 2nd party fare, London to Basle, available for independent return within 25 days, say ..	£3	10	0
[Ordinary individual return fare, as above, £5 5s.]			
Hotel accommodation, including room, light, attendance, breakfast and evening dinner, porterage of baggage to and from station; 14 days, at 7s. per day	4	18	0
Margin to cover postal and other incidental expenses—*e.g.*, gratuities, preliminary advertising, and unexpected losses or miscalculations	1	2	0
Swiss season ticket, 3rd class, available 15 days, but not 15 nights, and making a wonderful variety of excursions possible at no extra expense	1	10	0
	£11	0	0

Extras. There are possible extras that should also be pointed out beforehand.

CARRIAGE DRIVES. These should be optional, even where the drive is a long one and the cost known beforehand, and the journey absolutely necessary to complete the tour. Even in such cases there may be vigorous members of the party who prefer to walk, and may wish to save money by doing so. It would not be just, therefore, to include any such drives in the specified charge.

CHANNEL STEAMER. The shipping company will generally reduce greatly the price for transfer to first class if the whole party, or a real majority, take such transfer. This also may be treated very wisely as an extra, but strongly recommended, especially where a long sea passage is involved.

MOUNTAIN RAILWAYS. These are never included in the Swiss season ticket, except Brunig and St. Gotthard. It would therefore be better to treat them as an extra, on which considerable reductions can be secured by all Swiss season ticket holders, and also by small parties of twelve or sixteen who do not hold such tickets. It is not wise to include these in the main cost, because, again, some members of the party will greatly enjoy a good climb.

EXCURSIONS. If the season ticket is not adopted generally, but a "rundreise" ticket is secured for each member of the party to cover merely the tour arranged inside the country, a great deal may be saved in excursions by taking as much as possible en route from one centre to another. For instance, if Lucerne and Lugano were the two centres, a long but glorious day could be secured by taking Tell's Chapel and the Axenstrasse, with breakfast at Altdorf; then break again at Goeschenen, and drive to Andermatt for lunch, and finally reach Lugano at night. Or, a second instance, with Lucerne and Interlaken as two centres: on the day of change a magnificent excursion to the sights of Meyringen and the Geissbach (Fall) may be arranged. Such an arrangement can always be made on the day of change, and save both time and money.

Profits. These will vary according to the idea which leads to the formation of the party. If a minister in a church, or a chief teacher in a large school, or some manager in a business promotes the party with a view to bringing such pleasure within the reach of those whom they desire to help, he will generally be content with the free ticket which can often be secured from the railway company for him, and with the free hotel accommodation which the proprietor will often concede to him as conductor. If he drafts his programme with such an idea as this, he should arrange for part of the margin, allowed in the above sample of cost, to be a weekly levy. This would then protect him completely against any unexpected losses. If it is worked for a larger gain than this, the margin set down would probably provide for a second member of the party to get a free holiday, if all calculations had been carefully made. If it is worked as a purely business affair, then a percentage must be added as profits to the actual estimated cost. Worked on that basis, however, the private party will find it more than difficult to compete with tourist agencies.

Recommendations to Members. The conductor will be wise if he issue to every member of the party a list of instructions and recommendations. It is better to assume that the member is ignorant of the most elementary necessities for the excursion. We subjoin a form of letter which embraces the points to which notice should be directed.

DEAR SIR OR MADAM,

You may be glad of a few hints to prepare for our excursion. A list of hotels for addressing letters will be sent just before we start, with railway tickets, luggage labels and any final instructions.

Luggage: This should be as light as possible. In Switzerland only hand-baggage is free. The trouble, delay, and expense caused by registration make it therefore undesirable to have more. Porterage will be arranged to and from hotels. Through registration will be effected *together* from London to our destination, if possible.

Outfit: Washing can be done easily and cheaply en route. Evening-dress is not necessary. The following articles should be remembered: Toilet requisites and soap; slippers or light shoes; walking boots, light and flexible, but strong and worn to comfort beforehand; light mackintosh or cycle poncho; broad-brimmed hat and cap; only pilgrim-baskets, hold-alls, or gladstone bags should be used, no heavy portmanteaux or trunks.

Refreshments: It is a great convenience as well as economy to have an ample store of sandwiches, etc., packed for the journey. An outfit for making tea, and a supply of tea will always be found most useful.

Money: The balance due should be brought in Bank of England notes. All money can be changed by conductor. Tips will be given for party together and levied with porterage.

Sundry Items: Cameras, flower-presses and tins will be very useful. Music, etc., for evenings and wet days will be welcome. It is expected that all will do their best to help on friendly feeling. Complaints (if any) should be made at once and only to the conductor. Any suggestion will have every consideration.

Anticipating a very happy time together,

I am, yours heartily,

(Signed).

Books to Study. The volume to be mastered first and studied most will cost nothing. It is the Continental time-tables of the company by which the party travels. All the paragraphs about baggage registration and examination, routes and conveyances should be carefully gone through. Any that can apply to the party should be marked. The time-tables which touch the route selected should also be all taken out and pinned with pages on which those paragraphs are found. It will be very helpful to send to a bookseller in the country for the local railway guide so that journeys in the country may be mapped out before starting, and so save labour of choosing trains during the holiday.

Beside these there is probably no book so useful as a Baedeker. The tours sketched at the beginning are always suggestive of a wise expenditure of time where the desire to cover much ground prevails. Cheaper guides in such series as those published by Bradshaw, Cook, Lunn, and especially Paterson's, issued by Oliphant, may be well recommended to the party. It will make the holiday more interesting to the party and much less laborious to the conductor if some have read up well. An ordnance map should be ordered from a native bookseller. The money order sent for this may be made to cover cost of railway guide.

Then a few books relating to the rendezvous may be usefully recommended in the circular of instructions. Of course this will be for reading before or after the holiday. *E.g.*, *Paris*—Zola's "Paris" or Dumas' "Bastille"; *Switzerland*—Schiller's "William Tell" (Scott), or Ball's "Cause of an Ice Age," or Newnes' book on the Social Life of Switzerland.

GEOLOGICAL WORK OF THE SEA

Wave Action and its Results. Organic Life in Geology. Strata. Sedimentary Rocks and Their Formation. The Origin of Fossils. Ancient Sea-beds

By W. E. GARRETT FISHER

geological function of the sea is twofold. In the first place it acts as a very powerful erosive agency in attacking the coast-lines of the various continents and islands which it washes. In the second place, all great accumulations of water, both inland lakes and the ocean, act as receiving stations for the vast accumulations of detritus, which we have seen to be scraped off the surface of the land by rain and wind, rivers and glaciers, and cause this detritus to be laid down in successive layers, or strata, which have given birth to almost the whole of the sedimentary rocks. We shall first consider the *erosive action* of the sea. We all know that the sea is constantly in movement. The gravitational influence of the sun and moon cause its waters to oscillate in tides [see GEOGRAPHY and ASTRONOMY], which vary in rise and fall from a few inches in enclosed seas, like the Mediterranean, to 60 or 70 feet in confined spaces, like the Bay of Fundy. This rise and fall of the tide plays an important part in the erosive action of the sea

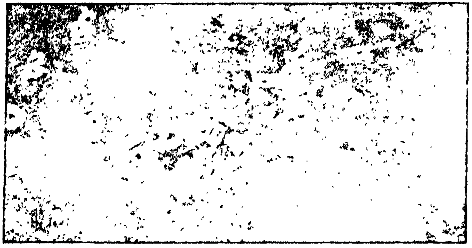
Tidal Action. Where, as on the British coast, there is a normal difference of 10 or 20 ft. between high and low water, the actual rise and fall of the water has a disintegrating effect upon the coast-line. The space between high and low water-marks is generally occupied by a beach consisting of shingle, sand, or mud, which are all alike the disintegration products of the rocks which line the coast. Tidal movement alone tends to widen this beach and make it slope more gradually out to sea. Where the coast is bounded by precipices of hard rock-like granite the beach may be altogether absent, and the water simply rises and falls against the cliff, as it does against the quay or breakwater of a harbour.

Erosion by the Waves. The chief disintegrating agency of the sea, however, consists in its waves, which are caused by the friction of the wind upon the water. These waves exert tremendous force when they strike upon the cliffs and beaches. In some cases on the coast of Scotland they have been known to exert a pressure of three or four tons on the square foot. The enormous force of these breakers tears off fragments from the solid rock, often many tons in weight, and washes them about like pebbles. These fragments are often launched against the coast-line by the returning wave, and serve as battering rams to increase the destruction. As a rule the sea cliffs are not a solid wall, but are penetrated in all directions by *joints* or *fissures*,

Valentine

68. BEDRUTHAN STEPS, CORNWALL, ILLUSTRATING THE ACTION OF THE SEA UPON THE LAND

which help the disintegrating action of the sea, just as in other cases they simplify the labours of the quarryman. The pressure of the onrushing waves and the air which they drive into all these cracks and crevices gradually enlarges the fissures and joints of the rock, until huge pieces come tumbling down into the sea, where they are washed about and ground together until they are ultimately broken up into mere gravel and sand. The vast accumulations of sand that form the ordinary sea-beach are all formed of quartz, one of the hardest of rocks, which has thus been broken down into mere dust.



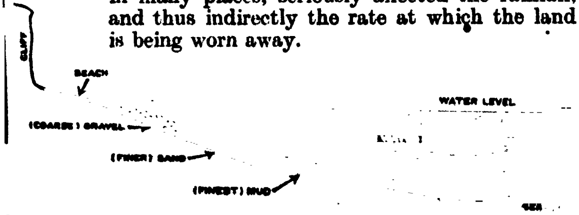
69. TRIPOLI POWDER UNDER MICROSCOPE

The actual rate at which the sea carves away the coast-line depends, of course, upon the hardness and structure of the rocks on which it breaks. Granite precipices like those of Peterhead scarcely change perceptibly in the course of a century, though the bold and picturesque features which they present are wholly due to the progress of marine erosion. The striking cliffs of the Cornish sea-board [68] illustrate every stage in the process. Where the coast is composed of comparatively soft rocks, as on the sea-board of East Anglia between the Wash and the mouth of the Thames, the sea eats rapidly into the land ; in some places four or five yards per annum are said to be washed away, and the erosion of our east coast at places like Southwold has become a very serious problem to the engineer as well as to the geologist.

Marine Transport. The sea also performs the work of transport, carrying much of the sediment derived from this erosive process long distances. We shall deal with this part of its action later, when we come to consider the construction of sedimentary rocks. It is enough to note here that, in addition to the ordinary transport of sediment by oceanic currents, a considerable quantity of rough and rocky fragments is carried out to sea by [illegible] glaciers of polar regions, and travel southward until they ultimately melt and drop their moraine-stuff on to the sea-bed.

Geological Effects of Life. The last agency which we have to consider as helping to break up rocks and rearrange their materials is that of life. Though it is less considerable than the inanimate agencies which we have already described, both *plants* and *animals* have played an important part in the superficial moulding of the earth. Their work is both destructive and reproductive—the latter being more important from a geological point of view. The destructive action of plants is necessarily confined to the superficial layers of the soil, since they can only live in places where they can obtain air and sunlight. The effect of their roots penetrating through the soil and wedging apart the joints of the rocks is sometimes very marked, as we frequently have occasion to see when a tree which happens to have taken root among the ruins of a building is seen to have detached portions of the masonry from its walls, or the growth of some tiny plant is found to have lifted paving stones out of their proper position. The disintegrating effect of plants on the soil, however, is more largely due to the *chemical products* of their decay, which frequently attack various kinds of rock, dissolving or changing their substance.

Animals and their Geological Work. The influence of animals on the soil is not very important, except in the case of the common earthworm, which Darwin proved to be a very diligent fertilising agent. These worms spend their lives in bringing up the deeper particles of soil to the surface, and thus play an important part in the operations of agriculture. Other animals sometimes modify the geological developments of the district by interfering with the courses of streams, as the beaver does in America by building dams which often divert the water into new channels or cause the whole upper part of a valley to be turned into a lake. Some molluscs riddle a considerable number of rocks with holes, which promote the work of disintegration by rain or sea-water. Of course, it is hardly necessary to add that man, in his various operations, sometimes becomes a powerful geological agency. Thus, to take only one instance, the erosive effect of the sea on nearly all civilised coasts has been very largely modified by human works, such as groynes, breakwaters, and embankments. The greater part of Holland has been reclaimed from the sea by the industry of its people. The cutting down of forests has, in many places, seriously affected the rainfall, and thus indirectly the rate at which the land is being worn away.



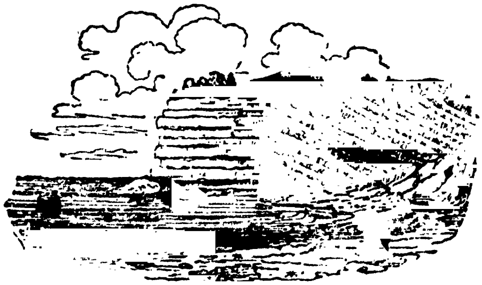
70. DIAGRAM ILLUSTRATING THE FORMATION OF MARINE DEPOSIT

Rocks Due to Organic Agencies. The *reproductive* action of life upon the earth is extremely important, at any rate, from the human point of view. The *coal measures*, or strata of carboniferous rocks on whose exploitation the modern development of industry has been built, are entirely the product of primeval vegetation which has decayed and been buried for long ages, to yield up its carbon at last for the use of man, who warms his house and drives his engines by unlocking the energy which these old-world plants once derived from the sunlight.

Soils. The fertility of our richest soils, such as the loam of the American prairies and the black earth of Russia, is due mainly to the long continued growth and decay of the vegetation which has given up its organic residue to mix with the mineral debris, and so form the best kind of soil for agriculture. The well-known Tripoli powder [69], which is used for polishing, mainly consists of the debris of diatoms of tiny plants which have the knack of extracting silica from sea-water and weaving it into their fabric, whence it ultimately accumulates in beds on the sea-bottom. The production of some important metallic ores, such as bog iron ore, is largely due to the agency of vegetation.

Coral and Chalk. Some important rocky formations are due to animal life. Great masses of limestone are derived from the shells of tiny marine organisms which have accumulated on ancient sea bottoms. Coral reefs [see page 558], which are chiefly composed of carbonate of lime, are entirely built up by the animals known as corals, aided—as we saw in an earlier section—by the slow subsidence or upheaval of the land.

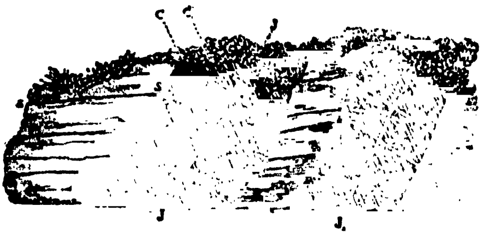
There are great masses of limestone found in the Alps and Pyrenees which were originally deposited as coral reefs in the warm prehistoric seas which once rolled over the sides of these mountains. The great beds of chalk, again, which form so large a portion of southern England, and furnish that most characteristic and beautiful of spectacles, the white cliffs, which look like frosted silver when one gazes at them from the other side of the Channel, consist almost entirely of the tiny shells and skeletons of minute organisms which once lived in the sea, and rained down these tiny shells and skeletons on the sea-bed as they died in countless numbers.



72. STRATA SHOWING DIP AND OUTCROP

FORMATION OF THE STRATA

We have seen thus far how many agents are at work to wear down the surface of the earth, and disintegrate the primitive rocks. These processes have been at work since the earliest and unrecorded beginning of things. No sooner had the crust of the earth solidified than the agencies of denudation and disintegration began to operate upon the bare and cindery surface of the igneous rocks. At first these agencies were less powerful than they became after the water had liquefied and the action of rivers and seas was added to that of atmospheric influence. But they have ever been at work, abrading the original rocks and wearing them into sand and debris. We have now to see how this loose material was again formed into new rocks, of which the greater part of the earth's surface is now composed.



71. THE FORMATION OF STRATA
S S. Planes of stratification. C C. Planes of cleavage. J J. Joints

As we have seen, the chief influence in the work of denudation and disintegration was running water. But water cannot run down hill for ever ; sooner or later it must sink to a level beyond which it can go no lower, and therefore ceases to move. The bodies of water which represent this lower limit of stagnation are known as *lakes* or *seas*.

Lakes. Lakes are bodies of water occupying depressions on the surface of the land. They may be either fresh or salt. It will usually be found that a fresh-water lake has an outlet for a great part of its waters in the shape of a river. When there is no such outlet and the water brought in by rivers is able to escape only by means of evaporation, the lake inevitably becomes salt, because the rivers are always bringing in a certain amount of dissolved material which is unable to escape, and the chief constituent of this material is common salt—the most readily soluble of all minerals. As the volume of water in a lake usually remains fairly constant, but the quantity of salt is thus being steadily increased, the lake must get salter and salter until its water reaches what is known as the *saturation point*, after which the water can hold no more salt in solution, and for every pound of salt brought into the lake a pound is crystallised out on the shores of the lake.

Seas. What we call seas or oceans are simply vaster lakes which occupy the gigantic depressions which were formed on the surface of the earth by ancient geological agencies. We do not quite know how these depressions were formed. Some of them are probably due to a general subsidence of the land. This is certainly the case, for instance, with the basin of the Mediterranean. There is a possible theory that the vast Pacific Ocean occupies the scar which was left when the huge bulk of the moon split off from the earth, as has been explained in an earlier section. But though the seas and oceans are incomparably larger than any of the *bodies which we call lakes,* there is no essential *difference between the two.* We may speak *of the great lakes of North America* as inland seas, or of the seas as vast salt lakes. A distinction is usually drawn by geologists between sedimentary rocks which have been deposited in a lake or in the sea, but there is no essential difference.

How Sedimentary Rocks were Formed. It is on the beds of these sheets of water that by far the greater part of the sedimentary rocks have been deposited. It is not difficult now to see how this has happened. We have already seen that every river brings down a considerable body of sediment—fine sand or mud, the débris of the rocks which have suffered disintegration under the various erosive agencies. The greater part of this sediment naturally remains suspended in the water by virtue of its motion. When the water ceases to flow, the sediment gradually sinks to the bottom. This process is illustrated by the familiar experiment of stirring up a bowl full of pea soup, which essentially consists of water containing a greater or smaller quantity of organic sediment—meat fibre and the like. After a thorough stirring the whole of the soup is turbid and fairly homogeneous. But if it be allowed to come to rest and stand for a time a great deal of sediment settles down to the bottom and leaves on the surface a comparatively clear liquid. Exactly the same process is involved in the common injunction to shake a bottle of medicine before pouring out a dose.

Deposit. When a river runs into a lake or the sea, it gradually loses its motion and comes to rest, though, in the case of great rivers like the Amazon or Mississippi, the current may still continue to move for many miles out to sea. As it slows down it steadily deposits its sediment on the bed of the lake or sea. The same thing happens along the bed of the river itself; whenever it passes into a quiet pool and suffers a temporary loss of speed, the sediment is thus deposited with fair equality in all directions. As time goes on the deposit becomes thicker and thicker, until, if there be no disturbing influence, a great part of the lake may be silted up by these deposits, through which the river goes on its way and keeps merely its own channel open. It is thus that *bars* and *sandbanks* are formed at the mouths of many rivers, and that *deltas* are constructed, stretching far and wide out into the sea.

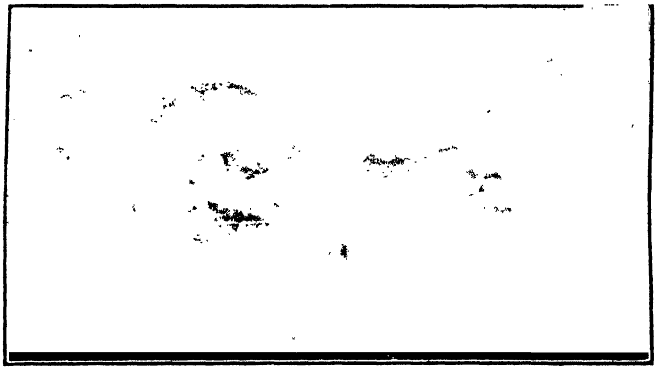
The Process Discontinuous. As a rule, the process of deposition is not continuous. On the one hand, few rivers run with an absolutely steady current. At one season of the year, when their waters have been fed by excessive rainfall, they come down bank-full with a rapid current thickly charged with sediments of all kinds. At other seasons, when rain is scanty, the volume of the current may be greatly diminished and trickles into the lake or sea almost devoid of sediment. Again, the recipient body of water may at one time be calm and ready to receive the sediment evenly on its bed; at another time it is convulsed by storms, and the sediment is thrown far and wide and heaped up in irregular accumulations instead of being spread in a homogeneous sheet. It must further be noted that when the deposits thus brought down by rivers become of considerable thickness, their lower portions are subjected to the pressure of the upper ones, which may in time amount to several tons per square inch. In this way the lower portions of the sediment are compressed and hardened into a more or less solid rock, just as powdered graphite and other substances can be made into solid blocks in a hydraulic press.

The Strata. We are now in a position to see why it is that the sedimentary rocks are almost always found to be arranged in *layers, beds,* or *strata* [71]. If the process of deposition were absolutely uniform we should expect to find the sandstones and shales, which are simply hardened deposits of sand or mud, showing no signs of *bedding* or *stratification.* But it is almost always found that the processes of Nature are not continuous, but work by fits and starts. This is generally the case with the deposit of sediment by water. Take the case of the ordinary river; when its current is full and swift, it brings down a great mass of sediment, which is deposited on the bed of the lake or sea into which it flows; then, with the change of seasons, comes a period during which little or no sediment is deposited. By the time that the rains again set in and the abundant deposit of sediment begins once more, the lower portion has settled down and formed itself into a roughly horizontal layer, with a well-defined surface, and a slight commencement of hardening on the surface under the pressure of the water. The next accumulation of sediment is spread over this and passes through the same process; there is usually a well-defined surface of demarcation between the older and the newer layers. This process is constantly repeated throughout long geological ages, and thus the rock which is finally formed on the bed of the sea or lake is found to be divided by planes of stratification or bedding [71], which are generally more or less horizontal and parallel to one another. Their thickness will be greater or less, according to the amount of sediment brought down each time the river is in flood, and to the relative intervals which elapsed between the arrival of fresh deposits.

The Origin of Fossils. Of course, the process of forming a sedimentary rock is here reduced to its simplest elements, and a great deal of modifying detail has been omitted. We may note, for instance, that a great deal of extraneous matter will be mingled with sand or mud brought down by the river. The organisms which lived in the water are constantly dying, and their remains settle down upon the floor of the lake or sea, and are there buried under the steady accumulation of sediment. This is the origin of the majority of *fossils,* which are so continually found in sedimentary rocks. The soft parts of the organisms decay, but they may leave their mould in the hardening sand or mud, which is often filled in and preserved for future ages by some mineral which the water holds in solution. Then the harder portions, such as bones, teeth, or shells, may be preserved almost unchanged, and it is the existence of such relics of long extinct species that enables us to form sound theories as to the gradual evolution of life.

Fossil Vegetation. Vegetation that has been swept into a lake or sea often becomes water-logged, and sinks to the bottom, there to leave its impress upon the growing rocks. A considerable part of the coal measures consists of vegetable matter, which was thus accumulated under water and buried by sedimentary accumulations.

It will thus be seen that the sedimentary rocks have mostly been formed near the shores of lakes or seas. Evidence of this is afforded by the fact that a large number of sandstones and shales bear proof of having been alternately covered and deserted by the sea as they were being formed. The sea-beach between high and low water-marks is simply a sedimentary rock in process of deposition. As the tide ebbs and flows it is alternately exposed to the air and dried by the sun, and then buried under the waves. As a rule, any markings which are made upon it by the rain, the footsteps of animals, or the elementary sculptures of the human child, are washed out by the return of the sea. But sometimes these marks have been preserved.



73. SANDSTONE, WITH FOSSIL FOOTPRINTS OF THE LABYRINTHODON, AN EXTINCT REPTILE

Footprints on the Sands of Ancient Seas. Where a beach is composed of mud rather than sand, its surface may dry so hard in the sun that any marks thus left upon it are retained [73] until a new layer of sediment is deposited upon them, and thus they are preserved to interest geologists of a future age. Many shales and other mud rocks when split open are found thus marked with the footprints of prehistoric animals, or pitted with the raindrops and sun-cracks of days that knew not man. If we take these markings in conjunction with the fossil remains that are found in the same rocks, and which all belong to creatures living in shallow water or between the limits of high and low tide, it is quite clear that such rocks were laid down at the edge of an ancient sea-beach. It is thus possible to trace the limits of long-forgotten seas and oceans, and to make maps of the distribution of land and ocean at various periods in the history of the earth, from which we see that the existing arrangement of the surface in this respect is quite recent.

British Geological History. Thus, to take a few examples from our own island record, we know that in the earliest Primary age the greater part of our islands was under the sea, but not far from a continent, whose rivers washed down the sand and mud which composed the slaty beds of Wales. The rocks on the top of Snowdon consist of volcanic ashes which were deposited on the floor of this shallow sea. In a later Devonian age, reef-building corals were at work in the warm seas which must then have covered the south-western parts of our islands. Their record is found in the limestones of Devonshire. The old red sandstone points to a period in which a great part of our islands was dry land, intersected by numerous arms of the sea, or perhaps covered by vast fresh-water lakes, on whose beds these rocks, so rich in fossils, were deposited. The great coalfields which have made our country so prosperous indicate that there was a time when semi-tropical vegetation covered great parts of the land, which must then, of course, have been raised again above the sea, into which it subsided once more in order to allow of the deposit of the sandstone which overlies the coal measures in so many places.

A British Sahara. The New Red Sandstone is thought to have been laid down under desert conditions, when our country formed part of a vast continent with a warm and extremely dry climate—not unlike that which now obtains in the Desert of Gobi or the Sahara. We can almost watch the gradual irrigation of this arid region by natural processes, and the appearance here and there of lakes, each of which has left its traces in deposits of gypsum and of rock salt. Once again the British area was submerged beneath the Jurassic seas, inhabited by strange fishy forms, whose beds were covered with sediment almost as fast as they continued to sink, so that many thousands of feet of sediment were coagulated into rock, and the seas remained comparatively shallow. The great chalk deposits, again, point to yet another age of submersion, followed by an Eocene period in which our country was occupied once more by land animals. Another continental period followed, and then came the ice age, on the very threshold of modern times. All this history, with much more that will be found detailed in the works on the subject, is deeply engraved on the rocks and written in the everlasting hills.

ALGEBRA

Terms and Operations. Definitions. Simple Substitutions. Positive and Negative Quantities. Addition. Subtraction

By HERBERT J. ALLPORT, M.A.

DEFINITIONS

1. Algebra, like Arithmetic, deals with the properties of numbers. Algebra, however, has much greater scope than Arithmetic; for, in Arithmetic, numbers are represented by *figures*, each figure having only one meaning; but in Algebra, numbers are represented by *letters*, and each letter may have any value we please, the only limitation being that, in any particular investigation, a letter keeps the same value throughout. Since the letters may have any value whatever, the results obtained must be equally true of all numbers. Thus, in Algebra, we are able to *generalise* the results obtained in Arithmetic.

2. The chief operations are the same as in Arithmetic—*viz.*, addition, subtraction, multiplication, division, and are expressed by the same signs, +, −, ×, ÷. Thus, $a + b$ means that the number which is represented by b is to be added to the number which is represented by a. Similarly, $a - b$ means that the number represented by b is to be subtracted from the number represented by a. If we do not know the actual numbers which a and b represent, we can go no further than writing the results in the form $a + b$ and $a - b$ respectively. When two letters, or a number and a letter, are to be multiplied together, the multiplication sign is usually omitted, or it may be replaced by a dot. Thus, $a \times b$ may be written either in the form $a.b$ or ab. The latter is more usual. Similarly, $3 \times x \times y \times z$ is contracted into $3xyz$.

As in Arithmetic, division is also denoted by writing the dividend above the divisor, with a line between them, so that $a \div b$ and $\frac{a}{b}$ each mean that a is to be divided by b.

3. When two numbers are multiplied together the result is called the product; or, if more than two are multiplied, the *continued product*. Each number is called a factor of the product.

If we separate the factors into two groups, either group is called the co-factor, or the *coefficient*, of the other. If one of the factors is expressed in figures it is called the *numerical coefficient* of the other factors.

In the product $3xyz$, 3 is the numerical coefficient, xy is the coefficient of $3z$, z is the coefficient of $3xy$, and so on.

The definitions of *power*, *index* (or *exponent*) and *root* given in Arts. 138 and 139 of Arithmetic also apply to Algebra.

Thus, the fifth power of a means $a \times a \times a \times a \times a$, and this is abbreviated into a^5, and [illegible]

is a collection of symbols, such as $3x^2y + 4xyz \div 2z - 6$. The parts of an expression which are connected by the signs + and − are called its *terms*. Thus, the above expression consists of three terms—*viz.*, $3x^2y$, $4xyz \div 2z$, and 6. It should particularly be noticed that $4xyz \div 2z$ is *one* term, so that $4xyz$ is to be divided by $2z$ *first*, and the result added to $3x^2y$. From this last result, 6 is to be subtracted.

This explains the reason for the statement in Art. 87 of Arithmetic. In the example there given $\frac{3}{4} \div \frac{7}{8}$ forms one term of the expression $\frac{3}{4} \div \frac{7}{8} + \frac{2}{3}$, and therefore its value must be found before the remaining term can be added to it.

5. A *simple* expression, or monomial, contains only one term; a *compound* expression contains more than one. A compound expression of *two* terms is also called a *binomial* expression; one of *three* terms is a *trinomial*; one of *more than three* is a *multinomial*.

6. Brackets are used in the same way as in Arithmetic [Art. 84]. In addition to the ordinary forms of brackets, a straight line called a *vinculum* is used. The line is drawn over the expression which is to be treated as a whole; thus, $2a - (c - \overline{a + b})$ has the same meaning as $2a - \{c - (a + b)\}$.

SUBSTITUTIONS

7. We shall now work examples to illustrate the foregoing definitions.

Example 1. If $x = 3$, what is the value of (i.) x^4, (ii.) $4x$?

x^4 means the continued product of four quantities each equal to x.

$$\begin{aligned} \therefore x^4 &= x \times x \times x \times x \\ &= 3 \times 3 \times 3 \times 3 \\ &= \underline{81 \ \textit{Ans.}} \end{aligned}$$

$4x$ means the product of the two factors 4 and x.

$$\begin{aligned} \therefore 4x &= 4 \times x \\ &= 4 \times 3 \\ &= \underline{12 \ \textit{Ans.}} \end{aligned}$$

Example 2. If $a = 1$, $b = 2$, $c = 3$, find the value of $5abc^2$.

$$\begin{aligned} 5abc^2 &= 5 \times a \times b \times c \times c \\ &= 5 \times 1 \times 2 \times 3 \times 3 \\ &= \underline{90 \ \textit{Ans.}} \end{aligned}$$

Note that the index, 2, only refers to the letter after which it is written. $5abc^2$ does *not* mean that we are to find the value of $5abc$ and square the result.

Example 3. If $a = 5$ and $b = 2$, find the value of $\sqrt{5a^2 - b^2}$.

$$= \sqrt{125 - 4} = \sqrt{121} = \underline{11 \ \textit{Ans.}}$$

Example 4. When $x = 2$, $y = 1$, and $z = 3$, show that

$$\frac{3x+y-z}{x-2y+z} - \frac{\sqrt{x^2+3y^2+z^2}}{\sqrt[3]{5x^3-3y^3+z^3}} = \frac{y}{z}.$$

The expression on the left

$$= \frac{6+1-3}{2-2+3} - \frac{\sqrt{4+3+9}}{\sqrt[3]{40-3+27}}$$

$$= \frac{4}{3} - \frac{\sqrt{16}}{\sqrt[3]{64}} = \frac{4}{3} - \frac{4}{4} = 1\tfrac{1}{3} - 1 = \tfrac{1}{3} = \frac{y}{z}.$$

Example 5. If $x = 5$ and $y = 2$, find the value of

$$2x - [1 + 3(x - \overline{1+y})].$$

The given expression

$$\begin{aligned} &= 10 - [1 + 3(5 - \overline{1+2})] \\ &= 10 - [1 + 3(5-3)] \\ &= 10 - [1 + 3.2] \\ &= 10 - [1 + 6] \\ &= 10 - 7 = \underline{3\ \textit{Ans.}} \end{aligned}$$

After substituting the values of the letters, we proceed exactly as in the example worked out in Art. 84 of Arithmetic.

8. If one factor of a product is 0, the product itself will be 0. Also, any power of 0 is 0. Hence, if we are required to find the value of such an expression as $a^2bx + 3ab^3 + 4a^2x^2$, when $a = 3$, $b = 2$, and $x = 0$, we neglect all terms containing the factor x. Thus, the required value is that of $3ab^3$, or $3 . 3 . 2^3$, which equals 72.

EXAMPLES 1

If $a = 3$, $b = 1$, $c = 2$, find the value of

1. $3a^2$.
2. $4abc^2$.
3. $a^3 + b^3 + c^3 - 3abc$.
4. $\dfrac{a+b-c}{a+c-b}$.
5. $\frac{1}{2}a^2b^2c^3 - \frac{1}{3}a^3bc$.

If $x = 6$, $y = 3$, $z = \frac{1}{2}$, find the value of

6. $\sqrt{2x^2 + 3y^2} + 4z^2$.
7. $\sqrt[3]{\dfrac{3xy}{z^2}}$.
8. $\sqrt{x+y} \,.\, \sqrt[3]{x + 4y^2 + 7z^3}$.
9. Show that $x^2 - 7x + 12$ is equal to 0 when $x = 3$, and also when $x = 4$. Find its value when $x = 5$.
10. If $a = 4$, $b = 2$, $c = 1$, and $d = 0$, find the value of $(ad + bc)^2 - 2(2a^2 - 3b^3) + (c^2d - 2b)^2$.

POSITIVE AND NEGATIVE QUANTITIES

9. The signs + and − have, in Algebra, a wider meaning than in Arithmetic. They are used to denote a *quality* of the quantities before which they are placed. Many quantities may imply either an *increase* or a *decrease*. For example, a sum of money may be received, or it may be paid. Hence, we agree that a quantity which *increases* the quantity we are considering shall be called a *positive quantity*, and have the sign + prefixed; while a quantity which *decreases* the quantity we are considering shall be called a *negative quantity*, and have the sign − prefixed. Thus, in calculating the amount of money a man is worth, + £5 will stand for £5 which he possesses, or which is to be paid to him; while − £5 will stand for £5 which he himself owes. But, if we are estimating the man's *debts*, + £5 will stand for £5 which he owes, while − £5 will stand for £5 which is owing to him.

10. Used in this sense, the sign + is often omitted, so that, when no sign is written before a term, the sign + is understood.

The necessity for distinguishing between positive and negative quantities has led to the word "sign" being applied only to the + and −, and not to the × and ÷. Thus, when we speak of *the sign* of a quantity, we mean the + or the − placed before it.

11. The magnitude of a quantity, considered independently of its sign is called its *absolute magnitude*.

ADDITION

12. When two terms contain the same letters, and the corresponding letters in each term are raised to the same power, they are called *like* terms. If the corresponding letters are not raised to the same power, they are called *unlike* terms.

Thus, $4xy^3z^2$ and $-2xy^3z^2$ are *like* terms, since each contains the letters x, y, z, and x is raised to the first power in each, y to the third power, and z to the second power. But $3a^2b$ and $2ab^2$ are *unlike* terms, since, although they contain the same letters, the letters are not raised to the same power in each.

13. A positive quantity makes an increase, and a negative quantity a decrease. Hence, to add a positive quantity to any expression, we *add* its absolute magnitude; and, to add a negative quantity, we *subtract* its absolute magnitude.

Thus, if we add $+2a$ to $+3a$ we get $+2a + 3a$; while, if we add $-2a$ to $+3a$, we get $+3a - 2a$.

Therefore, *to add a term to an expression, write the term after the expression, with its sign unchanged.*

Again, it is clear that to add an *expression* gives the same result as if we add the *terms* of the expression separately.

For example, if we add the expression $a + b - c$ to x we shall obtain the same result as if we first add the term $+a$ to x, then the term $+b$, and finally, the term $-c$.

Hence, *to add two or more algebraical expressions together, write down all the terms in succession, with their signs unchanged.*

14. After writing down all the terms we must collect together all terms which are *like* [Art. 12].

For this, we have the following rules:

1. The sum of like terms is a like term.
2. If the terms all have the same sign, add the coefficients. Prefix the same sign to the result. This will be the coefficient of the sum.
3. When some of the like terms are positive, and some negative, (i.) add the coefficients of the positive terms; (ii.) add the coefficients of the negative terms; (iii.) take the difference of these results, and prefix the sign of the greater. This gives the coefficient of the sum.

Example 1. Add together a^2, $5a^2$, $9a^2$, $11a^2$.

$$\begin{aligned} &a^2 + 5a^2 + 9a^2 + 11a^2 \\ &= (1 + 5 + 9 + 11)a^2 \\ &= \underline{26a^2\ \textit{Ans.}} \end{aligned}$$

We add together the four coefficients—*viz.*, $+1$, $+5$, $+9$, $+11$, giving $+26$ for the coefficient of a^2 in the required sum.

Example 2. Find the sum of $-12x^2y$, $-4x^2y$, and $-17x^2y$.

$$\begin{aligned}&-12x^2y - 4x^2y - 17x^2y\\ &= -(12 + 4 + 17)x^2y\\ &= -33x^2y \textit{ Ans.}\end{aligned}$$

Add together 12, 4, and 17, and put the same sign, *viz.*, $-$, before the result; giving -33 for the coefficient of x^2y.

Example 3. Add together $5abc$, $-9abc$, $-2abc$, $3abc$, $-4abc$.

$$\begin{aligned}&5abc - 9abc - 2abc + 3abc - 4abc\\ &= 8\,abc - 15abc\\ &= -7abc \textit{ Ans.}\end{aligned}$$

We find the sum of the positive terms as in Ex. 1, and the sum of the negative terms as in Ex. 2. Finally, to obtain the sum of $8abc$ and $-15abc$, we take the difference between 8 and 15, and prefix the sign of the greater number, the result being $-7abc$.

15. When the expressions to be added contain several sets of like terms, we proceed as above with each set separately.

Example 1. Add together $4bc - 3ca + ab$, $5ca - 6ab$, $-7bc + ca + 2ab$.

The sum

$$\begin{aligned}&= 4bc - 3ca + ab + 5ca - 6ab - 7bc + ca + 2ab\\ &= \underbrace{4bc - 7bc}_{-3bc} \underbrace{- 3ca + 5ca + ca}_{+3ca} + \underbrace{ab - 6ab + 2ab}_{-3ab}\\ &= -3bc + 3ca - 3ab \textit{ Ans.}\end{aligned}$$

NOTE. The second line of work is merely a rearrangement of the first, and is not necessary. It is introduced to show clearly how the third line is obtained.

It is more usual to arrange the terms in columns, with like terms in the same column.

The above example then appears thus:

$$\begin{array}{rrr}4bc & -\ 3ca & +\ ab\\ & 5ca & -\ 6ab\\ -7bc & +\ ca & +\ 2ab\\ \hline -3bc & +\ 3ca & -\ 3ab \textit{ Ans.}\end{array}$$

Generally, we combine the terms in the left-hand column first, and so on, working from left to right; but this, of course, is quite optional.

Example 2. Find the sum of $\frac{3}{2}a^2b - \frac{1}{4}ab^2 + a^3$, $\frac{1}{2}a^3 - \frac{1}{4}a^2b + \frac{3}{2}ab^2$, $ab^2 - a^2b$.

$$\begin{array}{rrr}\frac{3}{2}a^2b & -\ \frac{1}{4}ab^2 & +\ a^3\\ -\frac{1}{4}a^2b & +\ \frac{3}{2}ab^2 & +\ \frac{1}{2}a^3\\ -a^2b & +\ ab^2 & \\ \hline \frac{1}{4}a^2b & +\ \frac{9}{4}ab^2 & +\ \frac{3}{2}a^3 \textit{ Ans.}\end{array}$$

We have a column for the terms a^2b, another for ab^2, and a third for a^3. In writing the columns, note that we have to insert the sign $+$ before $\frac{1}{2}a^3$ and before ab^2, these terms having no sign in the given expressions, $+$ being therefore understood [Art. 10]. If the fractional coefficients cannot be added mentally, we proceed as in Arts. 80 and 81 of Arithmetic.

SUBTRACTION

16. Subtraction is the reverse of addition. Therefore, if to some expression we first add a quantity, and then subtract the same quantity, the expression remains unaltered.

Hence, $x + y - y$ is the same as x.

Now, if from the expression $x + y - y$ we take away the $+y$, we have $x - y$ left. That is, if we take away $+y$ from x we have $x - y$ left.

Similarly, if from $x + y - y$ we take away the $-y$, we have $x + y$ left. That is, if we take away $-y$ from x we have $x + y$ left.

We have, therefore, these two results,

$$x - (+y) = x - y$$
$$x - (-y) = x + y$$

from which we obtain the rule: *To subtract a term from a given expression, write it after the given expression, but with its sign changed.*

Again, to subtract an expression as a whole will plainly give the same result as subtracting the terms of the expression separately.

Hence: *To subtract one expression from another, write all the terms of the one expression after the other expression, but with their signs changed.*

17. After writing down the terms, we collect like terms exactly as in addition.

Example 1. From $5x - 2y + z$ take $-x + 3y - z$.

Writing the second expression, with all the signs changed, after the first expression, we get

$$\begin{aligned}&5x - 2y + z + x - 3y + z\\ &= 6x - 5y + 2z \textit{ Ans.}\end{aligned}$$

The work is often arranged as for addition, the expression to be subtracted being written underneath the other, with like terms under like terms. The signs of the lower line are changed *mentally*.

The above example then appears thus,

$$\begin{array}{lrrr}\text{From} & 5x & -\ 2y & +\ z\\ \text{take} & -x & +\ 3y & -\ z\\ \hline & 6x & -\ 5y & +\ 2z \textit{ Ans.}\end{array}$$

Say,
$+x$ and $5x = 6x$
$-3y$ and $-2y = -5y$
$+z$ and $z = 2z$.

Example 2. Subtract $x^3 - 2x^2y + y^3$ from $-x^3 + 2xy^2 + 2y^3$.

$$\begin{array}{lrrrr}\text{From} & -x^3 & & +\ 2xy^2 & +\ 2y^3\\ \text{take} & x^3 & -\ 2x^2y & & +\ y^3\\ \hline & -2x^3 & +\ 2x^2y & +\ 2xy^2 & +\ y^3 \textit{ Ans.}\end{array}$$

Say,
$-x^3$ and $-x^3 = -2x^3$
$+2x^2y$ and $0 = 2x^2y$

and so on.

EXAMPLES 2

Find the sum of

1. $3ab + 2ca - 6bc$; $-4ab + ca + 3bc$; $2ab - 2ca + 4bc$.
2. $x^3 - 2x^2 + 1$; $3x + 4x^2 - 2x^3$; $-5 - 2x$; $-3x^2 - x^3 + 6$.
3. $\frac{2}{3}x - \frac{4}{5}y + \frac{5}{6}z$; $-\frac{1}{9}x + \frac{1}{10}y - \frac{1}{12}z$; $-\frac{1}{18}x - \frac{3}{10}y - \frac{1}{4}z$.
4. $ax^2 - a^3 + 3x^3$; $2a^2x + x^3 - 4ax^2$; $3a^3 - 5x^3$; $2ax^2 - 3a^2x + a^3 + x^3$; $-ax^2 - a^2x - 3a^3$.

Subtract

5. $ab + cd - bd$ from $-ab - 2cd + 3bd$.
6. $5x^2y - 3xy^2 + x^3$ from $2xy^2 - 3x^2y - y^3$.
7. $\frac{1}{2}a + \frac{1}{3}b - \frac{1}{4}c$ from $\frac{1}{3}a - \frac{1}{4}b + \frac{1}{2}c$.
8. $6a^4 - 2a + 3 - a^2$ from $a - 1 + 3a^3 - a^4$.
9. From the sum of $7x - 4 + 3x^2$ and $2x^3 - 4x + 1$ take $x^3 - x^2 + x - 1$.
10. Add the sum of $3y - y^3 + 2$ and $1 - 4y^2 - y$ to the remainder left when $3y - 6y^3$ is subtracted from $1 - 2y$.

MACHINES AND APPLIANCES

Machinery for Cuttings, Trenches, Tunnelling, Rock-cutting, Dredging, and Pumping. Locomotives, Tip Waggons, and Dobbin Carts

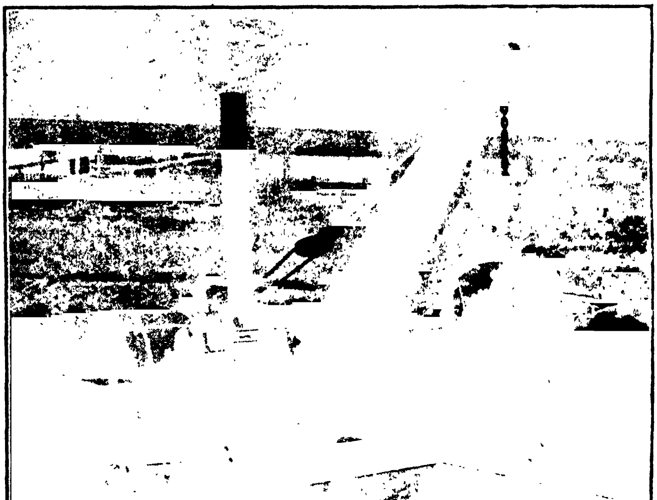
By Professor HENRY ADAMS

Responsibility of Contractors. The machinery and appliances used by a contractor in carrying out works of construction coming under the head of Civil Engineering, vary with the class of work and the magnitude of the contract. The contractor has to take the risk of the efficiency of any method he may adopt, and good judgment in the use of means is most essential if he is not to incur an actual loss; but it must be remembered that a contractor's nominal loss is frequently only the loss of further profit that he thinks ought to have been made. The risk is great, and it is only right that the profit should be correspondingly large when good judgment is exercised.

General Tools. The personal tools, such as picks and spades, barrows and wheeling planks, ladders, scaffold boards, blocks and falls, crab winches, crowbars, etc., will always be needed. A portable steam engine, mortar-mill, stone breaker, screens and concrete mixer will probably come next, with horses and strong carts for carrying bricks and earth. Then sheds for storing lime and cement, a smith's forge, a saw-mill; a portable office, and, for a large contract, a light locomotive, trucks and rails, steam navvy or portable excavator, pumps, derrick poles, overhead travellers and gantries, steam cranes, pile engines, etc. When any particular piece of plant is wanted for temporary use only, it may generally be hired at a charge of about 1 per cent. of its value per week, but large contractors find it cheaper to buy outright all they require for use.

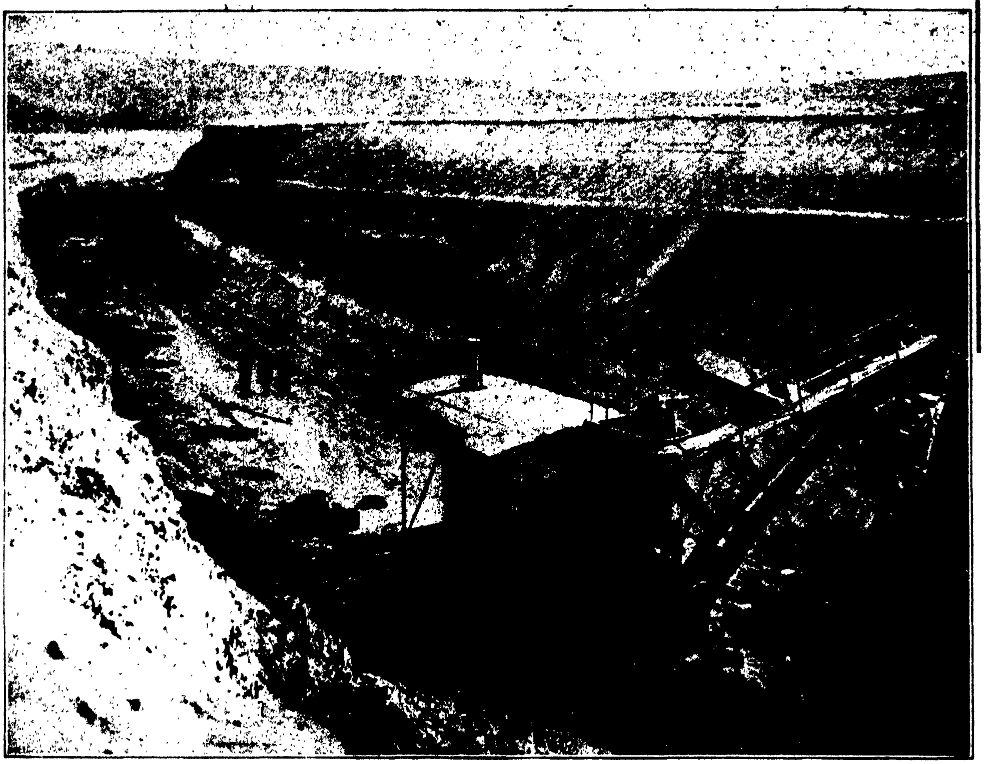
Excavating Machines. A navvy's pick and shovel and hand-barrow are only used on the smallest work, and machines have been introduced to economise both time and labour. The majority are of the steam crane type, such as **1**, by Wilson & Co., shown at work on the Cruden Railway, near Aberdeen; and **2**, by Ruston, Proctor & Co., Ltd., of Lincoln, shown at work on a railway cutting.

The former has a lifting power of 12 tons, and will excavate and put into waggons 750 to 1,000 cubic yards per day of ten hours, according to the nature of the ground. It will work a clear 22 ft. space and drive a gullet 50 ft. wide, turning round the whole circle. By removing a couple of cotters the digging gear can be disconnected, and the machine then becomes an ordinary 12-ton locomotive crane. Its total weight is about 35 tons. The latter has about the same power, with a different arrangement of gearing. The latest type of appliance for this kind of work is the electric navvy, shown in **3**, and constructed by Ernest Scott & Mountain, Ltd., of Newcastle-on-Tyne.

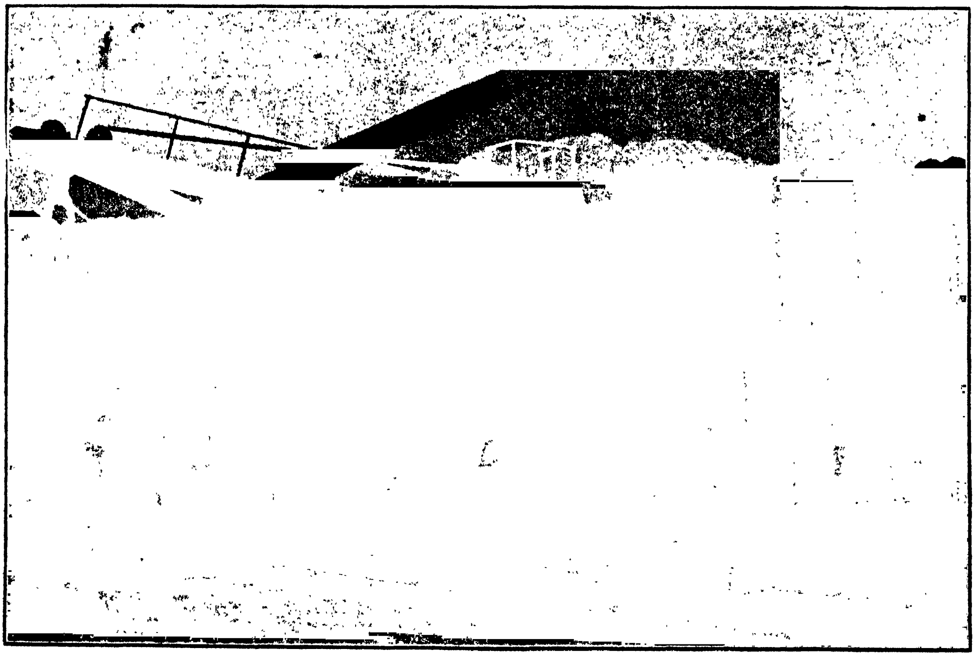


1. STEAM CRANE EXCAVATOR AT WORK

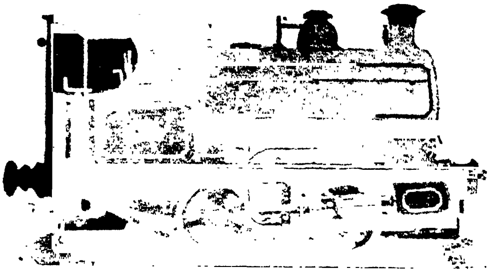
Contractors' Locomotives. As the waggons are filled they are run by horses to the tip, where the material from a cutting has to make up an embankment, or to be put into



2. STEAM NAVVY AT WORK ON A RAILWAY CUTTING



3. ELECTRIC NAVVY AT WORK



4. CONTRACTOR'S LOCOMOTIVE

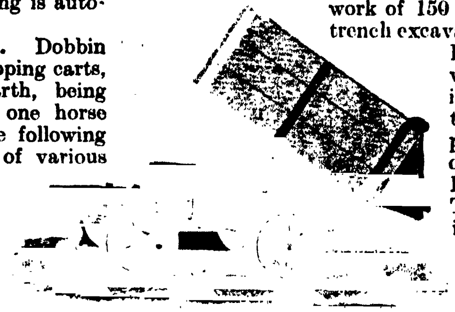
trains drawn by a contractor's locomotive (such as that in **4**, which is made by the Avonside Engine Co.), where the distance to be travelled is sufficiently great to warrant the additional expense. Tip waggons are generally used so that the unloading is automatic [**5**].

Dobbin Carts, etc. Dobbin carts are small, strong tipping carts, containing $\frac{3}{4}$ yd. of earth, being suitable for drawing by one horse over a rough surface. The following table gives the capacity of various appliances for removing earth :

		cubic yd.
A wheelbarrow, light	holds	$\frac{1}{18}$
A wheelbarrow, ordinary ..	,,	$\frac{1}{14}$
A wheelbarrow, large (navvy)	,,	$\frac{1}{10}$
A dobbin cart	holds	$\frac{3}{4}$
A one-horse cart (6 ft. × $3\frac{1}{4}$ ft. × $2\frac{1}{3}$ ft.)	,,	$1\frac{2}{3}$
An earth waggon, small, filled to level of sides, as with gravel, sand, etc.	,,	2
An earth waggon, small, when heaped, as with earth or clay	holds	$2\frac{1}{8}$
An earth waggon, large, filled to level of sides	,,	$2\frac{3}{8}$
An earth waggon, large, heaped	,,	3

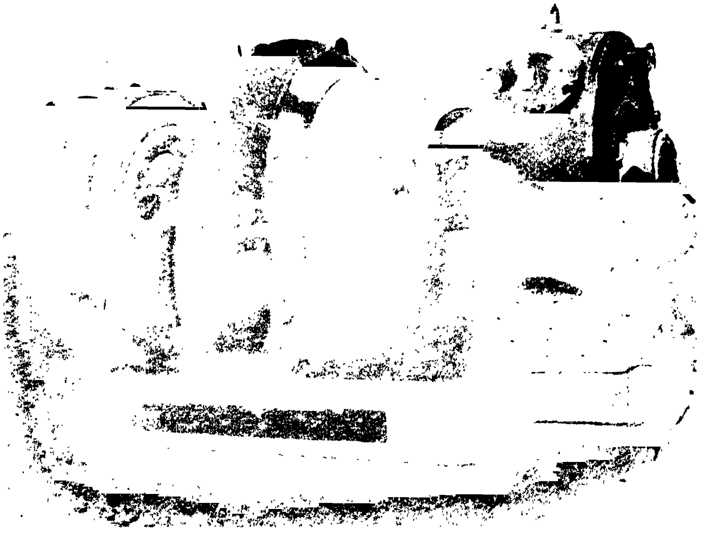
Pug-mills. When clay from an excavation is required for use to form a water-resisting medium, as in reservoir dams, coffer dams, etc., it is put through a pug-mill, to *temper* it or work it up to a homogeneous mass, in which condition, so long as it is kept moist, it is impervious to water.

Sewer Excavators. A novel form of excavator, by the Municipal Engineering and Contracting Co., shown in **9**, is used in America for cutting the trenches for laying sewers, gas and water pipes, etc. This machine excavates trenches 14 to 60 in. in width and any depth up to 20 ft. It is reckoned to do the work of 150 men. Another form of trench excavator, made by Van Buren, Heck & Marvin, and used with success in America, is shown in **7**. It is geared to travel at a speed of 2 ft. per minute, and is capable of digging trenches up to 12 ft. deep and $4\frac{1}{2}$ ft. wide. The machine shown in the illustration dug a trench 7 ft. deep and 26 in. wide in stiff clay at a rate of 700 to 900 lineal ft. per day. The trench excavating machine, made by The Helm Trench Machine Co., and shown in **8**, is of the bucket dredging principle. This machine is capable of digging trenches of any depth up to 25 ft. and any width from 24 in. to 36 in. by changing the buckets.



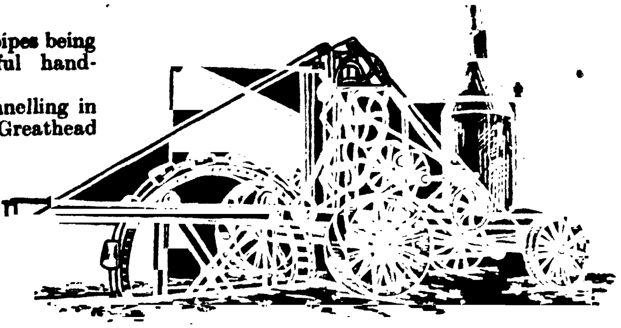
5. CONTRACTOR'S TIPPING WAGGON

Excavating machinery is, perhaps, the innovation of comparatively recent times that has done more than any other to economise the cost of large contracts. In the formation of canals and railway cuttings, where the soil is suitable, nearly the whole of the work can be done by a steam navvy, including the formation of the side slopes; and the trench excavators illustrated above, may be expected to prove as useful for work in the open country in England as they are in America. For town work, there are many cases where they would not be



6. AIR COMPRESSOR

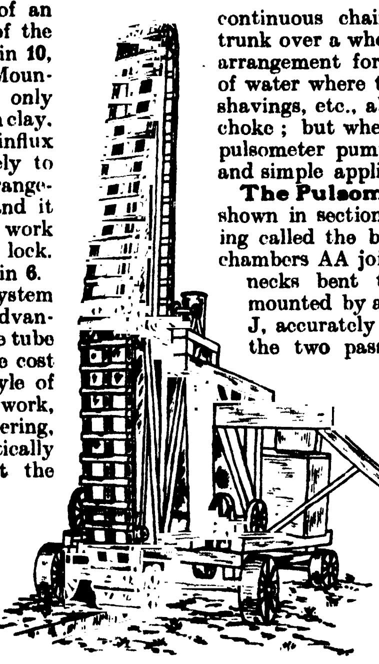
applicable, owing to gas and water pipes being in the way, and requiring careful hand-digging, to avoid damage.



7. BUCKEYE TRACTION DIGGER FOR EXCAVATING TRENCHES

Tunnelling in Clay. Tunnelling in clay is now done by means of the Greathead shield, which is a ring of steel forced forward by hydraulic rams bearing against the cast-iron lining rings, previously fixed. The direction is altered for a curve or gradient by increasing the stroke of the rams on a portion of the circle. The difficulty of driving the small heading in advance of the tunnel proper may be overcome by the use of an electric excavator in front of the Greathead shield, as shown in **10**, which is by Ernest Scott & Mountain, Ltd. Gravel is not only harder to drive through than clay, but it is more subject to the influx of water. When this is likely to enter, special pumping arrangements have to be made, and it may even be necessary to work under pressure with an air lock. An air-compressor is shown in **6**.

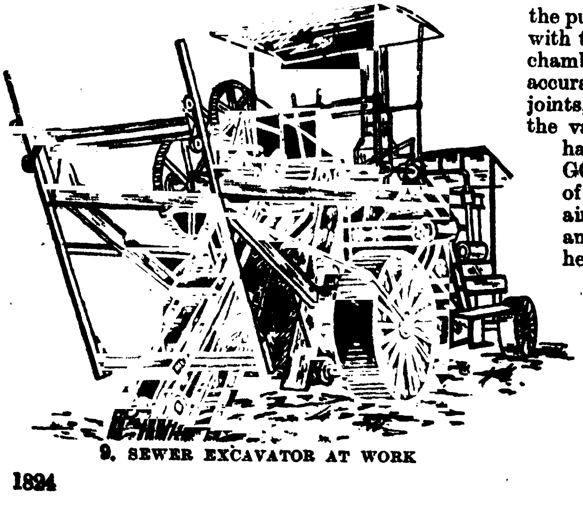
The introduction of this system has proved of inestimable advantage in the construction of the tube railways across London; the cost of the work in the old style of tunnelling, with massive brickwork, supported by a forest of timbering, would have been practically prohibitive, and now that the difficulties of ventilation have been overcome, a great extension of the tube railway system may be anticipated.



8. TRENCH EXCAVATING MACHINE

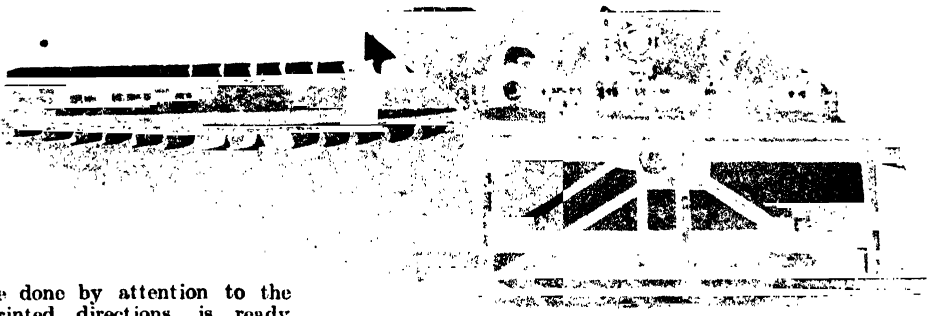
Pumping Appliances. A chain pump, consisting of float boards attached at intervals to a continuous chain, and drawn up a wooden trunk over a wheel at the top, forms a suitable arrangement for dealing with large quantities of water where there may be any straw, chips, shavings, etc., about, as it is not very liable to choke; but when the water is fairly clean, the pulsometer pump [**11**] is the most convenient and simple appliance.

The Pulsometer Pump. The pulsometer shown in section in **12** consists of a single casting called the body, which is composed of two chambers AA joined side by side, with tapering necks bent towards each other, and surmounted by another casting called the neck J, accurately fitted and bolted to it, in which the two passages terminate in a common steam chamber, wherein the ball-valve I is fitted so as to be capable of oscillation between seats formed in the junction. Downwards, the chambers AA are connected with the suction passage C, wherein the inlet or suction valves EE are arranged. A discharge chamber, common to both chambers, and leading to the discharge pipe, is also provided, and this also contains one or two valves FF, according to the purpose to be fulfilled by the pump. The air-chamber B communicates with the suction. The suction and discharge chambers are enclosed by hinged covers HH accurately fitted to the outlets by planed joints, and readily removed when access to the valves is required; in the larger sizes, hand holes are provided in these covers. GG are guards which control the amount of opening of the valves EE. Small air-cocks are screwed into the cylinders and air-chamber, for use as will be hereafter described. These are the general outlines of the construction of the apparatus, and they are sufficient for the understanding of the nature of its operations.



9. SEWER EXCAVATOR AT WORK

Action of the Pump. The pump having been filled with water, either by pouring water through the plug-hole in the chamber, or by drawing the charge, as can readily



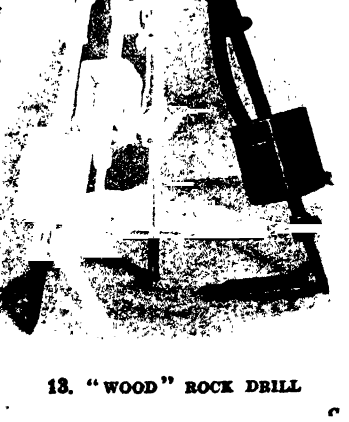
10. ELECTRIC EXCAVATOR FOR USE WITH THE GREATHEAD SHIELD

be done by attention to the printed directions, is ready for work. Steam admitted through the steam-pipe K—by opening to a small extent the stop-valve—passes down that side of the steam neck which is left open to it by the position of the steam ball, and presses upon the small surface of water in the chamber which is exposed to it, *depressing it without any agitation*, and consequently, with but very slight condensation, and driving it through the discharge opening and valve into the rising main.

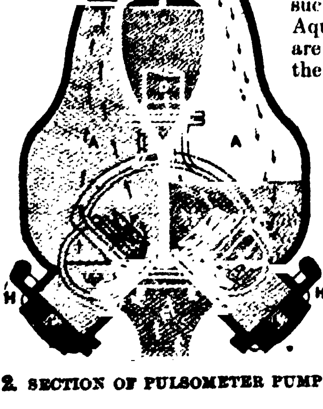
The moment that the level of the water is as low as the horizontal orifice which leads to the discharge, the steam blows through with a certain amount of violence, and being brought into intimate contact with the water in the pipes leading to the discharge chamber, an instantaneous condensation takes place, and a vacuum is, in consequence, so rapidly formed in the newly emptied chamber that the steam ball is pulled over into the seat opposite to that which it had occupied during the emptying of the chamber, closing its upper orifice and preventing the further admission of steam, allowing the vacuum to be completed; water rushes in immediately through the suction pipe, lifting the inlet valve E, and rapidly fills the chamber A again. Matters are now exactly in the same state in the second chamber as they were in the first chamber when we began our description, and the same results ensue. The change is so rapid that, even without an air vessel on the delivery, but little pause is visible in the flow of water, and the stream is, under favourable circumstances, very nearly continuous. The air-cocks are introduced to prevent the too rapid filling of the chambers on low lifts, and for other purposes, and a very little practice will enable any unskilled workman or boy so to set them by the small nut that the required effect may be produced. The action of the steam ball is certain, and no matter how long the pump may have been standing, it will start as soon as dry steam is admitted. A pulsometer pump is shown in operation in 15, pumping water from an excavation.

Other pumps, such as Bailey's Aqua-Thruster, are made upon the same principle. Their great advantages are simplicity and portability; they can be applied wherever a steam pipe can be led, and

11. PULSOMETER PUMP



13. "WOOD" ROCK DRILL



12. SECTION OF PULSOMETER PUMP

14. ROCK DRILL AT WORK

can be readily lowered as the water level is reduced.

Rock Cutting. When an excavation or tunnel has to be carried through solid rock, holes are drilled by steam or pneumatic drills or jumpers, such as **13** and **14**, which are made by The Wood Drill Works, U.S.A. Blasting cartridges are inserted to break away the material in portions suited to the quantity to be removed and the space which has to be cleared.

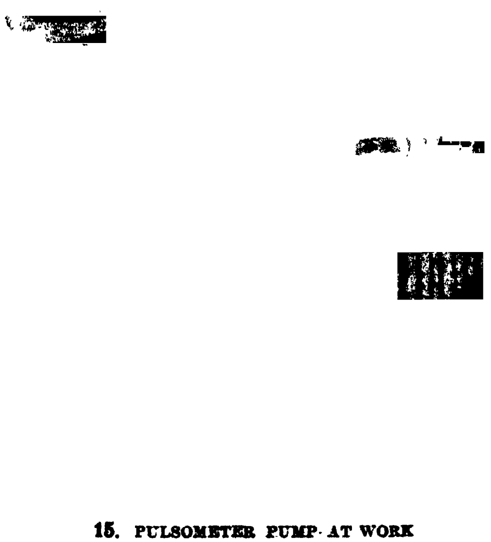
A general knowledge of surface geology is of much use to a contractor in estimating the difficulties he is likely to encounter, but most contractors depend upon their practical experience rather than upon any book knowledge which may be available.

An important matter in carrying out engineering work is to utilise the material found on the spot. Such, for instance, as using flints, ballast, or small broken stone for the aggregate of concrete; burning the chalk or limestone for producing lime; using the rough stone for rubble walling, and the better class of stone for block masonry, and so on.

Dredging Machinery. When the material to be removed is under water, suction dredgers [as **16**, made by J. H. Wilson & Co., of Liverpool], may be used if it is soft mud, sand or silt, and the material may be delivered by pipes to a considerable distance over the banks on either side. One form of dredger found very useful in keeping docks clear of mud consists of an air compressor, placed on board a tug to blow air through a trailing pipe and stir up the mud at the bottom, so that it will float out with the tide. Bucket dredgers [as **17**, by Lobnitz & Co., of Renfrew] are used when the material is more solid; and when it consists of rock, the rock may be broken up by dropping a heavy piece of metal, shod with a hardened steel point, on the Lobnitz system [as **18**].

This system was used on the Manchester Ship Canal, and **19** shows the operation, the rock cutter being suspended ready for dropping through the water on to the rock below. The lumps are then raised by the bucket dredger [**17**], or by hooks substituted for the buckets. The material from a bucket dredger is generally deposited in barges alongside, so that it may be taken away and delivered where it may be of use, or at any rate, where it will do no harm. Hopper-bottom barges are expensive in first cost but save their cost rapidly by the facility they afford for emptying mud and clay out at sea.

In the Thames, steam tugs sometimes have a giant rake dropped from the stern, which they drag through the mud that accumulates in front of jetties where ships are berthed, so that it may be carried away by the tide. This is very cheap, but not so effective as the pneumatic dredger described above.



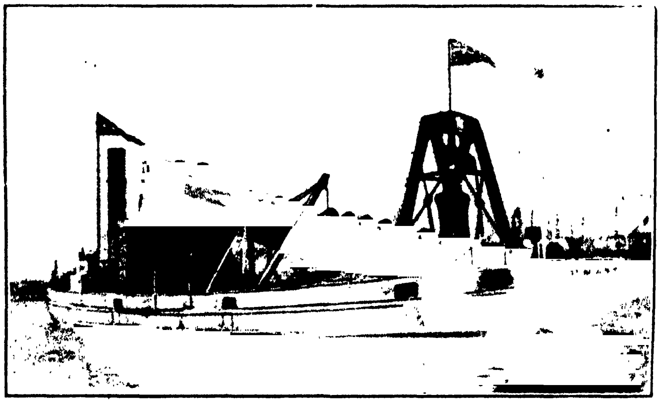
15. PULSOMETER PUMP AT WORK

16. SUCTION DREDGER AT WORK

Diving-bells and Dresses. For laying masonry blocks under water diving-bells were formerly in use, but these have now practically disappeared, as diving dresses [such as 20] permit of so much more freedom of action. The diver dresses in flannel for warmth, and then puts on the waterproof dress, in one piece from the feet upwards. Leaden soles to the feet keep him vertical when in the water, and leaden weights suspended by cords, are placed over his shoulders, to hang back and front, as sinkers, to overcome the buoyancy of the inflated dress. The hands remain uncovered, and indiarubber wrist-bands prevent the admission of water there. The opening at the neck is surmounted by a helmet, screwed on, having thick glass windows through which to see. An air-pipe is provided from an air compressor to supply fresh air, the expired air escaping through valves, and a life-line is attached to his body by which signals may be made to the surface.

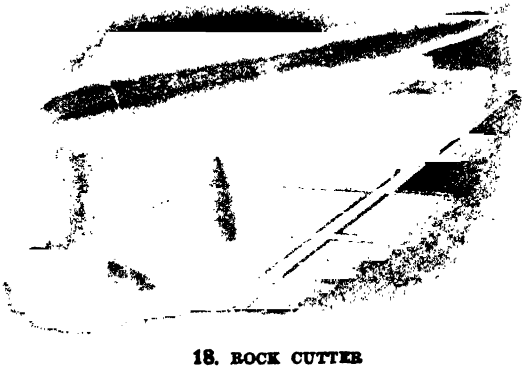
In harbour construction, this method of reaching the work under water is indispensable, and it is also necessary in clearing obstructions from the roller path of dock gates, clearing the windbore, or snore pipe, or perforated suction end, at the foot of a suction pipe in a dock, and for other practical purposes.

The air compressor used consists of a portable pumping apparatus worked by hand, which has to be kept in constant motion so long as the diver is encased in his dress. The pressure has to be sufficient to overcome the head of water so that the expired air may be discharged without permitting the ingress of water, but any excess of pressure is detrimental to the diver. He usually descends to his work by a ladder, and when more than one diver is at work at the same time, particular care has to be taken by each that the air-pipes and life-lines do not become entangled.

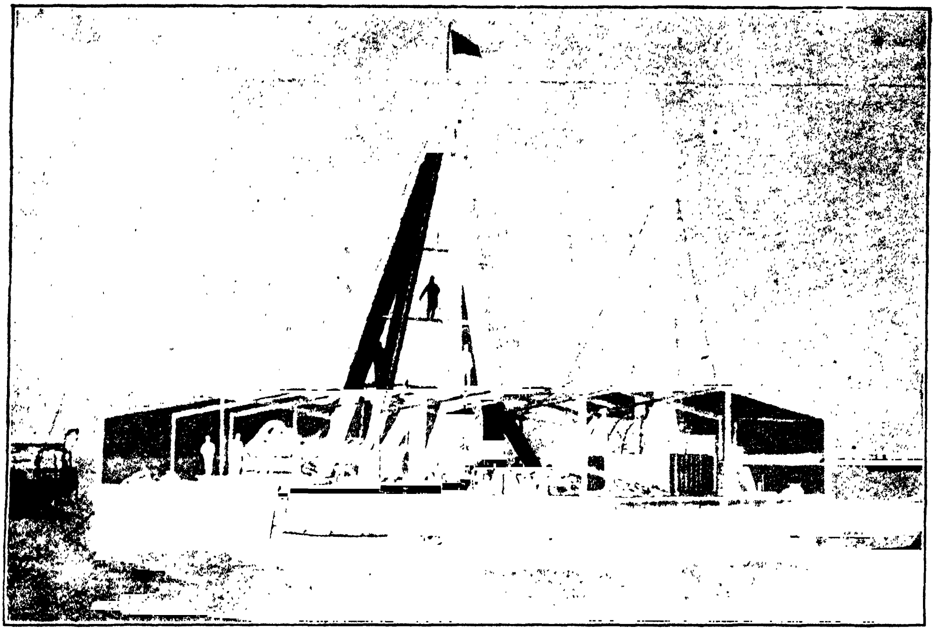


17. BUCKET DREDGER AT WORK

The Contractor's Engineer. There are many cases arising in the course of a large contract where a choice of methods is available for executing certain parts of the work, and very large differences may occur in the cost of construction, according to the method adopted. It is here that good judgment is of such primary importance, and large contractors usually employ a trained civil engineer to direct the actual work independently of the resident engineer representing the designer. An engineer loses caste to some extent by accepting such an appointment, but he gains vastly in experience and absolute knowledge, and, with a love for his work, has a much more interesting life than one who merely sits in his office and prepares schemes for others to carry out. There is great risk of the latter degenerating into a commercial man, and the exigencies of modern competition tend to foster a purely business view of every new scheme.



18. ROCK CUTTER



19. LOBNITZ ROCK CUTTER, USED IN MANCHESTER SHIP CANAL

What is an Engineer? In the early days of railway engineering, or about the period extending from the years 1830 to 1850, almost any man who could hold a staff or drag a chain could get employment as an engineer. The work was rough and ready, but sufficient for the purpose; the rolling stock was light and the speed slow, station roofs were an unnecessary luxury; with a few notable exceptions, bridges were of small span and easily constructed, and engineers' calculations were of the simplest. Now the engineer must be scientifically trained, must spend several years in acquiring the requisite theoretical knowledge before he can enter upon the practical study of his profession, and must exercise the highest degree of skill for a remuneration that represents only a small interest upon his outlay. The contractors in those days were, almost without exception, men who had risen from the ranks as gangers and foremen. Money came in freely and many fortunes were made. The contractor must now be a capitalist to start with, and he is fortunate if he does not finish with less than he had at the commencement. It is the province of the social philosopher rather than the engineer to account for all this, but it is interesting to note the facts.

ROME AT ITS HEIGHT

The Augustan Age. Tiberius Cæsar. Persecution of the Christians. Sejanus. The Rule of Caius Cæsar. Rome nnder Caligula

By JUSTIN McCARTHY

THE reign of Augustus would certainly have made its abiding mark on civilisation were it only for the encouragement which it gave to letters and arts. The Augustan age designates an era in literature, and the modern world has frequently applied the phrase to any epoch which has made itself illustrious by its writings. It is applied in England to the reign of Elizabeth and to that of Anne; in France to the reign of Louis XIV., and to other periods in different modern countries. Augustus was a lover of literature, and favoured its culture by every personal encouragement. He was the patron of poets, historians, and scholars, and of painters and sculptors as well. Virgil, the greatest of all the Roman epic poets, was one of the ornaments of the reign. Horace is famous as the author of lyrical and of satirical poems unsurpassed in any literature. Ovid, Tibullus, Propertius, and others, have written poems which form part of the reading of every cultured man. Livy is one of the most picturesque, fascinating, and philosophical historians of any era.

A Patron of Literature. Augustus made the culture of arts and letters fashionable in Rome. He probably inherited some of his love for art and letters from Julius Cæsar, and, although he had not Cæsar's capacity for writing books, any more than for making great speeches, yet he accomplished as much as even Cæsar could have done for the promotion of authorship. He set the example, and it soon became the fashion for the Patrician youth of Rome, and for all who desired to be ranked among the higher orders, to study the great poets and historians, to profess admiration for them, and to quote from their works. During the long period of comparative peace which prevailed while Augustus reigned, there was ample opportunity for young men to think of something besides soldiering, besides camps and invasions, and it was held to the credit of a youth that he took more delight in the reading of books than in the use of weapons.

The Augustan Age. A whole society of wits and humorists, makers of verses and writers of essays, flourished under the influence and the patronage of the Court, and Rome seemed like another Athens in its best days. The spread of culture was then due more to the direct influence of the Sovereign than has been the case in later times, when a ruler has been called the founder of an Augustan age. In some of these later instances, the great poets, romancists and historians obeyed their instincts without special encouragement on the part of the Sovereign and the Court, and the age became Augustan because there were men and women then living qualified to make an Augustan age, and not because there was a leader to encourage their aspirations.

Reforms of Augustus. Augustus was, above all things, a practical reformer. One of his earliest reforms was the establishment of a census, alike of individuals and of property. He introduced a new principle of finance and taxation; he based his taxing system mainly on the land and the personal possessions of the citizens, and he abolished a large number of unequal and capricious imposts which bore heavily on the poor. The financial accounts of the State were kept with strict accuracy, and he introduced the practice of framing what would now be called an annual State Budget. He appointed the governors of all the State provinces, and he personally arranged that the taxation of each province was fairly imposed, and properly accounted for. He took an interest in the affairs of the different municipalities, and he established a police force to keep good order in the towns. He developed, as far as possible, that system of municipal government which began in the Roman states under the guidance of Julius Cæsar.

The population of Rome amounted, during Augustus's reign, to considerably more than a million, and of these a large number were miserably poor. Augustus turned his attention to the removal of the causes which had helped to create that pauperism, and tried to give every man the best opportunity of benefiting by his labour, and to establish a civic equality among classes. The especial gift which Nature had bestowed upon him was the gift of administration. He had little or no genius for war, or ambition for conquest. If he did not inherit any of Julius Cæsar's marvellous capacity for war, he inherited much of his ability for civil administration.

Frontier Wars. During some of the later years of Augustus's reign, disturbances arose on the frontiers, which compelled him for the time to turn his attention from that system of domestic government which he loved and understood to the military work of a Roman ruler. There were frequent disputes going on as to the frontier lines of this or that outlying Roman province. New states forming themselves in Europe were becoming daily stronger, and were organising armies for the recovery of territory which they believed to be theirs by right. In one of these struggles an event occurred which forced some words of deep emotion from Augustus, words which are preserved in history and literature. There was a movement made in the north-west of Germany to shake off the power of Rome. A Roman force, led by a general named Varus, was sent to subdue this uprising; but the

Roman legions had been skilfully drawn into an ambush by the enemy and were cut to pieces, Varus himself being among the first to meet with death. The news of this great mishap brought consternation into Rome, and Augustus cried out with tears the words, " Varus, Varus, give me back my legions ! " Germanicus, who afterwards won celebrity, was sent out in command of the Roman force then stationed on the left bank of the Rhine, and succeeded in restoring victory to Rome. Augustus was greatly saddened by these events, for he regarded this outbreak of war as a cruel interruption to the peaceful glories of his later years. He determined for the future to make the Rhine the frontier of his Empire in that region, and thus to avoid the dangers arising from an effort to establish Roman rule over undetermined regions, and to leave his injunction to his successors that they should act upon this principle.

The End of a Notable Reign. Augustus lived for some five years after the events narrated. The wars which occurred during his reign were, for the most part, undertaken to maintain those lines of frontier in foreign regions which his predecessors had laid down. He had no ambition to extend the outlying territories of Rome, and he was willing to make concessions which accepted some obvious line of natural demarcation, such as a great river like the Rhine, for the mark and the limit of Roman rule. Augustus died at the close of August in 14 A.D. at the age of seventy-six. He had ruled over Rome for more than forty years, and his reign was the happiest and the most prosperous that Rome had known or was to know for many generations. He had married three times, but left no son to succeed him. His first wife left him a daughter, Julia, who, after the death of her first husband, married Marcus Agrippa, who died in 12 A.D Augustus adopted two of her sons by this marriage, the elder to be his successor to the throne. Both these sons died in their youth, and Augustus saw no better way of securing the succession than by designating Tiberius, the son of his last wife, Livia, by her former husband.

Tiberius Cæsar. The young man whom Augustus adopted as his heir, and compelled to marry his daughter Julia, bore the names Tiberius Claudius Nero Cæsar. The marriage was not a happy one. Tiberius had served under Augustus in several military commands, and had the reputation of being highly educated and capable. It was not because of any especial leaning towards Tiberius on account of his promising qualities that Augustus had determined to make him his successor. There was an embarrassing vacancy in the succession, and Augustus probably found that he could do nothing better than nominate for the Imperial position one who had a family connection with the house of Cæsar. To call into the Imperial circle an outsider, whatever his gifts, might have seemed too bold a step on the part of the Imperial ruler, and therefore the luck fell upon Tiberius. A familiar saying tells us that there is but one step from the sublime to the ridiculous. There were two steps from Julius Cæsar to Tiberius.

The Birth of Christ. In the meantime, during the Empire of Augustus, an event had occurred in a distant province of Rome which brought on the world the greatest change it has ever known in its history. That event was the birth of Christ and the founding of the Christian religion. It is no part of our task to attempt in this course a detailed record of the events which are told in sacred volumes, are represented in the creed of Christianity, and have opened a new hope and faith for civilisation. Our purpose is to tell the story of the Roman Empire. The tragedy which was enacted in Jerusalem was enacted, indeed, under the authority of the Imperial Government, but that Imperial Government and the Roman people took little interest in the rise of the Christian movement and in the steps taken by the authorities in Palestine to resist its influence. Many years later, Tacitus, the Roman historian, gave it as his opinion that although there might be much to condemn in the creed of Christianity, there had been much undue severity exercised in Palestine with the object of suppressing it. This manner of treating the subject only shows how entirely absent from the great historian's mind was any conception of the sublime influence which the events in Palestine were destined to have over the life of the human race.

Persecution of Christians. The spirit and the influence of Christianity soon spread over the dominions of Rome, and the Roman rulers resisted the invasion of the Christian religion with as much ferocity as they could have shown towards the invasion of some foreign enemy. The martyrdom of Christians soon came to be an event of every-day occurrence in the life of Rome, and the death and torture of the martyr were often made part of the spectacular entertainments for the crowd in a Roman amphitheatre. Not to many of those who gazed upon such sights did the idea occur that the tortures inflicted on the early Christian martyrs were awakening a new spirit of martyrdom, and that the blood of the martyr was already becoming the seed of the Christian Church. Even in Rome the minds of some among those utterly indifferent to such questionings before were beginning to ask what could be the real meaning and spirit of a faith which thus aroused human beings to make themselves the voluntary victims of such sufferings for the sake of the new religion ?

More and more as the days went on this noble spirit of inquiry was bringing those who followed it to a recognition of the fact that the world was then ready for the birth of a new faith which should liberate mankind from the sway of those divinities created by human superstitions, divinities that, when they represented power at all, represented for the most part the power of Imperial selfishness and the passions of men. The time had outgrown the gods and goddesses of a distant day. Literature of an advanced order took as little account of the old-world deities as the early literature of a more modern day would have taken of the fairies and hobgoblins whom it was pleasant to meet in fanciful poems and in grim ghost stories. Jupiter and Juno, Mars and Venus were to such men as Virgil and Horace no more realities than the "Faërie Queene" was to Edmund Spenser. The worship of the old gods had in that sense been completely put aside, and the faith and intellect of what was then civilisation were only waiting for a fresh and a full revelation of the truth. The growth of Christianity soon made itself apparent in other regions as well as in the dominions of Rome, and it was not long before the Apostles began to proclaim their mission, and to have their devoted disciples ready to follow them to any sacrifice for the promulgation of their creed.

The Reign of Tiberius. Tiberius had now, 14 A.D., begun his reign. He appears to have entered upon his dominion in a manner intended to impress his subjects with a belief in his mildness, intelligence, and justice. He had, in his earlier days, been accused of conduct, alike in his public and private life, which suggested cruelty and immorality, but he desired at the opening of his reign to present himself in a new character to his people. He declined to receive some of the extravagant demonstrations and honours offered to him by the over-loyal Senate. He had been invited to sanction the raising of temples to his glory and in his name, but he told his enthusiastic admirers that he only came to them as a man, and did not claim to be worshipped as a god. If he did not actually diminish the taxation imposed upon the country, he did not encourage any attempt to have it increased, and he endeavoured to find suitable men to hold office as governors of the various provinces. Some of his military commanders were able men, and had won much public honour. One of them, Germanicus, who had already won distinction under Augustus, was very popular among the Roman citizens.

Germanicus, who was a nephew of Tiberius, and belonged to the Cæsar family, was adopted by Tiberius. Under his leadership he had, during the reign of Augustus, won victories, which for the time appeared decisive, over the whole German country between the Rhine and the Elbe. Like others of the Cæsar family, he had a certain literary gift, and he wrote some books and composed some poems which were highly thought of.

Jealousy of Germanicus. Tiberius soon began to show his real character. In the ever-growing jealousy of Germanicus, because of the popularity and the great position which the distinguished soldier had already won, he recalled him from his most important commands, sent him into the Syrian provinces, and, according to the authority of trustworthy historians, sent emissaries of his own there with instructions to thwart Germanicus secretly in his projects. Germanicus, while still a young man, died in Syria, and there was a strong belief among his friends that he had died of poison, and also a shrewd suspicion that the poison had been administered by one of the agents of Tiberius. Even before this time Tiberius had committed many acts of private vice and public oppression. For some years of his reign he did not allow his real inclinations and his love of arbitrary power to show themselves in his public acts; but an event in his life brought about a complete change in his conduct as a ruler. His son Drusus, to whom he was devotedly attached, was in his confidence, and exercised a wholesome influence over his conduct. But Drusus had a rival in the counsels of his father.

Rivalry of Sejanus. This rival was Sejanus, Commander of the Prætorian guards, a man of immense ambition, unscrupulous character, and great persuasive power. Sejanus won more and more control over Tiberius, but he found Drusus a dangerous rival in his way. The impression of historians is that Sejanus aimed at nothing short of the control of the State, and that he even hoped to obtain, by some means, the position of Emperor. Drusus died suddenly in 23 A.D., and it was firmly believed by many at the time, and the belief has found recognition in history, that Drusus was done to death by poison through a secret plot of Sejanus. The death of Drusus left the Emperor wholly in the hands of Sejanus, who for a time played the part of an absolute tyrant. This was the more easy for him because, after the death of his son, Tiberius, who always disliked the work of governing and felt out of his element in the life of Rome, became possessed with a desire to change his atmosphere. He withdrew to an island in the Bay of Naples, where he shut himself up in seclusion, so far, at least, as consultation with Rome was concerned, and left Sejanus free to rule over Rome as he thought fit. Sejanus did his best to make himself popular with the Imperial troops, and banished or put to death any who openly opposed his machinations.

Tiberius in Retirement. The news of these events began to reach the ears of Tiberius, even in his life of secluded sensuality, and at last it became apparent to him that he must take steps if he would prevent the throne from being seized by Sejanus. So long as he believed Sejanus to be acting merely in the interests of his Imperial master, Tiberius, although he knew that some of his own supporters, even some members of his own family, had been made the victims of merciless cruelty, had taken no steps to assert his authority. He was easily made to believe that all these victims had been plotting against him. He had developed that state of mind which made him see a secret enemy wherever he turned his eyes, even among his own family. He seemed possessed by a demoniac combination of panic and anger, and wherever he felt suspicion he made the suspected man the object of his merciless vengeance. He did not return to Rome to find out whether there were any foundation for the reports made to him by Sejanus. In his island home he persistently remained, employing Sejanus as his messenger to Rome to report him the result of the inquiries.

He was now in his seventieth year, and the longer he lived the more tyrannical he became. He believed every story told to him by Sejanus, and was thus readily prevailed upon to suspect his own relatives of plotting his death in order to share his inheritance. The widow of Germanicus, who was described as one of his chief enemies, was, by his orders, sent into a sort of penal colony, where, some years later, she was allowed to die of starvation. Two of her sons were flung into prison—one of them was either put to death or committed suicide, while another was left to perish, like his mother, of starvation. The third son was allowed to live, because he was a mere child. All those of the family of Germanicus whom Sejanus feared because of his ambitious schemes, or Tiberius because of his personal safety, were thus put to death.

Downfall of Sejanus. Then Sejanus took a step which brought the whole fabric of his ambition to the ground. He asked Tiberius that he might be allowed to marry the widow of Drusus, son of Germanicus. This request was, under the conditions of the newly-formed Empire, much the same as if he had asked to be named the successor to Tiberius. It came as a flash of light upon the mind of Tiberius, dazed by sensual excess, by cruelty, and by fears, and that light revealed to him, for the first time, the character of Sejanus. He refused the audacious request. But he did more than that. He became convinced that Sejanus would make the refusal an occasion for plots against himself, and when the former returned to Rome, Tiberius sent his orders to the Senate for his arrest. That assembly ordered a trial, which ended in his conviction of treason against the Empire, and a sentence of death was immediately carried out.

Sejanus had long been hated by the Roman people, and they manifested their feelings by tearing his dead body to pieces in the streets and flinging the remains into the Tiber. The fury of the people rose so high that, before it could be stilled, the son and daughter, and some of the close friends of Sejanus, were put to death. The whirligig of time brought about its revenges, and the deaths inflicted by Sejanus had brought a like fate to himself and to some of his kindred.

Rome Torn by Factions. During the remainder of the Emperor's life Rome was the scene of incessant disturbances, brought about by the rivalries of factions and the plottings of political parties, each ambitious to place its own leader or favourite on the throne soon to be vacant. During his closing days, the mind of Tiberius completely gave way. His nerves were utterly broken down, and he appeared to be threatened with insanity. His frame was exhausted by years of sensuality, and he died on the 16th of March, 37 A.D. It is believed that he was suffocated by Macro, the Prefect of the Prætorian guards, the successor of Sejanus in the confidence of Tiberius. Thus closed one of the most sickening stories which even the worst days of the Roman Empire can tell.

The successor to Tiberius was named Caius Cæsar; he belonged to the Imperial family, but will ever be known to history as Caligula, although that was but a nickname given to him by the legions with whom he served in his boyhood, from the fact that he wore very small *caligæ*, or military boots. This ridiculous epithet is now universally accepted, even in the gravest histories, as the name of the fourth Roman Emperor, and is much the same as if a modern sovereign were to be known by the name of Bootikins.

A Chaotic Reign. Not long after he became Emperor he was seized with a severe illness which unsettled his reason, and this is, perhaps, the only explanation of the acts he perpetrated during the remainder of his career. His reign had begun in general hopefulness, and as the descendant of Germanicus he was welcomed with the greatest enthusiasm by the soldiers and the people. Until this malady came upon him he appeared likely to do well as a ruler; but with that change all was altered for him and for those he ruled. He gave up much of his time to gambling, and when he lost vast sums of money he extorted all that he wanted from this or that province or town, and put to death any leading men who endeavoured to resist his demands. He erected a temple to his own honour, declared that he must be worshipped as a divinity, and that he had come to make war upon and to extinguish the old gods of his forefathers. He squandered in less than a year the immense treasure accumulated by Tiberius, and he made the amount of his expenditure one of his boasts; he entered Gaul at the head of his troops, and plundered that province as if he were some robber chief.

Caligula Executed. He once amused himself by constructing a bridge of boats across an arm of the sea about three miles wide, covering it with earth, and erecting houses on it. The work being done to his satisfaction, he gave a banquet in the middle of the bridge, and crowned his joy by having numbers of his guests thrown into the sea and drowned. The Roman people became weary at last of this wretched madman, and soon after his return to the capital from one of his expeditions into Gaul a movement was got up against him by the leader of a Prætorian cohort and other men of influence, and he was murdered, or it might be more properly said, he was tried, found guilty, and put to death. The popular feeling was so strong against him that his uproused enemies were not content with the execution of the tyrant, but his wife and his daughter, who were believed to have encouraged him in his crimes, were made to share in the vengeance, and like him, were made victims of a death sentence. There was no civil organisation in Rome at that time which could have rescued the State and the man himself from such a series of calamities. The struggle of rival parties was too keen to allow the Senate and the Tribunes, even if they had been ready for such a work, to resolve that a raging lunatic must not be left to rule a great Empire, and then to place the madman in seclusion under humane control.

Group 20
MATERIALS & STRUCTURES
13

Continued from page 1704

By Professor HENRY ADAMS

Matter and Force. All material substances may be classed under the general term *matter*, but it is very difficult to give a definition of matter. It has been described as the element of resistance in the sensible world, and again it is that which is the subject of motion, or upon which force can act; while force has been defined as that which produces or destroys motion, or which tends to produce or destroy it, or which alters or tends to alter its direction. Force and matter are so intimately related that they are inconceivable apart and necessarily involve the conception of space and time. Fortunately it is not necessary to comprehend the ultimate reality of things in order to understand the laws by which Nature works and to be able to utilise them in producing the desired results.

Pressures and Reactions. If only one force act upon a body, motion must ensue, but two or more forces may be in equilibrium and the body is then at rest. Forces at rest are usually called pressures or reactions; for instance, a pound weight resting on a table produces a pressure by the attraction of gravitation, and the table resists this or reacts upwards with an

Parallelogram of Forces. It is a law of mechanics that each force produces its own result so that if, in **109**, force 1 would in a given time cause a body at A to travel to B, and force 2 would in an equal interval of time cause a body at A to travel to D, the two forces acting together would carry the body from A to C, that is, it travels north a distance equal to AB by the action of force 1 and travels west a distance equal to AD by the action of force 2. This is the foundation of the parallelogram of forces, and it is self-evident that the two forces may be replaced by a third one, marked 3, which forms the diagonal of a parallelogram two of whose sides are formed by the other two forces. Then force 3 is called the resultant of forces 1 and 2, or forces 1 and 2 are compounded into the one force 3 which will produce identical effects. The line AC, which is equal and opposite to the resultant, is called the equilibrant because it exactly balances the other two forces or their resultant. It will be seen that the arrow-head should be placed upon the resultant in the same direction as upon the two forces it replaces, but upon the equilibrant AC the arrow should point in the

posed it would be seen to be compressed, and this compression would perhaps be more clearly comprehended as tending to move the weight upwards with exactly the same force as gravity pulls it down.

Statics is the science of forces in equilibrium or pressures, which must be understood as free to move, but remaining at rest because they are balanced. The graphic delineation of forces, or their representation upon paper, is of the utmost practical importance and helps very considerably to reduce the labour of the engineer in calculating the stability of his structures.

Specification of a Force. Forces may be represented graphically by straight lines, whose position upon the paper gives their line of action or *direction*; the length of each line to any given scale represents the *magnitude* of the force; an arrow-head placed anywhere upon the line gives its *sense*, or the direction in which it presses; and if a force acts upon a body the point at which it touches is called the *point of application*. For example, **108** shows a body (A) acted upon by the forces which may or may not balance each other, as tests to be applied presently may determine.

forces have only one resultant, a single force may be resolved into an infinite number of other forces acting in an infinite number of directions. Generally, the required directions are given and sometimes one of the required forces. If it were desired to resolve force AB [**110**] into two forces in the direction AC AD, from point B draw a line parallel to AC to cut AD in E and also a line parallel to AD to cut AC in F as shown, then force AB might be replaced by forces AE and AF acting towards A.

Parallel Forces. When a force A [**111**] is acting at point B against an extended body CD, and is to be resisted by parallel forces acting at C and D, the force at C, multiplied by the distance CB, must be equal to the force at D multiplied by the distance DB, and also the sum of the two forces acting at C and D must equal the force AB. These forces may be found by calculation or by graphic construction. It is a question of leverage. Force A multiplied by the lever arm BD and divided by the lever arm DC will give the magnitude of the force at C, and vice versâ. The force A multiplied by the lever arm BC and divided by the lever arm CD will give the magnitude of the force at D. If the system be drawn to scale, and a force of unit value be added beyond C and D, and indefinite lines be drawn from the extremities parallel to A, then lines drawn from the end of A, through C and D, will cut off the last lines at a length equal to the required forces at C and D, as shown. If A be looked upon as a force, and C and D as reactions, then we may say that the sum of the reactions must equal the magnitude of the force, and the moments of the reactions must be equal to each other. A *moment* is the brief expression of a *force or reaction multiplied by a leverage*, so that if the force be in pounds and the leverage in feet, the moment will be in pound-feet. The expression is used in this form to distinguish it from foot-pounds, which is the form for units of mechanical work in dynamics.

Moments of Forces. A moment being the product of a force into a leverage, the moment of force 1 in **112** about point x will be the magnitude of force 1 multiplied by its perpendicular distance to x. In a similar manner the moment of force 2 about x will be the magnitude of force 2 multiplied by its perpendicular distance to x, but in this case the direction of the force must be produced in order to mark the actual perpendicular. The parallelogram being completed, the moment of the resultant 3 about point x will be equal to the sum of the moments of 1 and 2, and will tend to rotate the system in the same positive direction—*viz.*, anti-clockwise. The moment of the equilibrant about point x will have the same numerical value, but, in order to be an equilibrant, must tend to rotate the system in the opposite or negative direction, or clockwise, round point x.

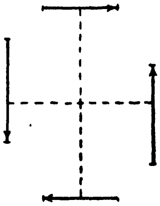
113 114

Triangles of forces



115 *Couples.*

Triangle of Forces. Turning again to **108**, if the forces are in equilibrium, we may remove them from their present position and place them in the form of a triangle, taking them in any order, but keeping them parallel to their present direction and making their *senses* to run consecutively round the triangle, as in **113** or **114**; if they did not form a perfect triangle, it would show that they were not in equilibrium. Any number of forces may be taken in the same way—even the parallel forces in **111** may be put together in this way; but the triangular shape would disappear, because two of the sides would coincide exactly with the third side. It is important, however, to look upon it still as a three-sided figure, and it may be called a triangle in the sense that a straight line is the arc of a circle of infinite radius. The reason for taking this view will be seen when reciprocal diagrams come under consideration.

Couples. When two equal parallel forces act in opposite directions, but not in the same straight line, they tend to rotate the body upon which they act with an energy equal to their moment, which in this case is the magnitude of one force multiplied by the perpendicular distance between them. They can only be balanced by two other forces [**115**] having an equal moment, but tending to cause rotation in the opposite direction. Thus the forces of the balancing couple may be equal to the original forces, or smaller or larger, and their distance apart will then be equal to or greater or less than the original distance in order to give the same product as before. A couple need not consist of two single forces, but may be composed of two groups of forces, each having a mean centre of effort, at which the sum of the group may be supposed to act. This will be illustrated in the next lesson in connection with the strength of beams.

Centre of Gravity. The centre of gravity has been variously defined; the simplest definition as regards its application to the parts of structures is "that point about which, if the body could be supported, it would be evenly balanced." It is also "that point at which, if the whole mass could be collected, the equilibrium would remain unchanged."

It is sometimes of assistance to make use of the centre of gravity of a load upon a beam, as when the load is distributed over a portion of the length at unequal distances from the abutments, the load upon each abutment, or the amount of reaction at the supports, will be the same as if the whole of the load were collected at its centre of gravity.

COUNTRIES DRAINED BY THE RHINE

Industries of Belgium. Course of the Rhine in Holland, Germany, and Switzerland. The Alps. Peaks and Passes. Industrial Resources of Switzerland

Continued from page 1684

By Dr. A. J. HERBERTSON and F. D. HERBERTSON, B.A.

Belgium—A Little France. Belgium (11,500 sq. miles) is a small country, only half as large again as Wales. Geographically, it is a continuation of Northern France, the flat surface being represented by the Plain of Flanders in the north, while in the south the land rises to the forested Ardennes. The rivers are the sluggish Scheldt and its tributary the Lys, and the swift, picturesque Meuse, coming down from the plateau of Langres in a forested gorge through the Ardennes, before it crosses the plain to the delta of the Rhine, which it enters, as does the Scheldt.

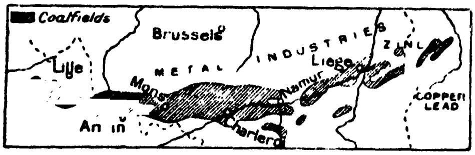
How the People Live. Though so small, Belgium is densely populated. In the plain the whole country is highly tilled, and looks like a vast market garden, unbroken by wall or hedge. Farms and cottages are built on every spot which can be used without reducing the area under cultivation. New land is drained in the marshes or cleared in the forests to supply the needs of the growing population. Enormous quantities of vegetables are grown, as well as rye, oats, wheat, potatoes, and sugar-beet.

Belgian Industries. The industries are equally important [83]. In Southern Belgium many manufactures flourish on the coalfield, which is continuous with that of Northern France. Iron is also abundant. Iron industries of all descriptions, including machinery, locomotives, and all requisites of modern engineering, are carried on extensively in and around Charleroi on the Sambre and Liège on the Meuse. The latter makes firearms of all descriptions, and may be called the Birmingham of Belgium. The woollen manufacture, partly due to the excellent wool of the Ardennes, has been important for centuries. The Leeds of Belgium is Verviers, east of Liège, where glass is also made. Brussels carpets are made at Tournai and elsewhere. In Northern Belgium the chief manufacturing city is Ghent, on the Lys, the Manchester of Belgium. It obtains raw cotton through Antwerp, on the Scheldt, the Belgian Liverpool, and the water of the Lys has remarkable bleaching properties. The linen manufacture has been important for centuries. Most towns make lace, especially Brussels, Ghent, and Mechlin.

A Word on Belgian Towns. Brussels, , on a tributary of the Scheldt, is a ty, with modern suburbs. Its grand cathedral, town hall (Hotel de Ville), and picturesque market-place, surrounded by fine old houses, recalls the ancient splendours of the Flemish cities, which, in the Middle Ages, were the busiest manufacturing and trading centres of Northern Europe. Hardly one of the many Flemish cities, now decayed, but has fine specimens of the domestic and public architecture of the Middle Ages. Even Antwerp, with its great docks, enormous commerce, and all that makes up a modern port of the first rank, its broad streets, and modern conveniences, its sugar-refining, distilling, shipbuilding, and other industries, preserves in its midst the mediæval city which attracts thousands of tourists annually. Ostend is the largest of Belgian watering-places, and an important packet station, especially for Dover.

CENTRAL EUROPE

A Difficult Task. So far we have described regions with a geographical as well as a political individuality; but in Central Europe, as any map shows, the boundaries of the countries do not correspond with any geographical features. The delta of the Rhine, for example, forms Holland, but the rest of its course is in Germany and Switzerland. Or, again, take the Alps. Following a political classification, we must describe the Alps of France, Switzerland, Austria, and Italy separately, as though they had no connection with each other. Such a plan entails waste of space, as well as confusion of ideas. Let us, then, select geographical rather than merely political divisions, and begin by tracing the course of the Rhine from its delta on the North Sea to its cradle among the Alpine snows. This will bring us to the Alps, the greatest geographical feature of Europe, after which we can continue the description of the various other divisions.

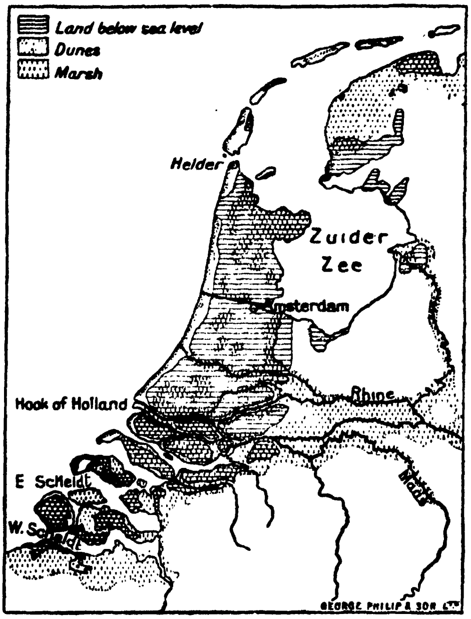


83. THE INDUSTRIAL FIELD OF BELGIUM

The Rhine and Central Europe. Let us, in imagination, stand on a commanding peak in the Swiss Alps and try to realise our position. We are, as it were, on the gable roof of Europe, with the land falling away in all directions to the surrounding seas. Looking north on a clear day, we see, beyond the world of snow-peak and glacier in the immediate foreground, low, rounded hills, forested—if we saw them nearer—showing as a faint blue line on the distant horizon. These are not Alps, but part of the Central Highlands

Alps. Beyond this blue line of hills, if vision permitted, we should see the land gradually sinking to a vast plain, broken by outliers of the Central Highlands, and ending at last in the flat, marshy shores of the North and Baltic Seas. Across this plain we should trace the silver threads of many rivers, following the slope of the land northward to these seas. But of all these rivers, one, and only one, would be the child of the glacier streams sparkling in the Alpine valleys actually beneath our eyes. This river, the one link between the Alpine snows and the seas of Northern Europe, would be the Rhine.

Entering the Mouth of the Rhine. Much of Holland consists of the delta of the Rhine [84]. The land along the North Sea is so low that the sea must be kept out by dykes, and so waterlogged that it must be drained by canals and pumped dry by windmills. Windmills and more windmills, canals, white houses, and green meadows are every traveller's first impressions of the Rhine and Holland. Of course, the sea has devoured great slices of such a coast, forming the shallow gulf of the Zuider Zee, and leaving a chain of sandy islands parallel to the coast. Across this flat region, which is largely made of sediment brought down by the river, the Rhine reaches the sea by many branches or distributaries, forming an intricate network of intersecting channels. We might, therefore, reach the main stream by many routes, from either the North or the Zuider Zee. The usual route is by the Hook of Holland and Rotterdam, on the Lek.



84. THE DUTCH LOWLANDS

in fishing. The capital, S'Gravenhage, or the Hague, is on the coast. Inland, a little to the north, is the university town of Leyden. The most important inland town is Utrecht, from

innumerable islands and sandbanks, is or is not a tributary, but it must not be mistaken for a distributary. Flushing, on the island of Walcheren at its mouth, is where the pilot comes on board for the intricate navigation of the Scheldt to Antwerp, the port of the Scheldt.

Holland, or the Netherlands. Holland (12,600 sq. miles) is an almost treeless, alluvial land, destitute of minerals or building stone, but fertile where it can be drained. The climate does not differ much from our own, but is rather wetter. Cereals, hops, and sugar-beet are grown. The polders, or reclaimed meadows, pasture many dairy cattle, and much butter and cheese are exported. In some respects, therefore, it recalls Denmark. The Dutch are great gardeners, famous for their bulbs. Whole fields of them may be seen in flower outside some towns in spring. There are many industries, the raw materials being cheaply brought by water. The chief manufacturing centres—Breda, Tilburg, and Maastricht—are in the south. Rotterdam, the port of the North Sea, and Amsterdam, the port of the Zuider Zee, both manufacture the colonial produce brought to their wharves from the Dutch East Indies. Amsterdam cuts diamonds for all Europe. Many coast towns trade in butter and cheese, and, of course, engage

where the great river port of Duisburg is built, has a large coalfield, which feeds the textile manufactures of Barmen-Elberfield, and the iron town of Essen, where the famous Krupp guns are made. It also sends coal by water to Krefeld, west of the Rhine, with silk manufactures. To the south is Aachen, or Aix-la-Chapelle, a woollen and cotton town, on a coalfield. Düsseldorf and Köln, or Cologne, the latter with the finest cathedral in the world, are accessible to ocean steamers, and their trade is enormous. So far both banks have been flat and uninteresting, though the regions on both sides are fertile and prosperous.

The Rhine Gorge. At Bonn, above Cologne, we enter the famous gorge cut by the Rhine through the northern part of the Central Highlands, between the Eifel and the Hunsrück on the west, and the Westerwald and Taunus on the east. Mile after mile we sail between mountain walls, each crag crowned by a ruined castle, and the lower slopes terraced for vineyards. At Coblenz, another great river port, the Moselle, from the Vosges, comes in on the west bank in a forested gorge between the Eifel and the Hunsrück. In its basin is the great fortress of Metz, the Saar coalfield with many
the independent Grand Duchy of

and the old Roman town of Trier. Nearly opposite the Moselle confluence, on the other bank, comes in the Lahn, flowing in a similar forested gorge between the Westerwald and the Taunus. The Rhine gorge continues to Bingen, where we emerge into undulating country, and soon reach Mainz, at the confluence of the Main. If we could follow up this noble tributary it would take us by the banking city of Frankfurt, the university town of Würzburg, and the picturesque scenery of the Central Highlands, far into the heart of the Franconian Jura. We should certainly want to visit Nürnberg, on a tributary, the finest mediæval city remaining in Europe, and now a busy manufacturing town.

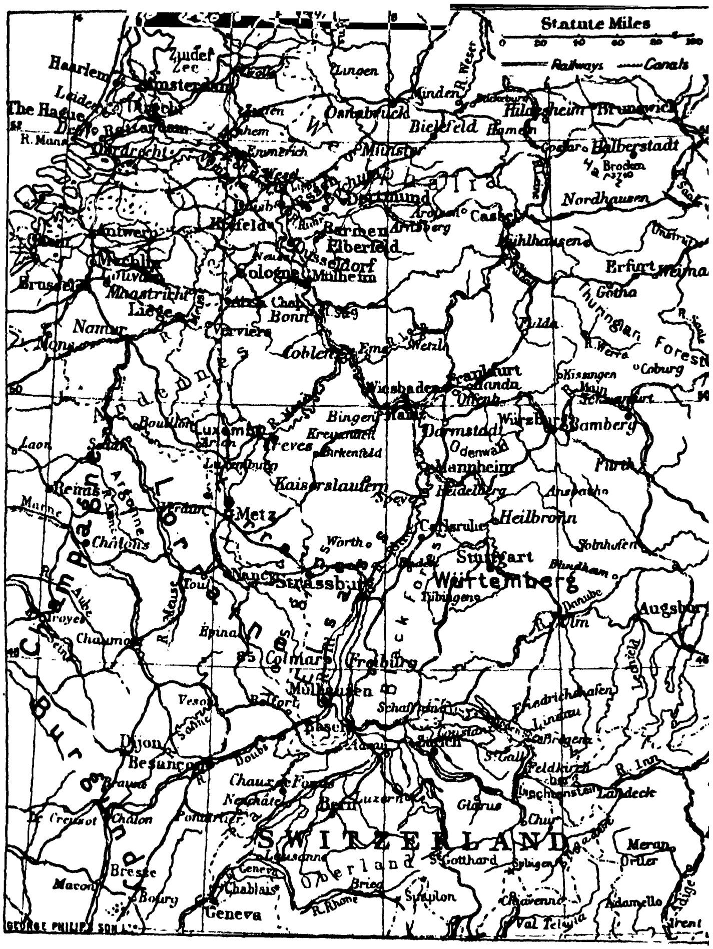
The Plain of the Middle Rhine. But we must follow the main stream across a richly cultivated plain, 20 or 30 miles wide, between the distant wooded Vosges on the west and the still more picturesque Odenwald and Black Forest on the east. At the busy port of Mannheim a glimpse up the Neckar makes us long to visit Heidelberg, on a lofty crag in its forested gorge. The Neckar is formed by many mountain streams, coming down in lovely valleys from the Swabian Jura, which separate the Neckar from the Danube. The chief town in its basin is Stuttgart, the capital of Würtemberg. The main stream of the Rhine continues across a land of cornfields, orchards, and vineyards. Karlsruhe, the capital of Baden, is connected with the Rhine by canal and has large engineering works; Strassburg, with a fine cathedral, is the port for Mülhausen and other cotton towns of the Vosges. Freiburg lies at the entrance of a lovely valley leading into the heart of the Black Forest. We now approach Basel, or Basle, the frontier town of Switzerland, a great centre of trade and railway traffic, about 750 miles from the mouth and 250 miles from the source of the Rhine.

The Rhine in Switzerland. The direction of the river valley now changes, narrowing between the Black Forest on the north and the Jura on the south. Above this it flows in a gorge between the Swiss and Swabian Jura, leading to Lake Constance. Swift tributaries, green with glacier sediment, rush down from the snowy Alps, now seen in the distance. The largest is the Aar, which rises among the highest peaks of the Bernese Alps, flows through Lakes Brienz and Thun, past Bern, the capital, and then northwards between the Alps and Jura, receiving, among many tributaries, the Reuss, from Lake Lucerne, and the Limmat, from Lake Zürich. At Schaffhausen are the Falls of the Rhine, where the river leaps madly down from the higher ground west of Lake Constance. We next reach its exit from that lake, and are but a few miles from the Danube, the great waterway of Western Europe. From a summit between the two we might possibly look down on waters flowing to the North and Black Seas respectively, so that here, in a sense, east and west, north and south, meet. After leaving Lake Constance, with its ring of towns, the valley leads us south, through scenery of increasing wildness. Swift rivers, leaping down 3,000 or 4,000 ft. in 20 or 30 miles, rush to the roaring torrent of the Rhine, whose valley narrows to a wild gorge. At last, 800 miles from the North Sea, our journey ends, at the source either of the Hither or of the Further Rhine, at a height of over 7,000 ft., among the grandest Alpine scenery.

The Alps. We have now reached the heart of the Alps, which stretch across Europe for 700 miles. We generally think of them as in Switzerland, but they extend west into France, east into Austria, north into Germany, and south into Italy.

To describe the scenery of the Alps in words is not easy. It varies greatly in different parts. In the limestone Alps of Austria the peaks and pinnacles are too steep for snow to lie, and they soar into the sky like fantastic obelisks of many-coloured rock. The familiar scenery of the Swiss Alps is something like this: Starting from our centre we climb on foot, or perhaps by rail or coach, up a smiling valley, between mountains clothed with forests of dark pine. Beside the road a swift torrent leaps from rock to rock in cascades of foam. Little villages of wood, with great overhanging roofs to carry the weight of the winter snow, are gay with vines, fruit-trees, and patches of maize. As we go on, the valley becomes more uphill, the mountain walls higher, the villages fewer, and the stream wilder. The bridges which cross it have canopies over them to prevent snow from breaking them down in winter. As we climb, the woods thin out, and their place is taken by steep meadows gay with flowers of every hue. The tinkle of the cow-bells and the little wooden cheese-houses tell us that we are among the high pastures, deserted in winter by man and beast.

An Alpine Glacier. Above the meadows appear walls of rock, and perhaps at the end of the valley a dazzling vision of snow-peak and glacier. The grass ceases, gay to the last with flowers. We are at the edge of the glacier, with its lines of moraine, rocks, and stones, which have fallen from the towering precipices above, clearly marked on its white surface. Most likely its end is hollowed into a glittering blue ice-cave, out of which gushes the stream we have been following. If we would reach the snowy summits, our way lies over the rough surface of the glacier, with its torn and twisted ice, split by deep chasms and crevasses of giddy depth and dazzling blue. The party is roped together, furnished with ice-axes, dark spectacles to dim the glare from the snow, and, above all, with good guides. Silently and cautiously, for a loud noise or a false step may start an avalanche of stones or snow and hurl all to destruction, the climbers make their way over glacier and snow-fields, or along a knife-edge of rock, to the summit, to behold a view no words can describe. They may descend on the Italian side, through similar scenery. The snow and ice will not come so low as on the Swiss side, and in the lower valleys chestnuts will replace pines, and mulberries, vines, figs and other fruit will speak of the Sunny South.

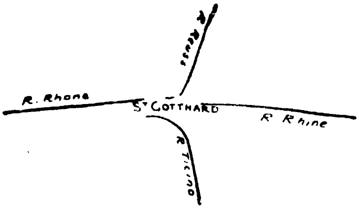


85. THE BASIN OF THE RHINE

Valleys and Peaks of the Alps. To understand the geography of the Alps, let us first be clear about the famous St. Gotthard region, the cradle of many Alpine rivers. We reach the St. Gotthard Pass, the gate of this region, from Lucerne, by following the lake, and its feeder, the Reuss, up to a height of 7,000 ft. A wonderfully engineered railway follows the valley to a height of 3,800 ft. and then plunges into the bowels of the mountains in a tunnel 9¼ miles long, emerging at the head of the Ticino valley, which leads down to Lake Maggiore, Milan, and the plain of the Po. Only a few miles from the source of these two rivers are those of the Further Rhine, flowing east, and of the Rhone, flowing west, while those of the Aar, in the Bernese Oberland, are also near [**86**]. Once clear as to these rivers, we can easily fix the geography of the rest of the Alps in our minds. The Rhone flows west in a great trough between the Bernese Oberland to the north and the Pennine Alps to the south. Zermatt, the needle-like Matterhorn (14,700 ft.), Monte Rosa (15,200 ft.) and other giant peaks, are at the end of valleys opening to it from the south. From Martigny, where the Rhone turns north to Lake Geneva, we may visit the highest peak in the Alps, Mont Blanc, over 15,700 ft. South of the Mont Blanc group two rivers must be noted, the Dora Baltea, flowing south-east down to the Po, and the Isère, flowing south-west through the French Alps of Savoy and Dauphiné to the Rhone. Further south the Durance flows to the same river and the Dora Riparia to the Po.

The Aar has already been traced from the glaciers of the Finsteraarhorn (14,000 ft.), the highest of the Bernese Alps, to its confluence with the Rhine. Interlaken, between lakes Brienz and Thun, commands a fine view of the Jungfrau, the queen of the Bernese Alps, and is the starting-point for their finest scenery. The courses of the Reuss and Rhine we also know. East of the Rhine is the Vorarlberg district, and south the Engadine, perhaps the finest of all, with peaks 11,000 to 13,000 ft. high. The Inn flows through grand scenery to the Danube, between the Bavarian Alps and the Tyrol, with Innsbruck as its chief centre. From the Tyrol the Adige, or Etsch, flows south, near the Ortler group (12,800 ft.), the highest part of the Austrian Alps, the only one of the many rivers flowing south in long parallel valleys which does not enter the Po. Near the source of the Adige is the Gross Glockner (12,400 ft). The scenery and direction of the valleys gradually change. The rivers no longer flow north and south, but east to the Danube, the largest being the Drave and Save. These eastern Alps form the Austrian provinces of Styria, Carinthia and Carniola. From the northern end of the Austrian Alps spring the forested Carpathians, and from the southern the Dinaric or Dalmatian Alps, which border the eastern shores of the Adriatic. The Apennines of Italy are also an offshoot from the Alps, but with quite different scenery.

Some Notable Alpine Passes. These are, of course, connected with the valleys already mentioned. In the centre the St. Gotthard leads from the head of the Reuss valley to the head of the Ticino valley, thus giving a through route from the North Sea to the Adriatic. In the west the Mont Cenis, also followed by a railway, with a tunnel 7½ miles long through the core of the Alps, leads from the valley of the Arc, a tributary of the Isère, to that of the Dora Riparia, a tributary of the Po, and to Turin. The Brenner, in the east, leads from the Inn to the Adige. All these give through routes right across the Alps. The Simplon, with a tunnel 12½ miles long, leads from the middle of the upper Rhone valley to the valley of the Toce and Lake Maggiore. Many famous passes, not accessible by rail, lead from one valley to another, but these need not be mentioned.



86. THE ST. GOTTHARD PASS

Switzerland. Switzerland (16,000 sq. miles) is a union of many independent cantons which grew up on both slopes of the Central Alps, round the lakes which fill many of the lower valleys, and on the plateau at their northern base. The Federal capital is Bern, on the Aar. Except on the plateau, the larger towns have become important because they command good routes across the Alps. Zürich, Luzern (Lucerne), Bern, Lausanne, and Geneva are examples.

Climate. On the plateau the climate is that of Central Europe, with hot summers and cold winters. In the Alpine valleys the winter varies in severity with elevation. Winter snow covers the summer pastures, blocks many of the passes, and renders the streets of the higher villages impassable.

Why Switzerland is Prosperous. Switzerland is a brilliant example of what can be done by utilising the national resources, whatever they are. A land of uninhabitable mountains, with hardly any lowlands suited for agriculture, with no coal to feed manufactures, and producing hardly any raw material, it would seem to have small hope of prosperity, yet it is one of the richest countries in Europe. Mountaineers are generally resourceful and energetic, and the Swiss are no exception. They make the most of agriculture on the plateau, their manufactures are flourishing, their dairy industries world-famous, and they have brought to perfection what they call the *Fremden industrie*, or trade in tourists.

The Tourist Industry. Switzerland discovered this industry and makes a fortune by it. Everything is done to develop it. Railways are carried everywhere, even up nearly perpendicular cliffs, and will soon reach the summit of the Jungfrau itself. Well-equipped hotels are built actually at the snow-line. Summer brings its tens of thousands of tourists, who enrich the army of caterers, cooks, waiters, porters, railway servants, and mountain guides who follow in their train. The favourite centres are the Engadine, where Davos is a sanatorium for consumptives, Zermatt, in the Pennine Alps, Interlaken, in the Bernese Oberland, Chamonix, for Mont Blanc, Vevey, and many other towns round the lake of Geneva, and Luzern and smaller towns round that lake for the fine scenery about the St. Gotthard.

Swiss Agriculture. Agriculture is confined to the plateau and the lower valleys, where rye, oats, and potatoes are the chief crops. The summer is hot enough, especially on Lake Geneva, to ripen the vine and maize, and in the valleys of the southern slopes the mulberry and olive are also cultivated. Not enough food is grown for the population, and food-stuffs are largely imported.

The Dairy Industry. With the rich pastures of the Upper Alps, dairy farming was bound to be important. Many Swiss cheeses are famous, and the manufacture of condensed milk is a specially Swiss industry. Notice how the character of a country affects even the way in which it pays to use milk. Other pastoral countries, Ireland, Denmark, Holland, make butter their staple, but they are maritime. Switzerland is in the heart of Europe, and transport is difficult and costly. Cheese and condensed milk are highly portable, and do not spoil by keeping. Hence their selection. Let us never forget to look for geographical explanations of this kind.

Manufactures. The manufactures are important, partly because the people are shrewd, industrious, and well educated, but also because there is an inexhaustible supply of cheap motive power. This is furnished by the irresistible force of the rivers rushing down from the Alps. Always important, water-power has become invaluable with the development of electricity as a motive-power. The electrical industries are growing all over Switzerland.

The mountain railways are driven by electricity, and the nearer a town or hotel is to the snow-line, the more certain is it to be lighted by electricity. Textiles are manufactured in the busy towns of the plateau, silk at Zürich and Basel (Basle), and cotton round Zürich and St. Gallen. Textile and electrical machinery are made at Zürich, the industrial capital of Switzerland, and locomotives at Winterthur. Geneva, the commercial centre of the west, gives its name to the watches and clocks made in the valleys of the Jura, in the canton of Neuchâtel, north of the lake of that name. Lausanne, magnificently situated on the north of Lake Geneva, is also a busy town.

TAILORING
continued from p. 1756

TAILORING FOR WOMEN

Plain Double-breasted Coat. Tracing the Pattern. Sleeve Drafting. Pressing. Preparing the Fronts. Pockets and Linings

By Mrs. W. H. SMITH and AZÉLINE LEWIS

Of late years the term "tailor-made," as applied to ladies' garments, has included the most elaborate confections, distant as the Poles are asunder from the original ideal—a plain, neat costume, distinguished only by the perfection of its fit and cut.

To a sartorial artist the former are but hybrid productions, and he inclines more to the real "tailor-built" coat or gown, which may be considered the foundation of all good ladies' tailoring.

A Double-breasted Coat. As it would be impossible to deal with all the varieties under this heading, we have selected for our first example a plainly-fitting, double-breasted coat, as that from which the most benefit can be derived, and so pave the way for more elaborate styles.

MATERIALS REQUIRED. 2½ yd. of cloth, 54 to 56 in. wide; 2½ yd. lining, 42 in., or 5 yd. silk, 22 in. wide; ½ yd. linen; ¼ yd. hair cloth; 1¼ yd. linen canvas; 3 in. collar canvas; 1 doz. fancy buttons; a reel of machine silk; buttonhole twist.

All the linings and trimmings required should be procured at a tailors' trimmings warehouse. It is well to have the finest linen canvas and the best fine linen for the stays.

Measurements: Bust, 34 in.; waist, 25 in.; sleeve (centre-back to elbow), 20 in.; elbow to wrist, 10 in.; neck, 15 in.; length of back, 16 in.; full length, 40 in.; front length (nape to waist), 21 in.

The measurements are taken the same as those for DRESSMAKING [see page 186], with the addition of one from the nape of the neck (at back) to the waist in centre-front, which gives "front length." The chest measure is taken 2 in. above the bust-line.

Working scale, half-bust; ¼-in. turnings are allowed on all seams.

The Drafting. A sheet of brown paper will be required, 36 × 48 in. Square lines 5 in. down from top and 4 in. in from long edge: letter the corner A [58]. A to A^a, one-sixth of neck (2½ in.); A^a to A^b, ¾ in.; A to B, one-sixth of back length (2⅝ in.); A to C, one-third (5⅜ in.); A to D, length of back (16 in.); D to D^a (2½ in.); D to E (7 in.); D to E^a (24 in.), or length required. Square all lines except waist; D to 1 (1½ in.); draw centre-back line from 1 to A, and from 1 through E line to bottom of coat, E^b. Back line to C^a (on bust-line) one-third of bust plus ¾ in. (6½ in); on to F, two-thirds (11⅜ in.); F to F^a, one-fourth of bust (4¼ in.); F^b midway between; F^b to X, ¾ in.; back line to G, half the bust and ½ in.; G to H, 3 in.; C^a to I, one-twelfth (about 1½ in.). Square line up from C^a, make J on B line.

BACK SHOULDER. Slightly curve from J to A^b, and neck from A^b to A. C^a to J^a, half the distance from A to C [see broken line]; make a dot ¼ in. below J^a, and K ¼ in. to the right of dot just made.

Square line from G to neck-line, and make L; L to M, one-sixth of neck (2½ in.); M to M^a, 1¼ in.; M^a to N, one-sixth of neck (2½ in.).

Square a line from N, one-fourth of bust, and make H^a; N to N^a, 1¼ in., or half the distance from N to M^a; curve the neck from H^a through N^a to M^a.

FRONT SHOULDER. Draw line from M^a to J; make O the length of back shoulder less ¼ in.; drop O ¼ in., to take off the sharp angle at that point.

ARMHOLE. Curve from O through F^a and X to I, and from I to K; I to I^a, ¼ in.; M^a to P the front length (21 in.) less the back neck measure, as from A to A^b (2¾ in.). Draw line from H^a through P, the length of coat make P^a; P^a to P^b (3 in.). Draw waist-line from 1 to P.

SIDE PIECES. F to I^b (1¼ in.); 1 to 2 (2 in.); curve from 2 to J^a; where the curved line crosses bust-line make dot 3; 3 to 4 (⅜ in.); 5 midway between 4 and I^b.

WAIST SUPPRESSION. 2 to 6 (1½ in.); 6 to 7 (½ in. less than 4 to 5); 7 to 8 (1½ in.); 8 to 9 (½ in. less than 5 to I^b); 9 to 10 (1½ in.); drop 6 ½ in. in order to make the curve on side-piece the same length as from 2 to J^a. Curve from 6 through 4 to K' from 7 to I, from 8 to I^a, and from 9 and 10 to I^b.

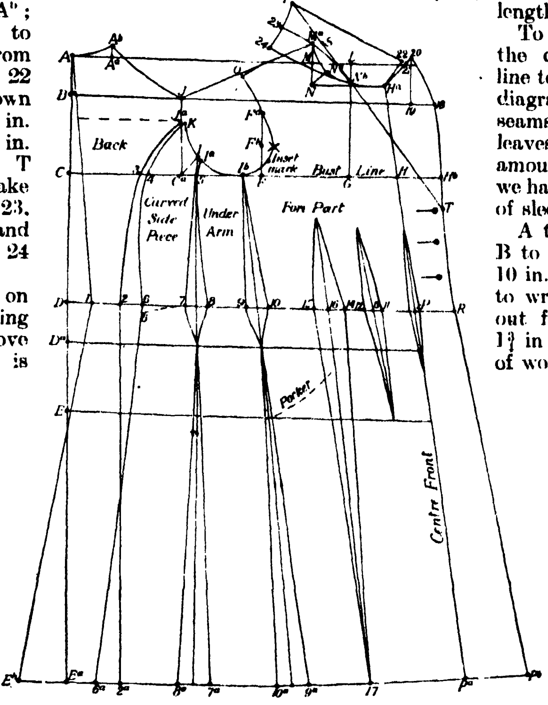
Now carefully measure up the waist—*i.e.*, between 1 and 2, 6 and 7, and 8 and 9; total, 7 in. Deduct the amount for turnings—*i.e.*, 1½ in.—this leaves 5½ in.; place this amount ¼ in. to the right of 10, with the inch-tape resting on P, and make a dot at half the waist measure.

The distance between the dot and P is the amount to be taken out in darts, which in this case is 3 in. P to 11, 2½ in.; 11 to 12, width of first dart (1 in.); 13, in the centre of dart; 12 to 14, 1½ in.; 14 to 15, width of second dart (2 in.); 16 in the centre. Draw lines through the centre of each dart from bust to seat-line parallel with centre-front line. Curve the darts to within 2½ in. of bust-line; extend the centre line of second dart to bottom of coat, and make 17; draw lines from 17 to 14 and 15.

Square lines down from the centre of 9 and 10, and 7 and 8, to the bottom of coat; make dots; 10^a 1 in. to the left of dot, and 9^a 1 in. to the right. Treat the second dart in the same way, making 7^a and 8^a ½ in. to the right and left of dot. Draw lines from 9^a and 10^a to seat-line, then curve from seat-line through hip-line to 9 and 10; treat the second dart the same; draw line from 2 to the bottom of coat; make 2^a, then 6^a, 1½ in. to the left of 2^a; draw line from 6^a to 6.

THE LAPEL. H to H^b 3 in.; P to R 2½ in.; draw line from H^b through R to bottom of coat, make P^b; extend B line 3 in. from centre-front, make 18; 1½ in. to left make 19; 19 to 20, 3 in.; slightly curve from H^b through 18 to 20. Draw line from 20 to H^a.

THE COLLAR. M^a to S, ½ in.; H^b to T. 2 in.; draw line from T to S; S to T^a, width of back neck as from A to A^b; H^a to 21, 2 in.; 21 to 22, ¼ in. Draw line from H^a to 22, and from 22 to T^a; square line down from T^a; T^a to 23, 2 in. for fall; 23 to 24, 1 in. for stand. Where T crosses neck-line make N^b; curve from N^b to 23, and from N^b to 24; and slightly curve from 24 to T^a.



58. COAT DRAFTING

A small dart ¼ in. on either side of P, tapering away to nothing above and below waist-line, is a great improvement to the figure. The top of dart should terminate 3 in. from bust-line and bottom 1½ in. below hip-line.

Tracing the Pattern. Place the drafting on another sheet of brown paper. The back should be cut first. Trace from 1 to 2; from E^b through 1 to A; from 2^a through 2 to J^a, on to J, A^b, and A, then E^b to 2^a. Remove the drafting, cut out the back, and replace the drafting on the paper, each piece being cut out in the same way.

CURVED SIDE PIECE. Trace from 6 to 7; 6^a through 6 to K; from 6^a to 7^a, from 7^a through 7 to I, and on to K.

UNDER-ARM PIECE. Trace 8 to 9; 8^a, through 8 to I^a; from 8^a to 9^a; 9^a through 9 to I^b, on to I^a.

FORE PART. Trace 10 to R; 10^a through 10 to 1^b, on through X to O; 10^a through P^a to P^b; centre-front from P^a through P to H^a, on to M^a, thence to O.

THE LAPEL. Trace from P^b through R round the lapel to H^a. Trace the fold of lapel from T to S, also the dot N^b, and the inset mark for sleeve ¾ in. above bust on armhole curve. Trace the darts carefully.

THE COLLAR. Trace from H^a through N^b to 24, on to T^a; from N^b to 23; and H^a to 22 on to T^a.

Sleeve Drafting. Working scale, half-bust, 17 in.; ¼ in. turnings are allowed on all seams [**59**].

Take a piece of brown paper, 30 by 16 in; 5 in. down from top and 1 in. in from edge, square two lines at right angles; letter the corner A.

A to B, half working scale (8½ in.); B to C, 2 in.; A to D, half the distance from A to B, less ¼ in. (4 in.); D to E, same distance as A to B; F, midway between D and E; F to G, one-fourth of working scale, plus 1 in. (5¼ in.); F to H, one-fourth (4¼ in.); F to F^a, ¾ in.; B to I, the length of sleeve to elbow.

To obtain this, measure the distance from back line to J^a [see broken line, diagram **58**]; deduct two seams—*i.e.*, ½ in.; this leaves 6 in. Deduct this amount from the 20, and we have the correct length of sleeve, 14 in.

A to J, 1 in. less than B to I (13 in.); J to K, 10 in. (length from elbow to wrist). Square a line out from K; K to L, 1¾ in; L to M, one-third of working scale (5¾ in.); draw wrist-line from L to M, and elbow-line from J to I; J to N, 1½ in.; N to N^a, one-third plus 1¼ in. (7 in.)

The wrist and elbow can be made smaller or larger, according to taste and fashion.

Curve from L through N to D; draw line from M through N^a to B, and from N^a to C.

For the top of sleeve, curve from D through H and G to B; and from D through F^a to C; this concludes the sleeve proper.

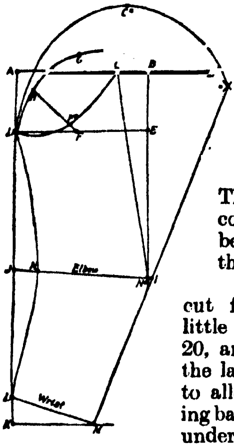
To obtain a leg-of-mutton shape, proceed as follows: C to C^a one-fourth (4¼ in.); B to B^a the same, plus ½ in.; 1 in. down from B^a make a dot; X is ½ in. to the right of dot. Curve from D, 1 in. to the right of A, through C^a to X.

Tracing the Sleeve. First trace the elbow and wrist lines, then from L through N to D, from M through N^a, X and C^a to D.

Under-part, L to D; M through N^a to C, and from C through F^a to D.

Chalk-marking the Pattern. Lay the various parts on the cloth as in **60**. Should the cloth be faced, they must all go one way (not be reversed). Chalk all round each piece; then chalk the waist-lines, the roll of lapel as from T to S, centre-front as from P^a to H^a, round all the darts and inset for sleeves. Inlays must be left on the shoulder, top of back-neck, darts, side-seam of fore part, and 1½ in. at the bottom for turn-up; 2 in., or more, on the bottom of sleeve, and ½ in. on the back seam of top part should also be allowed. Chalk-mark the turn-up and cuff.

Thread-mark all inlays, waist-lines, centre-front, lapel roll, darts, neck-curve, turn-up, position of pocket, according to directions already given for Boy's Coat.



59. SLEEVE DRAFTING

The cotton should be two yards in length, doubled and twisted. The twist causes the cotton to grip the material better, and prevents the threads from coming out.

The facings must be cut from the fore part, a little below T, a trifle above 20, and a little wider round the lapel. This is necessary to allow of the latter turning back freely, with the seam underneath. If this is not done, the lapel will curl up instead of under.

The facings must also go 2 in. below M^{1b} on shoulder, and 4 in. from the front at bottom. [See 58 and 60.] They can be joined, if necessary, to economise material. Should the cloth be firm and not inclined to ravel, the join can be stoated with silk. [See STITCHES.]

Now slightly damp the canvas all over with a wet rag, and press with a fairly hot iron. Fold and cut as in 61. Shrink the hair-cloth in the same way.

Lining. The lining must now be cut, ½ in. larger and longer than the cloth, the reason being that the latter is elastic, while the former is not. Leave the same amount of inlays, and sufficient for a pleat on the shoulders, and also two in front of armhole—*i.e.*, one at F^{a}, the other at the inset-mark. This gives plenty of room for the bust, and prevents the lining splitting.

Place each piece with the waist-line running with the thread of cloth, so as to prevent that part being on the bias; if this is not done, the garment will be twisted.

Then, again, the cloth itself is not always creased evenly, so that it is necessary to make sure that the selvedges are together, otherwise it will be found that, whilst one side is cut on the straight, the under-piece is not, which is bound to result in their pulling one against the other, causing what is called a "twist." When this does occur, it is a very difficult matter to put right, so the worker will see it is most important to carry out these instructions for placing before cutting out.

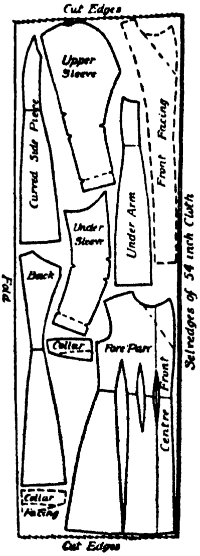
Before proceeding with the making, it is advisable to first read and study the following notes on machining and pressing, as the latter forms a most important part of tailoring, and must be carried out in every detail if the garment is to be a success; moreover, it has to be continually resorted to from the very beginning.

Machining. Before stitching the seams the worker should see that the machine is perfectly clean. If it requires oiling, it should be well worked to allow the oil to get into all the parts.

When this is done, try the stitch on a piece of the same material as the garment. To be perfect it should be locked in the centre, so that it is the same on both sides. Should the thread or cotton lie in a straight line along the back, the tension is too loose, and must be tightened by turning the tension-screw to the right—*i.e.*, towards you. Should it lie across the top, it is too tight, and the screw must be turned to the left. When once the stitch is made right it is advisable to leave it so. It is seldom necessary to alter the foot. Should there be any very thick seams it can be raised a little by the foot lever while working; this will be far better than altering the position of the foot.

Be very careful not to start or leave off machining with a jerk or violent start, as that will soon throw the machine out of order, and take half the service out of it; always loosen the top cotton and draw out both the top and the under together 2 or 3 in. before cutting.

Now as to the cottons, etc. That on the shuttle or bobbin should always be a size coarser than the top, let it be silk, cotton, or thread. In stitching all outside edges great care is needed to do so evenly and to keep the corners square or round, as the case may be. If the former, it will be necessary to come to a stop with the needle at its lowest point. The foot must then be raised and the work turned round, so that the stitching is quite square. If a rounded corner is desired, the lever must be kept up slightly with the left hand, and the machine kept in motion, but worked much slower while the corner is being turned.



60. ARRANGING PATTERN ON MATERIAL

The work must, of course, be carefully guided all the while. Care and practice are needed to accomplish good machining.

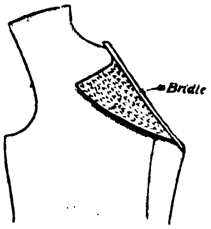
Pressing. The chief object of pressing is to make the seams and inside smooth, and yet to preserve, and in some cases improve, the shape of the different parts of a garment.

The seams of a bodice or coat should be smoothed on each side of seams before pressing them open. If the cloth is thick and heavy damp the edge of seams with a small sponge; this facilitates the opening process.

The iron must not be kept on too long, and must be lifted up to let off the steam generated by pressing; if kept on too long, the oil in the wool will be drawn by the heat of the iron to the surface of the cloth, which will take a great deal of steaming with a damp cloth to remove, and the cloth would need re-pressing. These remarks apply to all kinds of pressing; the newer the wool the more oil there is in it, and the greater the care needed in pressing. Care must be taken to preserve the shape and cut of any part of the garment. In sleeves, avoid stretching the elbow.

The seams, when laid on sleeve-board, must be smoothed on both sides, as already explained. Begin to press from the bottom to the top of darts, and gradually smooth the round away on the pressing pad described, taking care not to press to the front nor into the armhole; this is important to preserve the shape. After the canvas or linen has been put into the coat, stretch out the shoulder seams towards the neck.

Great care is needed here to make the waist fit closely when on. If the figure is very hollow it is best to strain out the hollow in waist-line 1½ in. above and below with the left hand while pressing this portion.

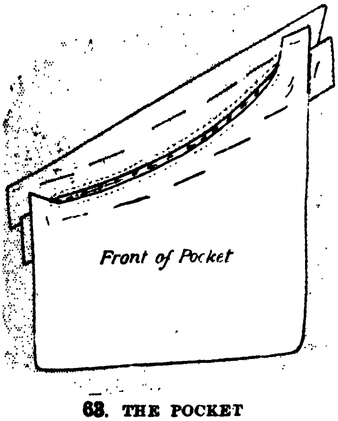


62. PUTTING THE LINEN ON LAPEL

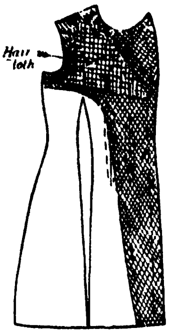
The Pressing Pad. The pressing pad is a most necessary adjunct to the outfit for ladies' tailoring to enable the rounded portion of the figure to be dealt with. It can easily be made as follows:

Cut two oval pieces of cloth, each measuring 11 in. in length and 8 in. across the widest part. Stitch them together to within about 3 in., and pack well with small pieces of cloth till the pad is perfectly hard; then sew up the opening.

The Making. We can now return to our material. Take the right front, baste the darts from top to bottom, stretching the back parts to meet the front, as at **11**, **12** and **14** and **15**; they must be stitched from the bottom to a fine point at the top, leaving no blister or bubble. Slightly damp the seams on both sides (if the cloth is thick), and press both sides on a bare board with a moderately hot iron until it is perfectly dry. If this is not done the seam will rise again, and no amount of pressing will flatten it. Slightly stretch with the left hand 1½ in. above and below waist while pressing; great care should be exercised here while doing so. The centre-front dart, as at P, must next be basted and stitched, tapering it to very fine points top and bottom. Now open the seams, slightly damp them, and press. The top of darts should be pressed on the pad described, over a clean, damp cloth (which should be folded), to press out all bubbles and give a rounded appearance to the bust. The bottom of centre and first darts must be pressed on a bare board or cloth, the latter for preference.



63. THE POCKET



61. HOW TO PUT IN THE CANVAS

The Canvas. We are now ready for the canvas. First cut the centre-front of dart, and serge the edges together closely to make them lie flat. If the canvas is very thin, as it should be, it can be seamed.

Place the right front on the table wrong side uppermost; place the canvas in position ¼ in. beyond the front of lapel to allow for padding, baste to the cloth, keeping it rather loose, particularly across the chest. Be sure and slit the canvas as in diagram **61**, and insert two wedges of canvas on the shoulder ½ in. wide at the top and 2 in. long, tapering to nothing. These must be secured to the canvas; then baste the bridle along the break of lapel, as from T to N". This consists of a strip of straight linen 1 in. wide, folded in half, with the fold placed to that of lapel, which must be held rather tight [**62**].

The Lapel. Pad the lapel to within ½ in. of the edge of cloth (the closer the stitches are the better will be the result); on no account must there be any ridges between the rows; and a fine needle and silk should be used, the silk being drawn up lightly.

Preparing Fronts. When this has been done the canvas must be pared away ¼ in. from the edge of cloth. Now cut the linen stay 1 in. wide and long enough to go from 1½ in. beyond the break of lapel right round front and down to the bottom of coat. When basting it must be held rather tightly 3 in. on either side the point of lapel, as at H", but less tightly down the front. Serge the inner edge of stay to the canvas. The outer edge must have a thread of the cloth taken up with the canvas.

Place the front on the table wrong side uppermost, on a piece of cloth, if possible, and press all round the edge and the lapel with as damp cloth over. The iron must not be too hot, and the cloth must be wrung nearly dry.

Now baste the hair-cloth very thickly to the canvas, to keep it in position; it must be slit at the shoulder and opposite the top of the darts. [See **61**.]

When this is done a strip of linen ¾ in. wide should be basted over the edges to prevent the hair working through the cloth; it must be caught to the canvas on one side and the haircloth on the other rather loosely.

Now take a piece of linen 6 in. wide for button and buttonhole stay; first press it, then place it ½ in. above the break of lapel to 7 in. below waistline. Baste to canvas loosely ¼ in. in from the edge, and secure to this with several rows of basting.

We are now ready for the facing; the outer edge of this must first be shrunk to match the edge of front from T to bottom. It is safest to place the facing on the front and measure carefully from T to find how much has to be shrunk out. This must be done with a damp cloth and a rather warm iron. Place the facing on the right side of fore part, face to face, with the shoulder to the left; baste from the bottom, keeping the facing easy at T to 1 in. below this, and quite full round the lapel; machine ¼ in. from the edge, beginning at the bottom, round the lapel to H" (any seams with a fulness on one side must always be stitched with the fulness underneath). Cut the edges even to within ⅛ in. of stitching, open and press the seam; turn the facing back, working out the points with a bodkin; baste the edge of lapel, working the seam ⅛ in. under, so that it shall not be seen on the right side; baste again along the break, pressing the cloth towards the point, and put one or two stitches more near the point; this should be done over the band to make the lapel curl under; now baste the edge below lapel, working the seam ⅛ in. in, keeping it easy at the portion marked T; baste again through the centre and the outer edge.

The left front must be made in the same way.

Putting Material Together. We next proceed to put the back and side pieces together. In all cases the waist-lines must be kept even. If this is not done there will be what is called a "twist." The seams must be basted thickly (four stitches to the inch), ¼ in. in from thread-marks. First baste the centre-backs together, next the curved side-pieces; one must be basted from top to bottom, the other from bottom to top—the back part must be uppermost when doing so.

Before basting the under-arm to fore part, a little attention must be given to the inlays. The edges must be damped and stretched on the sleeve-board with a warm iron, great care being taken to keep clear of the thread-marks, as the edges only are to be stretched until they have a wavy appearance. If this is not done the inlay will contract the outside.

Having stretched the edges, baste the under-arm to fore part and shoulders, remembering to stretch the latter towards the neck when basting to the back shoulder.

The coat is now ready to try on. If the measurements have been taken correctly, there should be very little, if any, alteration required; but, should any be necessary, it must be made at the shoulder and under-arm seams.

When the coat has been fitted, the seams (with the exception of the shoulder, which must have the basting removed and be left free) must be stitched with silk.

Remove the basting very carefully, otherwise the cloth will be damaged; press the seams, stretching 1¼ in. above and below waist, to make them fit in the hollow and fall freely on the hips.

Now turn the bottom up to thread-marks and baste.

This can either be stitched to match the fronts or serged to the cloth. If the latter, it must be done with a fine needle and silk, and only a thread of the cloth taken up, as on no account must the stitches show on the right side. Serge the bottom of facing to the inlay neatly, and the facing to the canvas. Turn back the lapel in its proper position and fold the edge of front back from centre-line; this is to prevent the facing being tight. Remove the basting of fore-part, except the centre-line. Stitch the edges close to the edge and at least ¼ in. from first row. Now space the buttonholes and work them. [See lesson on Buttonholes in BOYS' TAILORING.] Six should be worked 2 in. apart, the first being level with T and ¼ in. longer than diameter of button.

To obtain the positions for buttons place the right front over the left, with the centre-lines directly on each other, as from H to P. Mark through the eyes with a piece of chalk, which gives the correct position. Now turn the right front-back from centre-line to get the position for the other set of buttons; mark through the eyes as before, and place a thread-mark in each chalk-mark.

The buttons on the left front must be sewn on as already described in BOYS' TAILORING—*i.e.*, with a stem. Those on the right, however, do not need a stem, as they are only for ornament. The buttons must not be sewn on until the final pressing has been given.

If pockets are required, they can now be put in, and should be of the jetted or piped kind, which are made in this manner.

The Pockets. For the position and shape of the opening, see **58**. First make a heavy chalk-line along the opening 5 in. long; take a piece of cloth not less than 2 in. wide and ½ in. longer than the opening; place this over the chalk-mark face downwards, and pat well with the hand; raise the piece of cloth, and you have the correct shape of opening. This is for the piping, and should be cut 1 in. wide below the impression; cut another piece to match, for the top; place a linen stay on wrong side of opening on the thread-marks, ¾ in. on either side; baste all round, turn the coat over, place the two pipings above and below and quite close to thread-marks [63]; baste to coat.

Now cut the front of pocket 6 in. square, cut the top same shape as opening, leaving 1 in. at each end, which must be curved, as in **63**. Place this on the lower part of pocket, curved edge to curved edge, baste together, and stitch ⅛ in. above and below opening.

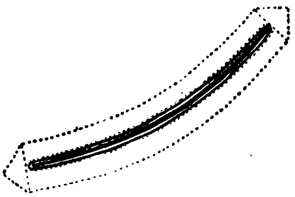
Before turning the pocket through stitch the bottom of piping to the pocket, cut the opening between the stitching to within ¼ in. of each end, and nick the corners, as in previous lessons; turn the piping through, work the corners even, press the seams and baste the piping of lower edge back. Treat the top in the same way.

Now take the back of pocket, which must be 1 in. longer than the front, stitch a cloth facing 2½ in. wide along the top, as described for boys' pockets, place on the wrong side of opening 1 in. above, facing underneath; baste in position, turn the coat over, stitch the top of pocket from end to end as close to the piping as possible. A second row of stitching can be made, if desired, to match the fronts.

Now turn back the back of pocket, and stitch the lower edge to match the top; turn the coat over, baste the front and back of pocket together, taking in the linen stay each end and round the corner. Machine all round, beginning and terminating ½ in. on each side of opening.

Turn the coat over and stitch the corners, as shown in **64**, both to strengthen and to give them a neat appearance; remove the basting, and close the opening with three or four stitches taken through the piping.

Now give it a good pressing on the wrong side, with a damp cloth over, to make the edges of opening as thin as possible.



64. POCKET OPENING

Place a piece of dry linen over the front facing, with the lapel turned back in its proper position, and press well with a warm iron.

Should there be any shine on the right side, caused by the pressing, take a piece of linen, wrung as dry as possible, and a *warm* iron, and go over the shiny parts very carefully. On no account let the iron rest on the cloth an instant, but lift it up and down all the while. Remove the linen, take a clothes-brush with an unpolished back and pat all over the parts pressed, to prevent the steam from rising, then lightly raise the nap with the brush.

The Linings. The greatest care should be exercised when basting linings inside coat, as here we have one of the chief difficulties in ladies' tight-fitting garments. As in the case of outside cloth, so it is with the linings; the curves and ease in length and width must be fairly equalised along all seams and over all portions of the body-pieces, as, if this is not attended to, the garment will be contracted, and twist in every direction, quite ruining the fit.

There must be an ½ in. pleat in the centre-back and shoulders, and two or three small ones round the front of the armholes. Each piece must be quite easy in width and length, particularly in the hollow of waist and across the bust, and should be nicked 1 in. above and below waist.

The seams of the linings should in all cases follow exactly the lines of outside seam. In basting allow each piece dealt with to lie smoothly in front of you, and, in addition to basting in position, baste them thickly along the seams previous to felling in position.

The linings can be made up separately if desired, in which case they must be basted together on the same lines as the coat itself, keeping the waist-lines together. The backs, curved side pieces and under-arm pieces should be basted and machined, then basted to the coat, waist-line to waist-line. Place front lining on the facing; baste on "easy," with the edge of coat towards the worker, keeping very full across the top of darts; baste and secure with back and fore stitch [see STITCHES, BOYS' TAILORING]; remove and baste carefully.

It is advisable to cut the threads here and there; turn the lining over, and give a thumb press, bringing the lining a little over to hide the stitches. Baste the darts to the darts of coat, and waist-line to waist-line, fulling the lining a little towards the facing. Turn in the edge of fore part, place over the under-arm seam, waist-line on waist-line; baste the bottom, and fell in place.

After inserting the linings, baste and machine the shoulders; remove the basting, open and press well, stretching towards the neck; baste the canvas to the shoulder seam, well stretching it; baste the lining over the canvas.

The Collar. Procure the proper linen canvas, cut on the bias—not quite on the cross—as directed for Boy's Coat, then place the pattern on the canvas, chalk-mark all round and along the creased row. Two pieces will be required, also two pieces of cloth on the bias, for the inside collar. Cut the pattern, allowing ¼ in. extra on the cloth all round, and mark the crease with chalk, both in canvas and cloth. The material for the inside collar—which is the part we have to turn our attention to first—may be either of the same as that of coat—thin Melton—or Italian cloth of the same colour.

Overlap the centre seam of canvas and baste with small stitches, to hold together; run a thread through the chalk-mark of crease, place the canvas on the table or sleeve-board, with the stand towards the worker.

Now press the edge of stand back with a hot iron until it lies flat on the fall, slightly stretching the outside and shrinking in the crease (the crease must not be stretched, or the collar will stand out at the back of the neck when on).

Inside Collar. Place the canvas on the cloth, with the crease-rows together; run a thread through the crease of both canvas and cloth, to hold together.

Machine the stand with several rows of the stitching; the closer the rows are together the better, the object being to give firmness to that portion of the collar.

The object of the padding [see BOYS' TAILORING] is to make the collar turn inwards, so the canvas is put on somewhat fuller than the inside collar to obtain this result.

It is absolutely necessary that the crease-rows should be kept together throughout the making of the collar, and the padding must be done as thickly as possible, starting at the crease and leaving the cloth clear ¼ in. all round. When this is done, a drawing-thread should be run through the crease-row and drawn tight—though not too tight—to prevent it stretching.

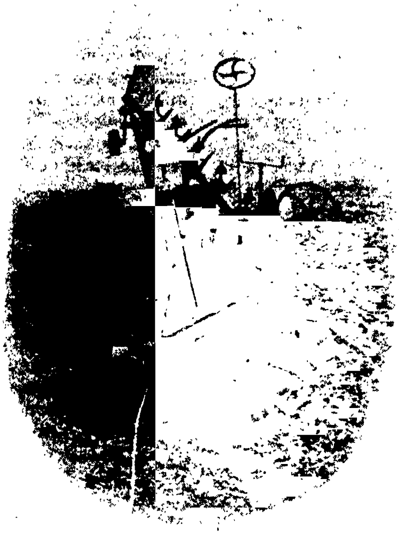
MACHINERY OF THE FARM

The Necessity for Up-to-date Implements. The Self-binder and Reaper. The Plough. The Smaller Tools

By Professor JAMES LONG

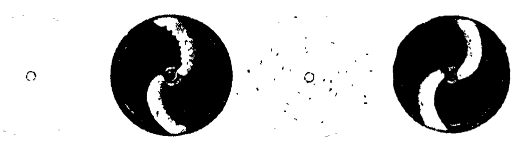
How to Purchase Tools. In the management of a farm perfect equipment is half the battle. Nevertheless, it is probable that on the majority of British farms the implements and machines employed are of old type, involving slow and inefficient work. The great feature of to-day is to save manual labour, and thus to minimise its cost. Farmers with capital are prone to pride themselves on a smart outfit, new and brightly-painted carts and waggons, costly harness, abundantly furnished in brass, with tools and tackle all of the best. Money is well spent if it is spent judiciously in buying not only the best, but no more than is required. A man with experience, however, is able to obtain many useful implements and machines as he needs them by attending farm sales, but the amateur or the non-expert, before attempting this method of purchase, should ascertain the market price of his various requirements, and, above all, which are the most substantial and useful. From time to time new implements are introduced by manufacturers, many of which are of great merit. For this reason the best agricultural shows should be attended at least once a year—the Royal, and, let us suggest, the exhibition of the county in which the farmer resides. Before making a purchase, however, it is well, where the same class of implement or tool is made by various firms, to compare them as far as possible on the show-ground in order to learn their relative price, strength, and capacity for work. Farm tackle bears a good discount, and the buyer should not forget this point, whether in dealing direct with the maker or his agent. As far as possible, implements should be manufactured of wrought iron or steel and wood—where wood is employed—of the toughest kind; and it is here that, as a rule, British goods are so much superior to those made both in America and on the Continent. Again, wherever possible, implements and machines should be selected in which the wearing parts can be most easily replaced, and here there is great difference in the productions of the various makers.



A STEAM PLOUGH

Carts and Waggons. Carts and waggons should be made of the best and toughest timbers especially where the greatest strain occurs, and provided with strong axles, substantial wheels, strong arms and raves, good bottoms and extra strong angles [p. 1629]. Care should be taken in making a selection that the wheels and tyres are of such a width as the nature of the soil demands. Good carts are sometimes—more often in the past than the present—made on the farm where a skilled wheelwright is obtainable. A cart should tip easily, and where intended for use in hay-time and harvest, it should be provided with ladders, back and front, which, like the arms, should be liable to as little strain as possible. Carts and waggons should be kept well painted, the best white-lead and oil being used, and always under cover when not in use. As a rule, it is probable that more damage is done to both by exposure to rain than by work. A liquid-manure cart is essential upon a farm of average size. There are many makes, some extremely clumsy, others light and strong, with well-arranged mechanism. The metal of the tank should be stout, choking or blocking should be impossible, while delivery should be wide and effective.

The Self-binding Reaper. The self-binding reaper is one of the greatest labour savers in modern agriculture. Few farmers have sufficient experience to differentiate between the various makes and to select the best with a degree of certainty. This machine should be little complicated and light in construction—a most important feature—but it should be strong. Bearing in mind the difficulty in the case of a buyer with little or no experience in making such a purchase, we would suggest that instead of depending upon his own judgment he should ascertain from other farmers the results of their experience with the machines they possess, and select that which has done the best work and required the least repair. It is well, too, to see two or three of the best binders at work on similar land to that occupied and on similar crops to those grown by the intending buyer. When a machine is decided upon, the buyer should learn from the seller to appreciate the value of every working part, and how to take the machine to pieces for the removal of breakages, and for replacing wearing parts. The farmer should, indeed, master the mechanism of the binder, and especially learn how far he can himself repair it, and when it becomes necessary to call in the aid of a skilled mechanic. All wearing and other parts likely to be required during harvest should be kept on hand, and especially the knife sections, fingers, rivets, nuts, screws and sheets.



Pulper
Finger-piece Cutter
Grater
Slicer

DISCS SHOWING ARRANGEMENT OF KNIVES FOR CUTTING UP ROOTS

The ordinary reaper cuts corn in a similar manner to the self-binder, revolving sails sweeping it on the ground in untied sheaves as it falls on the platform, leaving it to be tied by hand. This machine, although heavy to work, is less complicated, and is useful where tying is impossible. A combined grass mower and reaper is made by some firms, removable parts being attached for cutting corn; a second man rides with the driver, and sweeps off the corn by hand in sheaf-size lots as it is cut. In each case wearing parts should be in stock, the machine regularly examined, cleaned, oiled, painted where necessary, and always in workable condition.

Potato Raisers. There are several implements or machines in the market which are intended to raise the potato crop with expedition and completeness. The simplest is the ridging plough, to which a specially square-pointed head and breasts are attached. When at work the point of the implement passes beneath the tubers, which, with the soil, are thrown right and left, ready for picking up. A more elaborate machine is made with a broad, horizontal blade, which passes beneath and lifts the potatoes, with the soil and haulm attached, and which are separated by revolving tines at the back of the machine. Better and quicker work is performed than with the plough, which necessarily leaves some tubers in the soil, these being recovered only, but not always entirely, after harrowing. A still more elaborate and costly potato raiser, made on a similar principle, lifts the tubers clear of the soil, raises, sorts, and bags them at one operation. It is questionable, however, whether it is really economical in practice to bag potatoes which have not been allowed to remain exposed to the sun and air to dry before picking and bagging.

TYPES OF LAND ROLLER AND CLOD CRUSHER

Drills. Drills are made in great variety, but chiefly on two principles. In the cup drill the seed receptacle is carried between two wheels, a second pair of wheels in front being chiefly employed for steering. Passing through the seed receptacle is a rod upon which are discs fitted with small cups. When at work and in gear the rod revolves, the seed is picked up by the cups from beneath, and dropped into vertical cylinders, and thence into somewhat heavy metal coulters, which are drawn through the soil, in which they make narrow furrows, into which the seed is deposited as they pass along. Cups of various sizes are employed in accordance with the variety of seed used, while the quantity sown is regulated by the aid of cog-wheels, which are changeable, and which increase or decrease the revolutions of the cups as may be necessary. The cup drill does not sow exceptionally large or small seeds, such as beans or grasses, the system of regulating the quantity per acre is imperfect, and there is no possibility of measuring the area sown. The drill, too, is cumbersome and heavy in draught, and therefore slow in work, while it requires more horses and men than should be essential. On the other hand, the force-feed drill is of lighter construction, drawn by two horses instead of three, and worked by a man and a boy. A larger variety of seed can be sown with greater accuracy and speed, and the area sown can be measured.

The Mangel-drill. Small drills, drawn by one horse, are employed for mangels, and here specially-formed rollers are attached to fit the ridges beneath the surface on which the seed is deposited. Large numbers of farmers, however, employ the cup drill already referred to, but in this case the ordinary receptacle is removed and replaced by one of larger size, which takes both seed and manure, which are simultaneously drilled. Here, again, however, the machine is still more cumbersome and inadequate. The sowing of grass seeds by the aid of a separate attachment is practically impossible with the cup drill, but the practice is followed where the force feed drill is in use. The writer has long advocated the manufacture of a combined machine which, having the seed—both corn and grass—when required, harrows it in at one operation; but, so far, no such labour-saving machine has been produced which comes up to the requirements of the case.

The seed-barrow is an implement composed of a very long, V-shaped box with a lid, which is divided by partitions into compartments [p. 872]. At fixed distances there are discs with holes of various sizes, either of which are opened in practice in accordance with the quantity and variety of seed used. Passing through the length of the box is a rod upon which circular brushes are fixed. When in work these brushes revolve and push the seed through the holes opened for the purpose. The seeds sown by the seed-barrow are grasses and clovers, the implement being wheeled across the field by hand. There is, however, no system of regulation beyond that referred to, which is primitive and unworthy of advanced agriculture.

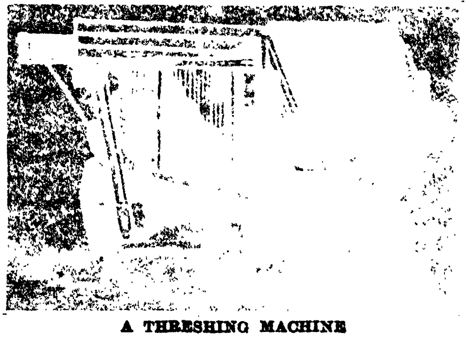
The Threshing Machine. The threshing machine is large and heavy, but cleverly constructed; it is driven by a steam-engine, to which a belt is attached. The machine is placed beside the corn rick, the sheaves or loose corn are tossed on to the platform, passed into the machine by the feeder, the grain is removed from the ears, screened, and in due course shot into a sack suitably placed to receive it. Simultaneously the straw, cavings, chaff, and rubbish—chiefly dust and weed seed—are deposited outside, while the tail, or inferior corn, passes into a second sack. *It is seldom that a threshing machine is found* upon a farm, the practice being to hire it when required, on conditions which vary more or less in accordance with the practice in the district.

The Straw Trusser. The straw trusser is now made for attachment to the thresher, so that, when required, the straw may be tied in trusses for sale as fast as it comes from the machine. It is costly, but is frequently obtainable on hire from those persons who let out threshing machines.

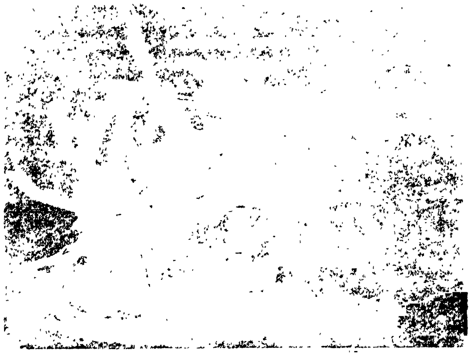
Presses. Hay and straw presses are now comparatively numerous, and are made for both steam and hand power, the smaller hand-machine enabling a capable workman to tie a large quantity of hay—for which they are chiefly used—in a day, string being employed instead of hay or straw bands, which occupy much time in making, while the pressed hay occupies much less space on the waggon and in the railway truck, and consequently costs less for conveyance to the buyer. It is important that the hay press should be strong, and that a weighing apparatus should be attached.

IRON LAND ROLLER IN SECTIONS

The Weighing Machine. The weighing machine is chiefly employed for granary work, or for checking the weight of cake manure and seed.



A THRESHING MACHINE



A POTATO RAISER

On some farms a weighbridge for weighing stock forms part of the equipment.

The Winnower. Before delivery the already threshed corn is passed through the winnower, that it may be further cleaned and dressed, and that in consequence the sample may be finer, and realise a higher price. The blast of this machine should be sufficiently effective to remove what is not rejected by the screens and riddles, especially in the case of barley. Hand samples of dressed and undressed barley, wheat, or oats, placed side by side, will show the importance of the process, two or three light grains being sufficient, in the buyer's eyes, to warrant a reduction in price.

The Mowing Machine. A necessary implement on all farms, the mowing machine is used for cutting grass, clover, lucerne, sainfoin, and mixtures [p. 1629]. The knife works on the principle adopted in the reaper, the crop being laid in even swathes. It is important that the mower should be at once light and strong, and among the many makes in the market it is now somewhat easy to obtain what is required.

The Horse-rake and Hay-drag. Made in two forms, it is desirable that the horse-rake should be as wide as possible, in order that a considerable sweep may be taken at one operation [p. 1630]. Owing, however, to the limit of the width of gateways, it is necessary that the wider rakes should be expansive and contractive at will, and thus it is that we have the telescope horse-rake. The machine should be light, suitable to one horse, and so simply constructed that the hay, when raked, may be easily released by the driver. The tines should be flexible, and all parts easily replaced when necessary. The horse-rake, which is used for both hay and corn, is now supplemented by the hay-drag, which is drawn by a team of horses, one at each end of the implement. The strength employed enables the driver to collect a very large quantity of hay, and to deliver it at the foot of the rick if necessary.

The Haymaker and Swathe-turner. The haymaker is an implement upon which are a number of revolving tines or spring teeth, which pick up the partially-made hay, lift and toss it into the air. The machine practically supersedes the old-fashioned and still common method adopted by the workmen with the hayfork [pp. 1628, 1631].

Attachment for lifting potatoes

Double breast for ridging

PLOUGHSHARES

The swathe-turner is a comparative new machine, which, the upper side of the newly-cut grass being dry as it lies in swathe, turns it over cleanly and rapidly, that the under side may be dried also. This machine is one of the most important and valuable on the grass farm.

The Hay-loader. A machine of American invention, the hay-loader is intended to pick up hay as it lies in windrows and elevate it to the waggon, thus dispensing with a couple of men [p. 1632]. Its work is rapid and useful, but the land still needs raking in the ordinary way.

The Elevator. The elevator is a large implement, worked by the aid of a horse, which conveys upon metal-tined carriers travelling on endless chains the hay or straw from the ground or the cart to the top of the rick which is being built. It is a labour-saving implement of great value, although costly in the first instance [p. 1629].

The Plough. The one implement without which arable land culture is impossible is the plough [p. 1229]. The number of

power, and as quickly as possible. The plough selected should be one in which the wearing parts of the breast, as well as the points and fins, should be replaceable. It may be that a double-furrowed plough will prove the most economical, and that three or four horses, driven by one man, will do as much work as two pairs of horses and two ploughs driven by two men, or that a riding plough will better satisfy the ploughman, and encourage him to do more or better work. It is time that the cumbersome ploughs employed in Kent and other English counties were replaced by the modern iron and steel ploughs, which do more, if not better, work, with less draught. Additions for skimming, sub-soiling, and broad-sharing should, if possible, be obtained for attachment to one and the same implement.

Harrows. Harrows are of various forms, sizes and weights [p. 1231]. Seed-harrows are light in structure, sharpened tines being fixed with nuts to iron frames. A set usually consists of three or four distinct harrows linked to a wooden bar, to which the draught-chains of the horses are attached. Heavier harrows for working down the soil and preparing a seed-bed are made both with iron and wooden frames, the latter sometimes being very clumsy. Drag-harrows are provided with bent tines, which enable them to pierce the ground to greater depth, and thus break up clods which are almost or entirely buried. Chain-harrows [p. 1379], made in various forms, consist of a number of iron links, which are usually provided with points on one side. These are intended for work on grass-land in spring, and, as occasion requires, on arable land, especially where it is necessary to collect weeds and other materials brought to the surface by sharp-pointed harrows.

ROOT PULPER

excused if he becomes confused and finds selection difficult. Having, however, decided upon the type and the maker, his wisest plan is to ask that a skilled workman may be sent to the farm with a suitable assortment, and that each may be tried on the land, for much depends upon the selection of the best and most suitable implement. Something may be learned by examining the work performed on neighbouring farms if the soil is similar, and noticing the principle adopted. Again, when several ploughs are being tested, it is well to invite neighbouring farmers of experience to witness and criticise the work, and to compare it with their own. The object of ploughing is chiefly to prepare a seed-bed. To this end the soil may be ploughed sufficiently deep and laid up so that it will pulverise as perfectly as possible. It is also important that the work should be done with as little draught or waste of

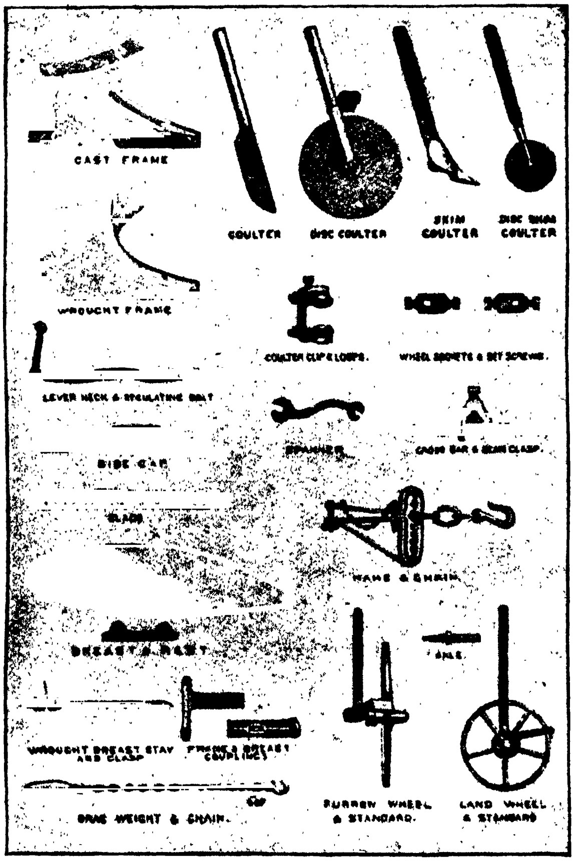
implements drawn upon wheels, and provided with curved tines intended for entering the soil, reducing the size of the clods, preparing tilth, and removing weeds, cultivators, grubbers, and scufflers, are made in various forms and sizes. In some cases modern cultivators are combined tools—broadshares for paring the surface, hoes, and duck-foot shaped points being provided for

HORNSBY'S DIGGING PLOUGH

replacing the tines as occasion requires. The tines, like the other wearing parts named, are raised from the ground by the aid of a lever when the implement is out of work. More recently flexible or spring-tined cultivators have been introduced.

Rollers. The roller is made in several forms, the modern implement being of iron [p. 1843]. The weight, width, and diameter of the roller depends upon the work it is intended to perform. It is made to resemble a whole cylinder, or a cylinder in sections, or it may consist entirely of rings, each of which fits loosely on an axle. The clod crusher, another form of roller, consists of rings, which are serrated. The roller is used on grass-land intended for hay, on arable land after sowing, and on land in process of cultivation at various stages, when it becomes necessary to reduce the coarse soil into fine tilth.

The Grinding, or Grist-mill. Used on most farms where steam is employed, the object of the grinding, or grist-mill, is to provide the meal intended for feeding stock in general and for crushing, bruising, or kibbling oats, maize, barley or wheat. In most instances the wearing parts of grist-mills, which are easily replaced when worn, are made of steel, but where the workman in charge is able to dress his own the stone mill is found the most satisfactory.



THE PARTS OF A PLOUGH

The Pulper, or Slicer. The pulper, or slicer, is intended for cutting up mangels and swedes into pulp, slices, or finger-pieces in the preparation of a stock ration. The knives [p. 1842] should be reversible or easily replaced, and the machine should be one which cannot clog. The knife discs are usually vertical, but a machine now exists in which they are horizontal.

The Chaff-cutter and Cake-breaker. The chaff-cutter cuts hay and straw into short lengths, either by hand, horse, or steam power. The material is placed in a wooden trough, drawn forward by the action of specially made rollers and under the revolving knives, which, fixed on a fly-wheel, pass rapidly over the face of the pressed fodder. It is now essential, to comply with the law, that a chaff-cutter should be so constructed that it is practically impossible for the workman feeding it to meet with harm. The cake-breaker is a machine intended to crush into small pieces the hard linseed, cotton-seed, and other cakes which are used for stock. As each cake is passed into the machine it is seized by the spiked rollers provided for the purpose of breaking it down. In the best machines there are two pairs of rollers.

On every farm there are many minor implements and tools which are essential, one or more being in demand on almost every working day. These include hand and drag rakes necessary in the hay and corn field; a hay-knife for cutting hay or straw from the stack; two or three scythes, with stone rubbers; a grindstone, which should be of the best make obtainable; a weighing machine, with a guard intended to hold up a sack of corn; milking-pails and stools; cattle-chains; stable equipment, including corn-bin, sieves, brushes, curry and mane combs; lanterns, forks, shovels, brooms, spades, hoes, and rakes for fine work; beetle and wedges for splitting timber; an axe; a cart-jack; various spanners; tools suitable for hedging, cleaning ditches, draining, the mending of gates and fences, and painting of waggons, carts, and the various implements of the farm.

THE POOR LAW SERVICE

The Administration of the Poor Laws. Outdoor and Indoor Relief. The Service as a Career

By ERNEST A. CARR

Administering the Poor Law. With a single exception, our survey of the municipal service is now complete. Hitherto we have been concerned mainly with the councils of the various counties, boroughs, and districts, each of which bodies, as we saw, is elected for a variety of purposes connected with local government. The boards of guardians, whose work we are now to consider, have no direct relation with these authorities, and are entrusted with no such general powers. They are elective bodies of a quite special class, charged with only a single function, but that a very important one—namely, the administration of Poor Law relief to the destitute poor.

The guardians of the poor, indeed, are the unpaid official almoners of the nation's charitable doles to those of its population whom adverse conditions prevent from supporting themselves. Under the strict direction of the Local Government Board, the funds raised for this purpose by means of the Poor Rate are administered by the guardians through the agency of a large staff of officers of various grades.

Indoor and Out Relief. The help thus rendered to the poor is of two classes. Outdoor relief, in the form of weekly grants of money, food, firing, and free medical aid, is sometimes granted in cases of temporary want, and is also given under certain conditions to enable the widowed, aged, and infirm to keep the grim wolf Hunger from their doors. For the rest of the sad army of poverty there is the system of indoor relief, comprising various institutions in which the destitute are housed and cared for. In addition to the workhouses, they include cottage homes and schools for the children, infirmaries for the sick, asylums for the insane, and casual wards as purely temporary shelters. This main distinction between indoor and outdoor relief runs through all Poor Law matters ; and, as we shall see, it affords a convenient means of classifying the various members of the staff employed by the guardians.

The Problem of Relief. The developments of the past year or two have awakened unusual interest in the problems of pauperism, and every thoughtful reader must have reflected on the grave responsibilities with which the guardians of the poor are entrusted, and the heavy cost of the pauper to the State. The growth of the Poor Rate, the classification of workhouse inmates, Poor Law labour colonies, the treatment of tramps, the wisdom or unwisdom of [illegible] of this great importance of the Poor Law service if we consider for a moment the latest official returns of pauperism.

These show 273,386 indoor and 575,613 outdoor cases receiving relief in England and Wales, which gives a total of 848,999 persons (including almost exactly a quarter of a million children) maintained at the public expense. During the last recorded half-year, their cost amounted to £7,096,847, made up as follows: Indoor maintenance, £1,769,607 ; outdoor relief, £1,576,865 ; support of insane paupers, £1,178,572 ; salaries of officials, etc., £1,203,920 ; and other charges, £1,367,883.

The Service as a Career. The item for officers' salaries reminds us that it is time to turn from more general considerations to discuss the aspect of the Poor Law service in which we are specially interested—namely, the prospects it affords as a career.

Excepting always the medical section, it must be admitted that the attractions of this branch of municipal work, for men of real ability and ambition, are somewhat scanty. The service, as a whole, suffers from lack of organisation and system. There are no educational tests prescribed for candidates on entrance, and no suitable qualifications by means of which an energetic subordinate officer may demonstrate his fitness for advancement. The complaint is general throughout the service that many efficient officers remain for weary years, not only without promotion, but without even the smallest advance of salary to reward ability or encourage endeavour. Further, while posts of distinctly inferior grade are properly remunerated, there are few appointments of intermediate worth, and still fewer really valuable prizes. These defects combine with the popular outcry against the burden of the Poor Rate to keep stipends small ; and the general level of salaries for clerical and executive work under the guardians is certainly lower than that prevailing under the local councils.

An Expert's Views. In connection with this matter, it should be mentioned that a powerful voluntary organisation exists in the service, under the title of the National Poor Law Officers' Association, for the dual purpose of increasing the efficiency of officials and of improving their status. A former President, Dr. James Milward, of Cardiff, has expressed himself so justly and wisely on the prospects of the service that his remarks merit quotation among the branches of the public service in not providing a career for its members. In our Civil Service generally the prospect of promotion is active in stimulating the official to do his duty—and a little more. Unfortunately, here there is no such motive. No matter how able, zealous, or efficient an officer may be, he never passes from one grade to a higher. There are no prizes in his profession."

Uninviting Prospects. That the state of things thus sketched calls for an effective remodelling of the Poor Law system is hardly to be denied. The aims of the Association in the direction of reform are thus summarised by the authority already quoted: "We have still before us the two great problems of the training and promotion of officers, with all that those problems involve. First comes the question of the examination of the candidates for the various branches of the service. Instead of adult applicants for posts relying on their own persuasive powers or the influence of friends, they should qualify themselves, as in other branches of the public service, by examination when young; and entering the service at the bottom, should learn their business in subordinate offices, and rise according to their abilities, with salaries graduated according to their posts and the length of their service." And in connection with this project, Mr. Watson Rogers, the present President of the Association, writes to endorse Dr. Milward's views, adding: "I may say that one of the planks in our platform to-day is the formation of an Examination Board for the issuing of certificates of proficiency for existing officers who desire promotion, and for others who desire to enter the service."

Humanising the Poor Law. There are indications that some such reorganisation as is here depicted may be expected in the near future, though it is as yet too early to attempt a precise forecast. The powerful Royal Commission on the Poor Law, which is now sitting, may effect some improvement. Its terms of reference include the following: "To consider and report whether any, and if so, what modifications of the Poor Laws, or *changes in their administration*, are advisable." The expression italicised is wide enough to include proposals for a complete reconstitution of the official staff and the advancement of its capable members.

Prospective candidates must not overlook the fact that the work of an officer of the guardians is almost always performed under conditions which to a sensitive nature are depressing or painful. He is brought into daily contact with the direst poverty and all its attendant miseries of dirt, disease, and vice. To a humane public servant, however, this very circumstance gives his work among the obscure poor its greatest dignity and worth. It offers countless occasions for helping the helpless and befriending those who sorely need a friend. In the case of applicants for relief or maintenance, the relieving officer is charged with the duty of fully investigating their circumstances and character before their request is submitted; and, in deciding the nature and extent of the aid to be offered, the board is necessarily guided in the main by that official's report. Similarly, the fortunes of the appeals of workhouse inmates for special leave in search of work, indulgences in the matter of diet, and other privileges, are largely determined by the views of the guardians' clerk and the master or matron of the house. These instances will show what responsibility and power the Poor Law officer possesses, and what scope his work affords for patience, conscientiousness, and humanity. In this connection it is noteworthy that a leading municipal authority, whose opinion the present writer sought as to the most useful branch of Local Government work, replied as follows: "For a career of sheer usefulness and service, as distinguished from high monetary reward, I regard the administration of the Poor Law as foremost, and would specially mention the valuable work of the nurses in our infirmaries and hospitals for the pauper classes."

How We Have Improved. How vastly official methods of treating pauperism have progressed since the days when the "sturdy beggar" was whipped, branded, and enslaved, readers will scarcely need to be reminded. The records of Exeter Workhouse show that two centuries ago the task of "performing cures on wounds and sores" on the hapless inmates was entrusted to the tender mercies of—the beadle! The strides made during even the last fifty years or so toward a humaner method can best be realised, perhaps, by comparing a modern workhouse with that described in "Oliver Twist." Yet much still remains for individual effort to accomplish in the humanising of the Poor Law.

A single instance, selected almost haphazard from among many such, will serve to illustrate the possibilities of kindly service awaiting the humane official. The introduction into Hull Workhouse of the "Brabazon" system of skilled work, which has added a new pleasure and interest in life to many of the unhappy inmates, was due in the first instance to the consideration of the master and matron. To be able to soften in ways like this the operation of a Poor Law system which in itself is apt to be hard and grim, is a prospect which might have tempted St. Francis of Assissi to become a guardians' officer.

Service Pensions. Under the Superannuation Act of 1896, servants of the guardians, in return for a deduction which in the case of new appointments is two per cent. of their pay, are entitled to resign on two-thirds salary after forty years' service, or on a smaller proportion if invalided earlier. Female nurses and attendants may join the scheme or not, as they please; but with all other officers the system is compulsory.

In our next paper we shall consider more in detail the various grades of Poor Law posts, classifying them, according to the main line of cleavage running through the service, into indoor and outdoor—or resident and non-resident appointments.

PROCESSES IN CEMENT MANUFACTURE

Details of the Dry and Wet Processes. The Machinery and Plant Used. Cement Compositions, Analysis and Tests

By CLAYTON BEADLE and HENRY P. STEVENS

Dry Process. In describing this process we think it best to take the case of a typical instalment just as if we were going over cement works using the process, and describing the plant [20, 21 and 22] we should find there.

In the typical process we have chosen the plant illustrated treats limestone of average hardness, and clay shale. The output is 60,000 tons of Portland cement per annum, so that assuming that the kilns work 300 days per annum, we get an average output of 50 tons for each kiln per day.

The raw materials are brought to the works in tip waggons on rails (1), and are weighed outside to control the proportion of the ingredients. The raw materials are tipped into the three crushers (2) and (2b), the first of which is used for shale, and the two others for limestone. These crushers are arranged between the four dryers (4), and connected with them by means of the elevators (3), so that each of the crushers can be connected with either of the two drying drums which lie one on each side of it. This precaution is taken in case one of the dryers should be put out of action for repairs.

The materials are kept separate as they pass through the dryers, and are thence distributed into the three elevators (5), each of which again can be connected with either of the two dryers. The dried raw materials are thus elevated and thrown into hoppers (6), whence they are loaded into tip waggons running on the two lines of rails across to the raw mill house, and shown in section [22.] Workmen push the waggons along the line, and at the same time look after the proper distribution of the raw materials.

Preliminary Coarse Crushing. The raw mill consists of three kominors or modified ball mills, each of which holds 2½ tons of steel balls. These kominors are marked 8, and the hoppers into which the raw but dried materials are fed are marked 7, on the drawing.

Two of these placed together are for limestone, and the third grinds shale. Each material is ground separately.

After being roughly ground in the kominors the raw materials are brought by the conveyors (9) and the elevators (10 and 11) to the mixing bins or silos (2 and 12b), the first of these taking the shale only, and the two others the limestone. At the bottom of these, extracting worms (13) are arranged, which draw out a considerably larger quantity than that required to keep pace with the supply to the kiln. This excess of material is returned to the elevators (10 and 11) and mixed with the fresh stuff coming from the mills, thus helping to keep the supply of uniform composition.

Weighing and Mixing. The elevators convey the coarsely-ground rock to the automatic weighing machines. There are two separate machines, each of which is regulated so as to weigh the exact proportion of the raw material, one for the shale, and the other for the limestone. They are coupled together, so that they may automatically discharge when both are filled with the right weight of material. The surplus brought up by the elevators (10 and 11) and not required by the weighing machines is returned to the bins, and in this way a large quantity is constantly circulating through them, so that as the material is drawn off for use it represents a very fair average of the whole.

The weighed and mixed raw materials from the automatic weighing machines are discharged into the worm (16) and thence distributed to the two tube mills (18) through their feed hoppers (17). These are full-sized machines, each taking about ten tons of flint pebbles. Here the mixture of raw materials is not only finely ground but very intimately mixed.

Mixing Machinery. After leaving the tube mills the finished fine raw meal is taken by the elevator (19) and the conveyer (20) to the three mixing bins (22). A distributing worm, not shown in the drawing, runs above them. The three bins are provided with six extracting worms (23) which discharge into the collecting worm (24) on the ground level. This, again, discharges into the raw meal elevator (25), from which the raw material is distributed by means of a distributing worm (26) to the feeds (27) of the four rotary kilns.

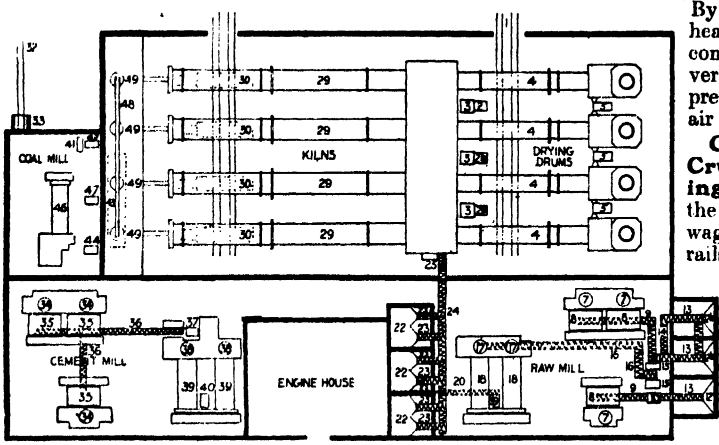
The extracting worms, collecting worms, and elevators, however, are constantly circulating a considerable quantity of raw meal over and above that required for the immediate use of the kilns, and this surplus is returned to the bins through another distributing worm (28). This, again, is a necessary precaution, in order to ensure thorough mixing of the raw meal, and to obviate any variations which may occur from time to time in the composition of the raw materials.

The Kilns. The four rotary kilns (29) are 30 metres, or about 100 ft. long, and 2·1 metres, or about 7 ft. in diameter. The hot clinker, which falls out of the kiln at its lower end, passes through the double clinker cooler (30), consisting of two cylinders, one inside the other. The clinker, moving along, meets a strong current of air drawn through the cooler. This air gets heated gradually to a high temperature as it is drawn along through the brick-built room in which the drying drum for coal (43) is situated. It returns to the kiln through the fan (52).

The cool clinker falls into tip waggons (31), and is taken to the cement mill, which will be described later on.

The rotary kiln is fired by means of coal dust; this replaces coal or coke as the source of heat for burning the raw materials to clinker.

Coal Drying Plant. Special drying and grinding plant is provided for reducing the coal to dust. It is found that, as in the case of raw meal, the coal must be thoroughly dried before it can be effectively powdered.



20. PLAN OF A DRY-PROCESS CEMENT MILL

The coal dryer, which has already been mentioned, is built in a brick-built chamber, so that both ends jut out through the walls. The coal is fed in at one end of this dryer and leaves at the other, and at the same time a small amount of air is drawn from the hot air chamber through the dryer by means of a special little fan. The coal, as it enters the works, is fed in through an aperture in the floor (11), covered with a coarse grating to prevent big lumps from getting into the elevator inadvertently.

Coal Grinding. By this elevator (42) it is taken up to the place where it is fed into the drying drum. The dried coal falls into the elevator (44), by which it is fed into a small kominor (45). Here it undergoes a preliminary, or coarse grinding, after which it is discharged into the "feed" of the tube mill (46), where the fine grinding is effected. By the "feed" of the tube mill we understand the opening where the material is introduced or "fed" in.

The coal dust is carried up by means of the elevator (47) and distributed through the worm (48) to the four coal dust hoppers (49), one for each of the four rotary kilns. Each of these coal dust hoppers is provided with a small extracting worm, the speed of which can be easily regulated by the burner or workman who controls the kiln. This worm discharges the coal dust into a nozzle (50) through which a strong current of air is driven from small blast fans (51). This is a contrivance for sucking or forcing a current of air through a machine. We may see the principle employed in ventilating restaurants and public buildings, and we have also met with it in the process of drying bricks [see BRICKMAKING].

The blast pipe enters into the large pipe for hot air driven in from the fan (52) and discharges the coal dust in a strong blast of hot air, which actually surrounds it and forces it right into the centre of the lower end of the kiln. The two pipes are seen clearly in illustration [page 1732]. By this means the waste heat is fully utilised, and the combustion of the fuel is very complete, owing to the presence of the surplus hot air surrounding it.

Clinker Cooling, Crushing, and Grinding. The clinker falls from the coolers direct into tip waggons on the systems of rails (31) and is taken away to a clinker store arranged in the yard. Later on, it can be taken on tip waggons running on the line of rails (32), or direct from the system of rails (31) to the line of rails (32).

In both cases, tip waggons are lifted by the waggon "hoist" (33), a sort of lift, to the continuation of the line (32) on a floor above the cement mill. Here the clinker is distributed to three kominors, marked 35 in the drawing, through the feeds and feed hoppers (34). After undergoing a preliminary grinding, the coarse cement is collected by conveyors (36) and by the elevators (37), and fed into the feed hoppers (38) of the two tube mills marked on the drawing 39, in which the finishing and fine grinding takes place. An elevator (40) delivers the cement on to a "belt conveyer," not shown in the drawing, which carries the cement across to the warehouse. A belt conveyer is simply a long band or belt passing over pulleys, which keep it constantly moving. The belt is horizontal, or nearly so, between the two pulleys, and the material falling on it is carried along and tipped off at the further end. It is a contrivance used for conveying material from one part of the works to another, and can be used for a great variety of materials; we shall meet with it in grain stores, flour mills, etc.

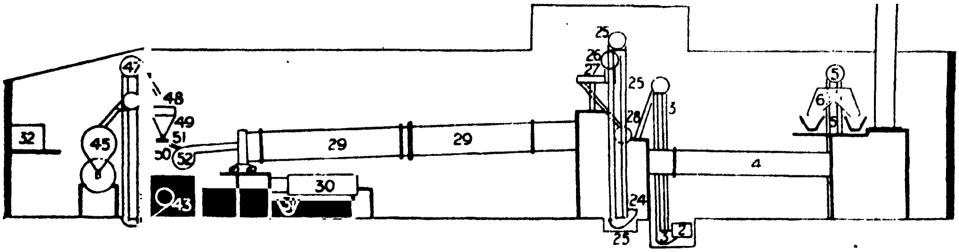
Motor Power. For driving the machinery, two triple expansion engines of 600 h.p. each are provided. One of these drives the raw mill, and the other the cement mill; but, besides this, it is arranged that either of the two engines can drive the kiln plant, with the accessory crushing and drying plant for the raw materials, and drying and grinding plant for the coal. Then, if one engine breaks down, the other is available. This precaution is necessary, as it is of the greatest importance that the rotary kiln plant should never be stopped, for a stoppage will mean cooling down of the kiln and serious interruption, and also damage to the firebrick lining.

Wet Process Plant. We shall take a typical installation to describe the process, just as we did in the dry process plant.

In **23** and **24** we show a large modern wet process plant. The raw materials are ordinary white chalk, containing about 25 per cent. of water in the state in which it is quarried, and gault clay, which also contains 25 per cent. of water on an average.

The raw materials are brought in on rails (1), passing the weighing machines (2), where each waggon-load is brought up to a standard weight by taking off or adding to it from a small store of raw material always at hand in the weighing-house. The weights are made up so as to correspond exactly to the proportion in which the two materials have to be mixed. They are tipped into the three wash mills (3). These are large-sized wash mills, about 25 ft. in diameter. The washing is done with the least possible quantity of water, and the slurry contains only about 33 per cent. of water to 67 per cent. of raw material. The slurry from the wash mills is pumped by three double-acting plunger pumps (4) through a system of pipes distributing the slurry evenly to the two "wet tube mills" (5). Each of these takes a charge of 10 tons of flint pebbles. The quantity of slurry which passes through these tube mills is very considerable, amounting to more than 400 tons a day.

Travels of the "Slurry." The tube mills discharge the slurry into six large triple mixing basins (6), each of which is capable of holding about 200 tons of slurry, and fitted with three systems of agitators; they consist of vertical shafts, with "channel iron" arms revolving slowly, so as to keep the whole contents of the basins in constant movement.



21. ELEVATION OF A DRY-PROCESS CEMENT MILL, SHOWING ONE KILN AND DRYING DRUM

The purpose of the basins is partly to mix large quantities of slurry, so as to do away with any variations in the composition of the slurry as it comes from the wash mills, and partly to provide a means of checking its composition. As a basin fills gradually, the chemist will watch it, and, if necessary, see that more clay or chalk is added to the wash mill from which the basin is being filled. When this is accomplished the contents of the basin are kept in movement until required. In this way the basins act as reserves of slurry, so that there is no need to stop the rotary kiln plant should any breakage occur in the wash mills.

Each of the basins is provided with a slurry pump (7). All of them pump the slurry through a system of pipes ending in a standpipe (8), from whence the six kilns are fed with slurry through valves (9) and shoots (10).

To ensure that the pressure under which the slurry flows into the kilns may remain constant, and the flow consequently regular, the standpipe (8) enters into a small tank (10), with an overflow (11) which leads back into a system of pipes, through which the overflow can be returned to any one of the six basins.

The Kilns. The six rotary kilns (12) are of the usual construction, the upper end being enclosed in a brick chamber, allowing the draught to sweep back outside the shell of the kiln before it goes away to the chimney to increase the drying capacity of this end of the kiln.

These kilns are 30 metres, or about 100 ft. long by 2·1 metres, or about 7 ft. in diameter.

From the lower end of the rotary kiln the hot clinker falls into the clinker cooler (13), shown by dotted lines under the kiln. This is of the usual type, with two cylinders, one inside the other. The cooled clinker falls into tip waggons on a system of rails (14), and is taken away to the cement store and mill.

Coal Dust Plant. The coal drying and grinding plant are of the usual construction, such as we have already described. The coal drying drums (15) are shown by dotted lines. There are three of these drums, all of them surrounded by brick-built chambers underneath the floor on which the burners work the kilns. The coal is fed in through three "jaw crushers" (16), one for each of the drying drums, and thence lifted by the three elevators (17) into the feeds of the drying drums.

The dried coal is lifted by the two elevators (18) into the two kominors (19), the coal from the outside drying drum being conveyed to the elevator by the worm (20).

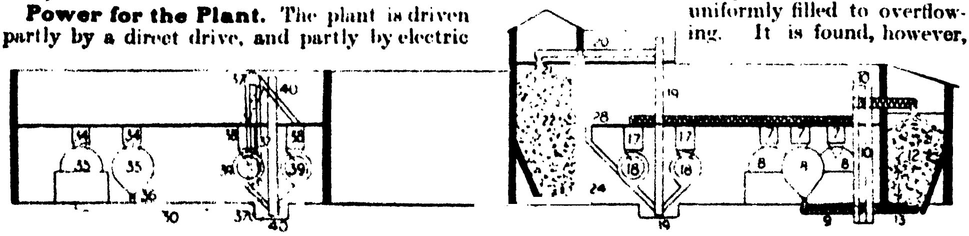
The Kominors. The two kominors for coal are a size to take 1 ton 4 cwt. of steel balls, are provided with screens of about 20 meshes to the lineal inch, and discharge the coal direct into the two underlying tube mills (21), where the fine grinding takes place. These mills take a charge of 10 tons of flint pebbles. The finished coal dust is elevated direct from the tube mill outlets by means of the elevators (22) into the two distributing worms (23) over the six coal dust bins (24).

The small blast fan (25) provides the blast for the injectors into which the coal dust is fed by the variable speed extracting worm in the bottom of the coal dust hoppers. The large fan (26) draws the air through the clinker cooler, the chamber in which the coal dryer is arranged, and blows the hot air into the kiln through the pipe (27) surrounding the coal blast pipe, as described previously.

Precautions for Continuous Working. It may be stated here that it is of the greatest importance to be able to run the rotary kilns practically without stoppage. For this reason, all the auxiliary machinery is made amply large enough. Two wash mills of the size given would, under usual circumstances, be sufficient for the quantity of slurry required, and the third is introduced purely as a reserve. One tube mill would be almost sufficient for the quantity of slurry to be ground, but another one has been introduced, so as to be on the safe side, and, as a rule, both work so as to ensure the greatest possible fineness of the slurry.

For the same reason the coal mill plant is made larger than appears necessary; one tube mill should, under ordinary circumstances, be sufficient to produce the necessary quantity of coal dust, and the other one is practically a stand-by. For the same reason all elevators and distributing worms over the coal dust hoppers have been doubled, so that if anything happens to one, there will be another always ready to start at once.

Power for the Plant. The plant is driven partly by a direct drive, and partly by electric motor. Two steam engines are used, of the same size and construction, each of them provided with a dynamo to supply current to drive the rotary kilns and coal mill plant and pumps by electric motors. Each of them is connected with the main driving shaft which drives the wash mill plant.



22. ELEVATION OF DRY-PROCESS CEMENT MILL, SHOWING KOMINORS, TUBE MILLS, AND SILOS

Either of the machines can be connected to the main driving shaft. The pumps can be driven either by electric motors or direct from the main driving shaft. In this way every possible provision is made for working the rotary kilns uninterruptedly at all times.

If any larger repairs are necessary, they will, as a rule, be made by stopping the works once a year for a few days, and putting everything into thorough order.

The arrangement of the milling plant for grinding the clinker is of much the same nature as described before in the dry process plant.

Composition of Portland Cement. We have already emphasised the importance of seeing that the ingredients, whether chalk, limestone, or clay, are in exactly the right proportions. We must take every precaution to avoid leaving any free lime in the finished cement. Lime particles would not readily slake, and the cement would be unsound; on the other hand, the amount of lime present should approximate as nearly as possible to the maximum amount allowed, and this limit is approached so closely in modern cement-making that it requires only a very little variation in the proportions of the raw materials to raise the percentage of lime to a dangerous excess. Where lime is burnt in the old-fashioned kilns it becomes mixed with a considerable amount of ash from the coal. This ash is essentially of a silicous nature, and as it combines with some of the lime to form calcium silicate, we can in such cases allow rather more lime than the theoretical amount required by the clay. On the other hand, in the rotary kilns a comparatively small quantity of ash is mixed with the ingredients, much of the fine dust being carried off in the air blast, so that in this case the proportion of lime is kept down to the ordinary limit.

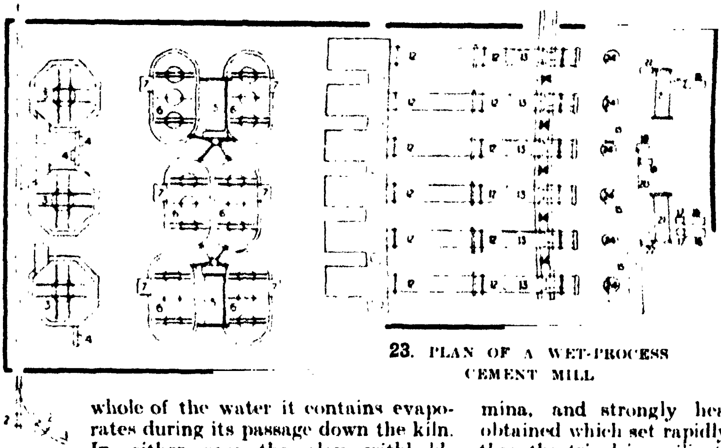
Control Tests. We have explained how quantities of chalk, clay, or limestone are measured off on automatic machines, but it is more usual in the Thames and Medway districts to use all chalk by measure and clay by weight. Chalk is delivered in trucks always of the same size and uniformly filled to overflowing. It is found, however, that the clay is best weighed in the trucks in which it is delivered, and by keeping count of the number of trucks emptied into the mill the proportions can be easily regulated.

The mixed materials should always be tested by a chemist before taking to the kilns. As the mixture is stored in large reservoirs holding as much as 1,200 tons of slurry, any slight variations in the material tend to equalise themselves.

In testing slurry the amount of carbonate of lime is estimated, and it is usually found that the slurry as it leaves the reservoir does not vary to the extent of ½ per cent. The amount of calcium carbonate is tested chemically by means of some form of calcimeter. The principle of this apparatus depends on the evolution of carbon dioxide gas when calcium carbonate is treated with an acid. A certain quantity of the slurry is put into a closed vessel and treated with a small quantity of mineral acid sufficient to decompose all the chalk or limestone contained in it. The carbon dioxide gas given off is collected and measured.

Chemistry of Cement Making. We have already explained that, under the action of the great heat developed in the kiln, certain substances known as silicates and aluminates of calcium are produced. We will trace briefly the formation of these substances.

When the materials are fed into the kiln, any water still held is driven off. Of course, if we use wet slurry direct in a rotary kiln, the whole of the water it contains evaporates during its passage down the kiln. In either case the clay withholds some water very tenaciously, and a temperature of 600° C. is necessary to drive this off completely. As the mass sinks into a hotter zone in the kiln, or passes further down the rotary kiln, the carbonate of calcium, whether of chalk or limestone, gradually loses its carbon dioxide and is converted into caustic lime before it reaches a temperature of 900° C. After this, the lime begins to react with the clay, and certain fusible substances, traces of alkaline silicates and aluminates of calcium are produced. The melting of these substances helps to bring the remainder of the lime into contact with the silica. This results in the formation of calcium silicate, which is the essential hardening constituent of the cement, but is not itself fusible in the kiln. The temperature is not uniformly high enough to fuse the whole mass and render the reaction between the constituents complete, but should any free lime be there, there will certainly be the correct proportion of clay to react with it. There is no danger of free lime rendering the cement unsound, provided that it is not present in excess, and that the clinker has been thoroughly burnt.



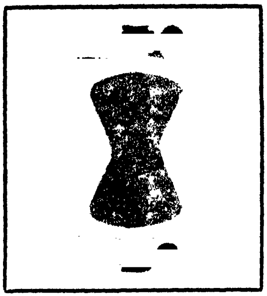
23. PLAN OF A WET-PROCESS CEMENT MILL

Chemical Research. A great deal of research work has been done on cements with a view to finding out in what way the elements which form the constituents are combined with one another, and what chemical substances are present in the finished cement. Most of the work done in this direction we owe either to Le Chatelier or to two American chemists, S. B. and W. B. Newberry. The latter investigators succeeded in preparing definite aluminates and silicates of lime by fusing together alumina and lime and silica and lime in certain proportions. They nvestigated the properties of the resultant compounds, and came to the conclusion that lime could be combined with silica in the proportion of three molecules to one, giving a product of constant volume and good hardening properties, although the hardening was a very slow process. If, however, they increased the proportion of lime to three and a half molecules as against one molecule of silica, the resultant product was unsound, that is to say, it cracked on setting in water. They thus isolated the tricalcium silicate ($3CaO . SiO_2$) and showed that it is capable of accounting for the hardening of Portland cement.

Lime and Alumina. As for the combination of lime and alumina, they found that when mixed in a proportion of two molecules of lime to one of alumina, and strongly heated, a product was obtained which set rapidly—much more quickly than the tricalcium silicate. This substance we shall term dicalcium aluminate ($2CaO . Al_2O_3$). As the volume remains constant when gauged with water and allowed to set, its *presence in* Portland cement would account for the rapid setting, and also partially for the subsequent hardening. On increasing the amount of lime to two and a half molecules to one of alumina, the product obtained was not sound. Hence they concluded that to obtain a satisfactory cement the quantities of the ingredients must be so chosen that for every molecule of silica there are three molecules of lime, and for every molecule of alumina two molecules of lime, or, put otherwise, the percentage of lime should equal the percentage of silica multiplied by 2·8 + the percentage of alumina, multiplied by 1·1. This formula agrees pretty well with the results of analyses of numerous Portland cements manufactured in the ordinary way. The exact proportions used in practice depend on the method of manufacture, the purity of the clay, chalk or limestone deposits, and the care exercised in burning, and it is found that good cement will contain anything between 58 and 67 per cent. of lime. All cements contain a small quantity of oxide of iron, and it is a moot point whether this may or may not be regarded as replacing some of the alumina. Some authorities reckon the alumina after deducting the oxide of iron; others neglect the latter in their calculations.

Analysis of English Portland Cement. We give below an analysis of English Portland cement, made from chalk and clay:

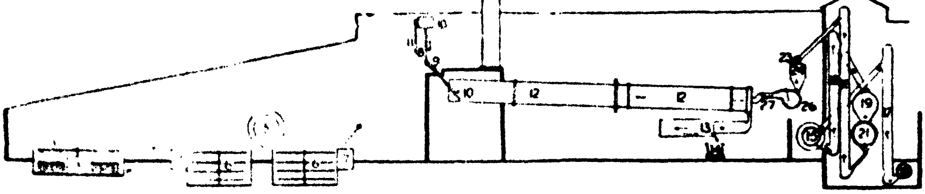
Silica (SiO_2)	22·04
Alumina (Al_2O_3) ..	7·35
Oxide of Iron (Fe_2O_3) ..	4·14
Lime (CaO)	61·94
Magnesia (MgO)	0·91
Soda and Potash (Na_2O. K_2O)	0·59
Sulphuric anhydride (SO_3)	1·38
Moisture and carbon dioxide (H_2O. CO_2) ..	1·65



25. MOULD FOR MAKING CEMENT BRIQUETTES

Portland cements all the world over do not differ much in composition. Besides the three chief constituents, lime, silica, and alumina, there is always some oxide of iron, usually between 2 and 5 per cent., a trace of magnesia, usually not exceeding 2 per cent., and traces of other substances. The sulphuric anhydride should not exceed 2 per cent. As sulphate of calcium is sometimes added to prolong the time taken by the cement to set, and as its amount is usually limited by agreement to 2 per cent., the raw materials should be as free as possible from sulphates.

Testing Cements by Chemical Analysis. Cements are very frequently analysed in the laboratory, to see if their composition is within the limits found compatible with a good cement. Thus, if the lime be found to exceed 67 per cent., we should probably reject the consignment as over-limed, or we should be very suspicious as to its durability. The engineers' specifications often fix a limit to the proportion of lime; thus, for instance, we might specify that the cement in question should contain at least 60 per cent. or not more than 62 per cent. of lime, but in order that our results may not mislead us, we must be careful to see that the sample is dry and has not been unduly exposed to air. The percentage of the ingredients changes a little if cement be spread out so as to expose a large surface to the atmosphere; this is owing to the absorption of small quantities of carbon dioxide, and moisture which reduces the apparent quantity of lime present.



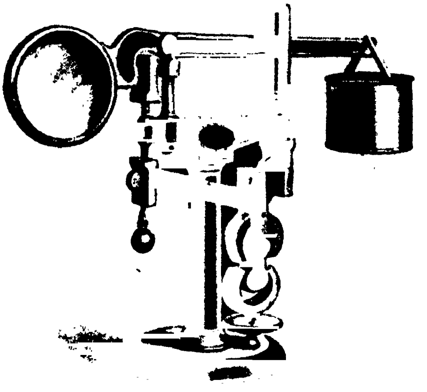
24. ELEVATION OF A WET-PROCESS CEMENT MILL

As the clinker manufactured by the rotary process is more free from ash, the percentage of lime is found somewhat higher than in clinker prepared in the stationary kilns. Moreover, the reaction in the rotary kiln is more uniform, and there are no unburnt or partially burnt lumps of clinker. It is, therefore, possible to work nearer the limit—that is to say, with a higher percentage of lime than in the older process—with the result that a rather better class of material is produced.

In the Laboratory. When the sample of cement comes to hand it is carefully preserved in an airtight bottle or tin, so that it cannot absorb anything from the atmosphere. If a chemical analysis is to be made, there are several modifications of the ordinary analytical methods which can be used to advantage. For most purposes it is sufficient to decompose a weighed quantity of the cement with hydrochloric acid, care being taken to see that the cement is first very finely ground. If necessary, a small quantity should be re-ground in an agate mortar before starting the analysis. After decomposing with hydrochloric acid, assisted by a few drops of nitric acid, the contents of the basin in which the operation is carried out are evaporated to dryness and "baked," to render the silica insoluble. On adding hydrochloric acid, the silica separates out, and is filtered off and weighed in the usual manner [see ANALYTICAL CHEMISTRY]. There remains in solution as chlorides the iron, aluminium, and calcium. Excess of ammonium chloride and ammonia precipitates the iron and alumina together as hydroxides. For many purposes it is not necessary to separate them, and it is sufficient to filter off the precipitate, ignite, and weigh it.

Detailed Analysis. If the amount of iron and alumina be required separately, it is better to determine the iron by itself in a fresh sample by some other method, and deduct its weight from the weight of the iron and alumina taken together, which will give the quantity of alumina. We have now determined the proportion of all the chief constituents, with the exception of the lime, which we now have in solution. To estimate its amount, it is better to precipitate it in ammoniacal solution by adding an excess of ammonium oxalate, which deposits the lime as calcium oxalate. This is collected on a filter paper, and washed thoroughly with hot water.

It may be estimated by a number of methods, for which we refer the reader to Analytical Chemistry. It is often necessary to estimate the amount of sulphuric acid to see if an excess of calcium sulphate or gypsum has been added to the cement. For this purpose we may take a filtered solution in hydrochloric acid of a fresh sample of cement, and determine the sulphuric acid by precipitating as barium sulphate in the usual manner.



26. BAILEY'S CEMENT TESTER, SHOWING BRIQUETTE IN POSITION

Results of Chemical Analysis. The percentage of lime is not always a guide to the soundness of the cement, as a thoroughly burnt cement will stand a greater percentage of lime than an imperfectly burnt one where the temperature has not been sufficiently high to bring about complete combination of the lime and silica. It is not possible to determine the amount of uncombined lime by ordinary chemical analysis, so that its presence is only indirectly inferred by the behaviour of the cement under another test—*viz.*, that for soundness—which we shall describe later.

If the raw materials are not thoroughly ground and intimately mixed there may be incomplete chemical combination, and consequently free lime in the cement, although the percentage shown by analysis is not higher than in an average good sample.

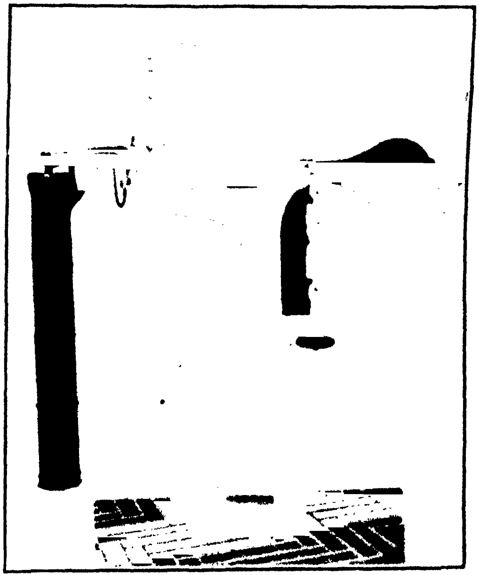
The amount of alumina in cement may be anything between 5 and 10 per cent. As a rule the greater the proportion of alumina the quicker the "set," and the setting may be so rapid as to render it useless for many purposes. Calcium aluminate has not the peculiar hardening qualities of the silicate, so it stands to reason that with too much alumina the strength of the cement will be reduced.

All cements contain more or less iron, which is shown in the analysis as ferric oxide, although it exists in the cement in the ferrous state. The amount does not usually exceed 5 per cent., and is not regarded as harmful if kept within this limit.

Causes of Colour. The cement owes its grey colour to the iron it contains. If the cement were free from iron it would be white, so that, as in the case of bricks, the colouring is brought about by the iron present, and will vary in intensity with the amount.

As to magnesia, opinions seem to differ a good deal as to what percentage should be allowed. Many of the natural rock cements contain very large proportions of magnesia, while, on the other hand, many people object to a Portland cement containing 2 or 3 per cent., or, at most, 5 per cent. It is generally considered that the presence of magnesia tends to cause the cement to crack. The amount of alkalies should be small. They probably do not play such an important part in the manufacture of cement as was at one time generally supposed. Some cements made from alkali waste naturally contain large quantities, but a good sample of Portland cement should not contain more than 2 or 3 per cent. Usually it will be less than 1 per cent. We have already explained that gypsum is added in small quantities to get a slower setting cement, and that, in consequence, the amount of sulphuric acid is limited to 2 per cent. There seems to be no doubt that anything over 5 per cent. of calcium sulphate is injurious.

Cements usually contain traces of carbonates. Of course, if there is any quantity present, it will point to an imperfectly burned cement; but cements prepared in this country are frequently exposed to air for a fortnight or so, in order that any trace of free lime may be rendered harmless by taking up carbonic acid with the formation of calcium carbonate. The amount of carbonic acid absorbed in this manner will seldom exceed 1 per cent.



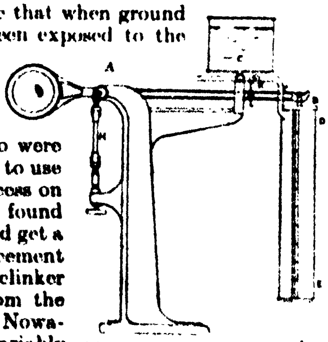
27. BAILEY AND REID'S CEMENT BUILT WITH ONE LEVER

"Setting" of Cement. We must emphasise again the distinctions between the setting and the subsequent induration or hardening of cement. The test is usually carried out by mixing a small quantity of the cement with only just sufficient water to make it a uniform paste.

The pat is mixed or "gauged" as quickly as possible, and thrown on to a glass plate, so that it forms a mass 2 or 3 in. wide and, say, ¼ in. thick. It is then tested with a weighted needle applied to the surface every now and again, until it no longer makes an impression. The needle weighs 2½ lb., and is provided with a square point, measuring $\frac{1}{10}$ inch each way. Although sufficient water must be taken to produce a plastic mass, an excess of water must be avoided, as the time taken to set will in that case be much altered.

Atmospheric Influence. The temperature and humidity of the surrounding atmosphere influences considerably the rate of "set." These conditions should be kept as constant as possible. A good temperature to take is that of 60° F., or 15° C., which is the ordinary temperature of the laboratory. The atmosphere should be moist, so that the water does not evaporate from the pat while it is setting. This is a point of much importance in slow-setting cements, which may take an hour or more to set, and the pats should be covered over to prevent evaporation.

With the increasing degree of fineness to which cements are nowadays ground, manufacturers have had some difficulty in producing a quality that would not set too fast. It has been known for a long time that when ground cement has been exposed to the atmosphere in thin layers it takes longer to set. The Americans, who were among the first to use the rotary process on a large scale, found that they could get a slower setting cement by wetting the clinker as it came from the clinker cooler. Nowadays, this is invariably effected by passing steam into the tube mill used for grinding the clinker. It is found that by carefully regulating the quantity of steam admitted the rate of "set" can be very efficiently controlled.



28. BAILEY AND REID'S CEMENT TESTER

How Fine is Cement Ground? Not very many years ago manufacturers were content to produce cement sufficiently finely ground not to leave more than 15 per cent. residue on a 50-mesh sieve. Nowadays a residue not exceeding 15 per cent. on a 180-mesh sieve is the usual standard. When we speak of a 50-mesh sieve, we mean one in which you may count 50 wires to the lineal inch, and as there will be another 50 wires crossing these to make one square inch of the wire gauze, there will be 50 × 50, or 2,500 holes altogether in the square inch.

The same considerations apply to 75, 100, and 180-mesh sieves, which are those usually used for testing cement.

The Mesh of the Sieve. Now, the size of the hole in a sieve of any particular mesh will depend upon the thickness of the wire. The thicker the wire, naturally the smaller the holes, so that it is important to use a standard wire in making these sieves. It is so arranged that whatever be the mesh of the sieve, the diameter of the wire shall be just equal to half the space between the wires. Thus, taking, say, a 100-mesh sieve with 10,000 holes, the space in one lineal inch will occupy two-thirds of an inch, and the 100 wires, if placed together, will occupy one-third of an inch, so that the diameter of the wire in a 100-mesh sieve will be $\frac{1}{300}$ inch.

Bamber gives the following figures for the fineness of cement in ordinary practice:

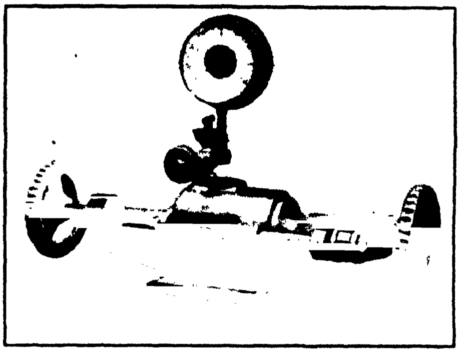
Mesh.	Residue left in sieve.
50 (2,500 per sq. in.)	Trace per cent residue.
76 (5,776 ,, ,,)	1 to 2 ,, ,, ,,
100 (10,000 ,, ,,)	3 to 5 ,, ,, ,,
180 (32,400 ,, ,,)	15 to 20 ,, ,, ,,

When testing cement in this manner it is usual to take 100 grammes of the cement and to weigh what remains on the sieve, and not that which passes through, as some of the latter, being ground to the finest dust, would be lost.

To make sure that you have got as much as possible of the powder through the sieve, you should tap it while holding it over a clean sheet of paper. Any more powder passing through will then be easily detected. The advantages of a finely-ground cement are self-evident. As it is invariably mixed with sand, the particles of the latter are more completely surrounded by particles of cement when the latter is fine ground. The strength of the resulting concrete or mortar is, in this manner, considerably augmented.

Specific Gravity of Cement. This test is useful in detecting some adulterants. It is found that the specific gravity varies little from the figure 3·125, and should it differ from this, you may suspect the addition of some inert material. As examples of such adulterants, we may mention a rock known as "Kentish rag," which is not unlike cement itself in appearance, but has a much lower specific gravity. It used to be regularly added to cement—in fact, some people asserted that cement was thereby improved. This view is now generally discredited. Ground blast furnace slag is another adulterant which closely resembles Portland cement, both in colour and chemical composition.

Density and Quality. Imperfectly or under-burned cement will be lighter and have a lower specific gravity than properly burned material. The test is usually performed in a specially designed bottle, with a graduated neck, and depends upon the principle that equal weights of bodies of different specific gravity occupy different volumes. This principle is no other than that handed down to us in the story of Archimedes and his bath. The bottle, which holds 50 to 60 cc., is filled with dry turpentine to a given point marked on the neck. A weighed quantity of cement is then added. The volume of turpentine displaced by the cement will be apparent by the extra volume occupied by the turpentine in the graduated bottle. Two precautions must be observed in making this test; first, care must be taken to see that no air bubbles hang to the particles of cement, but that they are thoroughly "wetted" by the turpentine; secondly, turpentine expands a good deal with rise of temperature, so that the temperature must not be allowed to vary during the experiment. It is best to immerse the bottle and the turpentine in a large vessel of water, at, say, 60° F., until the turpentine attains exactly the same temperature as the surrounding water.



29. BAILEY'S CEMENT-CRUSHING TESTER

After adding the cement to the bottle, it is again immersed in the same water long enough to enable the temperature to become constant before the next reading is taken.

Testing the Strength of Cement. As cement is usually employed in admixture with sand in the form of mortar or concrete, it is usual to test the strength not only of the neat cement, but of cement mixed with three parts of sand. We may either determine the power required to crush a block by compressing it, or break it by pulling it in two. Although the former method corresponds better to the conditions to which cement is exposed in practice, it is a more difficult operation to carry out than the latter method—testing tensile strength—so that most of the testing machines and the cement specifications are based on, and apply to, the tensile strength. For this purpose, a weighed quantity of cement is gauged with as small a quantity of water as possible, and filled into a mould shaped in outline somewhat like a dumb-bell [25]. The mould is first slightly greased to prevent the cement from sticking as it sets. A number of moulds are similarly filled up with cement, for which it is better to gauge each lot of material separately. The moulds are made of definite size and dimensions, so as to give uniform results.

When set, the "briquettes" are taken out of the moulds and tested under different conditions. A special sand from Leighton Buzzard is used for making mixtures with cement, or else crushed quartz, and of such a degree of fineness that the whole will pass through a 20-mesh sieve and be retained by a 30-mesh sieve.

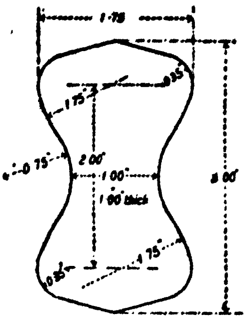
The Testing Machines. When the briquettes have set they are immersed in water for 24 hours before testing. Others are kept 7 days and longer. It is usual to have several briquettes and test them regularly at different intervals. Although the narrowest part of the briquette is frequently only 1 in. across, the power required to break such a briquette is considerable. The instrument used is made up of either a single lever or a combination of levers. The block is held between clips [26], and, by means of a *double lever great force is applied*. The two levers are situated one over the other. It is essential that the power be applied regularly, and this is done by running either water or small shot at a regular rate into a pan hanging at the end of the second lever. The instrument shown in **26** works with shot. By an automatic arrangement, not shown in **26**, the supply of shot is cut off directly the briquette breaks. The can full of shot is then taken to a balance and weighed. By multiplying this weight by the ratios for the leverage we obtain the power required to break the briquette under examination. Thus, the leverages may be 5 to 1 and 10 to 1, so that the total leverage will be 50 to 1; hence the weight of the can with water or shot must be multiplied by 50 to give the tensile strength of the briquette. A good average sample of cement will give figures somewhat as follows:

TENSILE STRENGTH NEAT				
1 day	7 days	14 days	28 days	6 months
Av. 204 lb.	462 lb.	485 lb.	553 lb.	754 lb.

ONE PART CEMENT TO THREE PARTS SAND			
7 days	14 days	28 days	6 months
Av. 116 lb.	125 lb.	163 lb.	268 lb.

Figs. **27** and **28** show Bailey & Reid's machine for testing the tensile strength of cement. It is built with one lever AB [28] instead of two, and the strain is applied by running water from the small cistern C into the long graduated can DE. In this manner the strain is increased gradually and in a *very regular manner* without any vibration. When the briquette shown at H breaks, and the end B of the lever begins to sink, the supply of water to the can is cut off automatically at K by the attachment or trigger L. To read the instrument it is simply necessary to note the height of water in the can DE, for which purpose it is fitted with a gauge-glass and graduated.

Fig. 29 shows an apparatus for testing the resistance of cement to a crushing strain. The small block is inserted in position, as may be seen in the illustration. Hydraulic pressure is applied by a piston actuated by the hand wheel at the further end of the apparatus. The pressure is read on the gauge on the top of the instrument. The blocks of neat cement, or cement and sand, are usually made 1 in. square.



31. STANDARD BRIQUETTE FOR TESTING

Is the Cement Sound? We come now, lastly, to perhaps the most important test of all—the test for soundness.

The tensile strength may be exceedingly high, but, unless sound, the cement is worthless. It often takes some time for cement which is unsound to develop suspicious indications, and the tests for soundness are often designed with a view to producing artificially the effect of age. Some cements rapidly develop faulty qualities, and the simplest test is to immerse the pat in water for 24 hours as soon as it is thoroughly set, while leaving a similar pat exposed to the air. Both pats are carefully examined from time to time to see if there are any indications of cracking due to expansion of the mass after it has once set. If the cement will not stand this simple test it is to be condemned unhesitatingly. On the other hand, there are certain appearances which occasionally mislead, and against which one must carefully guard. Thus, should some of the water evaporate before the cement sets, which may easily happen with a slow-setting cement, the pat may show certain contraction cracks although the cement is perfectly sound, so that in examining slow-setting cements care must be taken to prevent the moisture evaporating before the cement has set by keeping the pats under a cover.

31. SKETCH OF "NEEDLE" FOR ASCERTAINING SETTING TIME OF CEMENT, AS ADOPTED BY THE ENGINEERING STANDARDS COMMITTEE

Exacting Tests. It is usual to apply more stringent tests for soundness. There are many modifications of the method applied, but in principle it consists in placing in water the pats, which have been given time to set, and gradually heating up the water. This will bring out in a pronounced manner any tendency to crack, as any free lime is far more rapidly slaked under these conditions.

When a very stringent test is required, the actual expansion in warm water may be measured by Le Chatelier's apparatus. This consists of a small cylinder of brass split down the middle so as to be elastic. Sufficient cement is gauged to fill the cylinder, which stands upright on a glass plate. It is covered with another glass plate, and left 24 hours to itself. Each side of the split cylinder is provided with a long pointer, and the cylinder containing the cement, which has now had time to set, is placed in water at a temperature of about 60° F., and left for 24 hours. The distance between the indicator points is carefully noted. The water is then gradually heated until it boils, and is kept boiling for 6 hours. After cooling, the distance between the indicator points is again measured, and if any expansion has taken place it will be immediately apparent.

Cement which is capable of standing this stringent test may be considered perfectly satisfactory, and even cements which show slight expansion under these conditions are often good enough for most purposes.

Standard Quality. The Engineering Standards Committee approved a report in December of 1904 for the basing of standard specifications for Portland cement. As the conditions laid down by the Committee are of paramount importance, both to cement makers and cement users, we give by permission some quotations from this Standard Specification bearing on the important points. All those who are interested in the matter are advised to purchase a copy of the full report, which may be obtained from the offices of the Committee, 28, Victoria Street, S.W.

"No addition of any material shall be made after burning, except when desired by the manufacturer, and if not prohibited in writing by the consumer, in which case calcium sulphate or water may be used." The amount of water or calcium sulphate allowed is 2 per cent.

Special precautions are to be taken with regard to the sample, so as to obtain a representative portion of the whole.

Provisions are made for the testing and chemical analyses of consignments of 100 tons or more. In cases of smaller consignments, "manufacturers shall, if required, give a certificate of each delivery, to the effect that such cement complies with the terms of this Standard Specification."

Grinding for Testing. The cement is to be ground so as to comply with the following degrees of fineness—namely, the residue on a sieve 76 × 76 = 5,776 meshes per square inch, shall not exceed 3 per cent., and the residue on a sieve 180 × 180 = 32,400 meshes per square inch, shall not exceed 22½ per cent.

The sieves shall be prepared from standard wire, and the size of the wire for the 5,776 mesh shall be ·0044 in., and for the 32,400 mesh, ·002 in. The wire shall be woven (not twilled).

The specific gravity of the cement shall be not less than 3·15 when sampled at the works, or 3·10 if sampled after delivery. The proportion of lime shall be no greater than is necessary to saturate the silica and alumina present, as represented by $\left(\frac{CaO}{SiO_2 + Al_2O_3} = 2\cdot75\right)$. The percentage of insoluble residue, it is stated, should not exceed 1·5 per cent., the magnesia should not exceed 3 per cent., and the sulphuric anhydride 2·5 per cent.

For testing tensile strength, the sample is to be spread out to the air for 24 hours before gauging, and the water used should be sufficient in quantity to form "a smooth, easily worked paste."

The briquette [30] is to be placed "in a damp atmosphere for 24 hours after gauging," after which it is to remain in fresh water until required for breaking.

For testing neat cement "the briquettes shall bear on the average not less than the following tensile stresses before breaking :

7 days from gauging .. 400 lb. per sq. in. of section.

28 „ „ „ 500 „ „ „

The increase from 7 to 28 days shall not be less than :

25 per cent. when the 7-day test falls between 400 lb. to 450 lb. per sq. in. of section.

20 per cent. when the 7-day test falls between 450 to 500 lb. per sq. in. of section.

15 per cent. when the 7-day test falls between 500 to 550 lb. per sq. in. of section.

10 per cent. when the 7-day test is 550 lb. per sq. in. or upwards."

Testing Sand and Cement. For testing a mixture of sand and cement the briquettes are to be prepared from a mixture of one part of cement and three parts of dry standard sand.

"The cement and sand briquettes shall bear the following tensile stresses :

7 days from gauging, 120 lb. per sq. in. of section.

28 days from gauging, 225 lb. per sq. in. of section.

The increase from 7 to 28 days shall not be less than 20 per cent."

Quick, medium, and slow setting cements are thus defined :

"*Quick.* The setting time shall not be less than 10 minutes, nor more than 30 minutes.

"*Medium.* The setting time shall not be less than half an hour nor more than two hours.

"*Slow.* The setting time shall not be less than two hours, nor more than five hours."

The needle for testing the set of the cement [31], and also the Le Chatelier method of testing for soundness [32], both already referred to, are the standard machines adopted by the British Standard Specification.

THE MODERN CASH BOOK

The Two Systems of Bookkeeping. Method Adopted where a Journal is Subdivided. The Cash Book. Monthly Bank Totals

By A. J. WINDUS

THE synopsis already given has preceded the observations and remarks which it was at first intended should accompany it. By this arrangement, an educational objection has been removed. It is unwise to encourage the facile reception of teaching of the kind that carefully forestalls every difficulty, because to do so is to discourage the much harder, but far more precious, habit of independent thought and speculation.

In the absence of premature explanations, readers have had an opportunity of forming their own judgment as to the rival systems of double-entry bookkeeping which have been described. No opinion is worth much, however, which either does not take into account all the facts known at the time, or which distorts one or more of them to bolster up a pet theory. But opinions which have been honestly arrived at as the result of mental toil and fairplay, will possess permanent interest and value for the student, even though they fade away in the light of fuller knowledge, or, at least, need revision. If now we complete our synopsis by adding to it the postponed observations and remarks to which reference has been made above, we shall be enabled to put these opinions in some measure to the test.

The Two Systems of Bookkeeping. Once again, then, we must go through the now familiar list of transactions lettered *a* to *u*, this time with the object of noting and explaining, as they arise, the chief points of difference between the two systems of bookkeeping illustrated in the synopsis. Incidentally, there will be a clearing up of one or two little mysteries concerning those transactions for which, in the modern system, the double entry has hitherto appeared to be lacking.

Transaction (*a*). Cheque £5, drawn for petty cash. Here, on the very threshold of our subject, we discover a remarkable divergence between the old system and the new. Where the former has been preserved in its integrity, all cash items are journalised prior to being posted one by one, first to the cash account, and then to the personal accounts in the ledger. For sheer waste of time in the fatuous assumption that there is no better plan, this method is hard to beat, and has, moreover, done much to render the old-fashioned bookkeeping laborious to a degree that almost surpasses belief. There is a forcible illustration of this in transaction (*d*). Mr. Allday purchased for cash goods value £1 5s. 9d. Dealing for the moment with the cash alone, we first debit cash account because the money comes in, and credit Allday the giver. Next, we credit cash account because the money goes out, and debit the bankers, because they receive it. After this, we proceed to post up the accounts of cash, bank, and Allday (or cash sales) respectively.

Cash a/c v. Cash Book. Still considering the cash amount of £1 5s. 9d., we notice that this is repeated four times in the journal and four times in the ledger, or eight times in all; while under the modern system one amount in the cash book [see diagram, page 1751], and another in the ledger, suffice for all purposes.

Small wonder, then, that in many quarters where the desire to abolish or curtail needless labour co-exists with a reluctance to surrender the old-style journal a compromise has been effected, whereby the distinctive features of the journal have been retained unaltered, except that cash and discount items are rigidly excluded therefrom, being entered directly into the cash book, from whence they are posted to the ledger.

But this reform, while it relieved the overburdened journal of a mass of detail which could be dealt with to better advantage in the cash book, wrought a curious change in the character of the cash account itself.

Considerations of space forbid any sort of chronological treatment of our subject, and, therefore, we shall not enter upon an inquiry as to the time when the custom of writing up the cash account from the journal into a special book, instead of, as formerly, into the ledger, became prevalent. But this much is certain. As long as the cash account derived its component items from the journal in the same way as any other ledger account, so long was it entitled to be regarded as a part of the ledger, even though it was contained in another book. But as soon as the cash book assumed functions hitherto exercised by the journal, in other words, as soon as it became a book of original entry, it ceased to be a part of the ledger, and was in reality a journal. Now, the true conception of a journal is that of a book in which each day's transactions are entered in due form for posting to the ledger, and the words "in due form" signify that the entries must be so arranged as to ensure that the money totals of the debits and credits journalised and posted shall equal one another. We observe that this is the case in the example before us where the debits and credits of the journal each total £469 15s. 2d., and that the debits and credits in the ledger epitome which formed part of the synopsis also severally aggregate £469 15s. 2d.

Classified Transactions. But where the journal is sub-divided, separate books being devoted to special classes of transactions, it is unnecessary to set out every entry in debit and credit form. It is sufficient if one term of each equation is recorded, care being taken to see that the terms are either all debit or else all credit. The equalisation of the debits and the credits is performed at stated—usually monthly—intervals, and resolves itself into a question of correctly casting the debits (or credits) previously entered and posted to their several accounts. The double entry is completed by posting the total ascertained as above to some account in the ledger on the opposite side to that to which the details have been carried.

We could not have a better illustration of this principle than is afforded by the day book shown on page 978. The total sales for September, 1905, are there stated as £791 16s. 2d. As a matter of fact the amount includes sundry charges for foreign parcel-post, but for present purposes this element may be neglected. The figures between transverse lines in the margin of the day book refer not to the accounts in our ledger epitome, but to the folios in Messrs. Bevan & Kirk's Sold ledger, where the respective accounts of Springer, Bruce, and Aird Bros. are to be found. In like manner the three ledger accounts will each contain a reference to D.B. 355.

It needs but a glance at the day book to see that the entries are not set out as in the old style journal—that is to say, in debit and credit form; but at the same time it is quite clear that if all the September day book debits posted separately to the sold ledger amount to £791 16s. 2d., the requirements of double-entry are sufficiently complied with by posting that amount *in total* to the credit of the sales or goods account in the ledger. We may remark in passing that in actual practice it would be advisable to split the total of £791 16s. 2d. into two amounts—the one representing sales and the other the various sums charged for postage of goods to places abroad. If the total postage amounted to £3, then £3 should be posted to the credit of trade expenses account, because that account was debited with the sums paid out in the first instance from petty cash in this connection. The balance of £788 16s. 2d. should be carried to the credit of sales account.

The Debit Side of the Cash Book. Having demonstrated the principle that the total debit for a given period in a book of original entry demands an equal credit, and vice versá, let us apply that principle to the cash book. We find on page 779 a specimen folio of Messrs Bevan & Kirk's bank cash book. First let us examine the debit side.

Bearing in mind what has already been said on the subject, we shall experience little difficulty in arriving at the following conclusions: (*a*) Since all receipts of cash are lodged regularly at the bank without deduction, whatever moneys are credited to customers' and other accounts should simultaneously be debited to the bankers. (*b*) This process, if carried out, would constitute perfect double-entry, and there would be no object in keeping a separate cash account as distinguished from a petty cash account. (*c*) The entries in the bank column are in the form advocated for specialised books of original entry—that is to say, every item furnishes one term of an equation:

Bank Dr. to Customer.

(*d*) The several items being posted in detail to the *credit* of the various personal accounts, the debit is derived from the total of the bank column, £514 16s. 11d., less the balance as at September 1st, say £50. The double-entry is, therefore, completed by posting £464 16s. 11d., which represents the actual amount of cash received during September, to the debit of bank account in the ledger.

The items in the discount column (Dr. side) are similarly treated, except that there is no starting balance to take into account; thus the details composing the total of £9 3s. 0d. are posted separately to the various personal accounts, while the total itself is carried to the debit of the discount account.

The Credit Side of the Cash Book. Coming now to the credit side of the cash book, the discount items will be posted to the debit of the personal accounts affected, while the total of £13 9s. 9d. must go to the credit of discount account.

The amounts appearing in the bank column (Cr. side) represent cheques drawn by Messrs. Bevan & Kirk on their bank, and paid away to different persons who are debited, the bankers being simultaneously credited. But whereas the debits must be posted separately, it will suffice to post one credit to the bank account for cheques drawn during the month, the amount of the credit being derived from the total of the bank column, £514 16s. 11d., less £34 5s. 1d. balance carried forward—that is, the cheques drawn in September, plus the bank charge for discounting Wake's acceptance, totalled £480 11s. 10d.

Dr.	Bank a/c						Contra				Cr.
1905						1905					
Sept 1	To Balance	b/f	50			Sept 30	By Bank charges			3	
30	" Lodgments		464	16	11		" Cheques drawn		480	8	10
							" Balance	c/d	34	5	1
			£514	16	11				£514	16	11
Oct 1	To Balance	b/d	34	5	1						

Bank Accounts in the Ledger. Here is an illustration of the bank account in the ledger. The commencing balance of £50 has been brought forward from August 31st in the same way as the balance as at September 30th has been carried forward to October 1st. The debit of £464 16s. 11d., and the credits of 3s. and £480 8s. 10d., are authorised by journal entries as follows:

27

Journal

1905

Sept	30	Bank Dr	GL4	464	16	11			
		to Sundry Debtors	CB45				464	16	11
		Cash received and paid into bank during month							
		Trade Expenses Dr	CB45		3	.			
		to Bank	GL4					3	
		Charge for discounting trade acceptance							
		Sundry Creditors Dr	CB4.	480	8	10			
		to Bank	GL4				480	8	10
		Cheques drawn during month							

Some bookkeepers consider the bank account in the ledger superfluous, because it is simply an epitome of the figures contained in the bank columns of the cash book. In other words, the bank account is already in the cash book in detail, and does not need a place in the ledger. Where the bank balance is carried forward month by month in the cash book, as in the example before us, it is true that the bank account might be omitted from the ledger without much harm being done. But there is something to be said in favour of having *every* account in the ledger, and the extra time expended in securing this result will not be wasted. Sometimes the balances are not shown in the cash book, and then it is imperative to have a bank account in the ledger. In such case the bank columns in the cash book are totalled monthly and ruled off without being equated, and the totals are posted to the ledger direct. Had this plan been adopted in our example on page 779 the debit total would have amounted to £464 16s. 11d —actual receipts during September, and the credit total to £480 11s. 10d.—actual payments for the same period. After the direct posting of these items the bank account in the ledger would, of course, show the same balance as it did when the lodgments and drawings were first journalised and then posted.

Application of Principles of Double-Entry. Although the principles of double-entry are inflexible, nothing is more elastic than the method of applying them in given cases. For instance, if it be objected that a bank account in the ledger is useful, but that it takes too long to journalise the monthly totals in the manner described, the answer is that this is desirable but not essential. Reverting to the bank cash book on page 779, we can if we please split the columnar totals thus:

Dr.		Cr.	
Balance 1st Sept.	50 0 0	Bank charge -	3 0
Lodgments -	464 16 11	Drawings -	480 8 10
		Balance carried forward -	34 5 1
	£514 16 11		£514 16 11

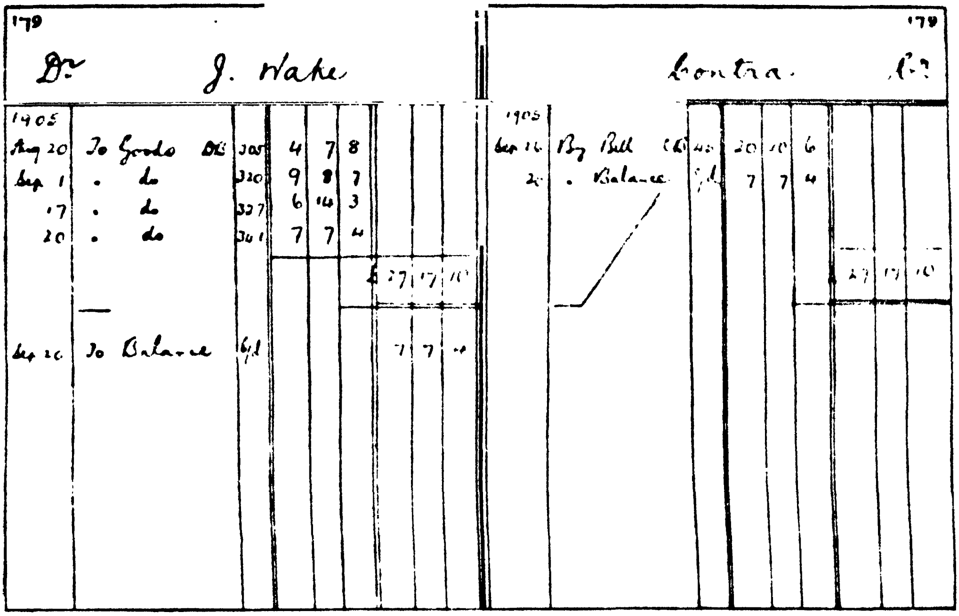
The best place for these new figures is: debits immediately beneath the discount total on the Dr. side, credits immediately beneath the discount total on the Cr. side.

We may now post the lodgments total direct to debit and the drawings total direct to credit of bank account in the ledger, marking in the cash book folio columns the ledger folio occupied by the bank account, marking also in the folio columns of bank account the cash book folio from which the posted items have been copied.

Cross References. Particular attention is directed to the cross-references here mentioned—namely, the references in cash book to the ledger folio and the references in bank account to the cash book folio. Every

ledger posting should reveal its place of origin, and every entry in a cash book or other journal should reveal its station in the ledger. Folio columns, annexed to the money columns, are provided for the purpose in the vast majority of account books, and it seems absurd that anyone should find difficulty in adopting a system of mutual reference which is as simple as it is efficacious.

We will return to our dissected figures for the bank columns in the cash book. The lodgments total having been posted to debit of bank account, the drawings total will go to credit of same account, as will also the bank charge of 3s. But with regard to the commencing balance of £50, and the ending balance of £34 5s. 1d., these amounts cannot be posted to the ledger, as they are contras to equivalent amounts appearing elsewhere in the cash book. Thus the debit of £50, with which September starts, is offset by the credit of £50, with which August ends. The two amounts explain and justify each other. The very condition of their existence is that they shall take opposite sides to one another, so that the credit of £50 cannot be created unless a debit of equal amount be created at the same time, thereby vindicating the primary law of a debit for every credit. By the same rule the ending balance of £34 5s. 1d., which at September 20th is carried forward on the credit side, is brought forward on the debit side as at October 1st as the commencing balance for October. It is evident that to post either the £50 or the £34 5s. 1d. to the ledger would be to transgress the law, since the double-entry for both these items has been already completed in the cash book itself. This point is worthy of notice, because the theory involved underlies every "balance" entry made in books of account—that is, every entry the amount of which is preceded by the words "To balance" or "By balance." Consider the account of J. Wake as set out below:



179

Dr. J. Wake

1905								
Aug 20	To Goods DB	305	4	7	8			
Sep 1	" do	320	9	8	7			
17	" do	327	6	14	3			
20	" do	341	7	7	4			
						£27	17	10
Sep 20	To Balance	b/d				7	7	4

179

Contra. Cr.

1905								
Sep 16	By Bill CB	45	20	10	6			
20	" Balance	c/d	7	7	4			
						£27	17	10

The rule is that entries cannot be made in the ledger except through the medium of the books of original entry. Thus the first four debit entries in Wake's account are posted from the day book—the first credit entry from the cash book. But in the case of "balance" entries the rule is relaxed of necessity, because a ledger balance is neither a transaction nor a transfer. At all events it is not a transfer in the sense of registering an internal change, for the state of a ledger account is the same after bringing down a balance as before. The presence in J. Wake's account (or the absence therefrom) of balance entries makes no difference to the fact that after the sum of £20 10s. 6d. had been passed to credit of his account there was a balance due from Wake of £7 7s. 4d. We may, therefore, look upon the entry "Sept. 20th. To balance brought down £7 7 4" as amounting to nothing more than a concise declaration of the state of Wake's account on a particular date. The entry tells us that the debits then exceeded the credits by a certain sum, namely, £7 7s. 4d. If we accept this figure as the starting-point of a new account, we virtually promise to close the old account by making a balance entry on the credit side, the amount of which shall equal the new debit. The credit entry: "Sept. 20th. By balance carried down £7 7 4" is in fact our warrant for the contra entry, and the two entries together constitute a double-entry, thus conforming to the established principle of a debit for every credit.

Treatment of Monthly Bank Totals. The journal entries exhibited earlier remain to be dealt with. These are intended to show how the monthly bank totals should be treated where the system prevails of passing all monthly totals from the books of original entry through the Journal on their way to the ledger. With regard to the posting of these entries the effect on the bank account has been explained. "G. L. 4" means that the bank account is on folio 4 of the General ledger. There should be a reference also in the folio columns of the bank account to Journal 27.

In the Journal folio column level with the credit of £464 16s. 11d., there will be found, in place of the usual reference to a ledger folio, a reference to CB. 45. On referring back to CB. 45 we discover the reason for this—namely, that the various items of which the journal credit is composed have been posted to the credit of their respective accounts *from the cash book*. In like manner, the journal debit of 3s., and the several items *aggregating* the journal debit of £480 8s. 10d. have been posted to the debit of their respective accounts from the cash book. There is therefore no need to post them again from the journal.

How to Test the Balance. Before deserting the bank account, let us see how the accuracy of the balance may be tested by comparison with that shown in the bank pass book. The pass book discloses the state of Messrs. Bevan & Kirk's banking account as it appears from the records of the bank, and not necessarily as shown by the firm's cash book. Naturally enough, the pass-book balance and the cash-book balance seldom coincide. On the one hand, cheques received by the firm are entered in the cash book under date of *receipt*, but they are acknowledged in the pass book under date of *clearing*, which, in the case of long distance cheques—say a cheque drawn on Dublin and remitted to London—would be several days later than the date of receipt by Bevan & Kirk. On the other hand, cheques drawn by Bevan & Kirk are entered in the cash book under date of *issue*, but in the pass book they appear under date of *payment by the bank*.

Delay in presenting cheques for payment frequently occurs, and must be taken into account in trying to agree the pass book with the cash book. A simple illustration of a pass book agreement will now be given. Mr. Kirk obtained the firm's pass book from the bank on October 5th, and found there was a balance of £42 6s. 11d. at credit of the firm on October 1st. Having succeeded in reconciling this balance with that shown in his cash book, he made a red ink memorandum on the cash book thus:

1905.				
Oct. 1.	Balance as per P.B.	42	6	11
	Add cheque not cleared (Jones)	29	8	2
		71	15	1
	Less cheque not presented	37	10	0
	Balance as per C.B.	34	5	1

It is probable that as Mr. Kirk has postponed the checking of the pass-book until October 5th, he will be able to satisfy himself from it that since October 1st the commission cheque from Jones has been duly cleared and the rent cheque duly presented and paid, but that does not affect the position as at October 1st with which he is at the moment concerned.

RUNNING, LEAPING, & CLIMBING ANIMALS

Hoofed Mammals. Comparison of the Bones of the Hand. Kangaroos. Moles and Monkeys. The Value of the Tail. Man's Origin

Continued from page [illegible]

By Professor J. R. AINSWORTH DAVIS

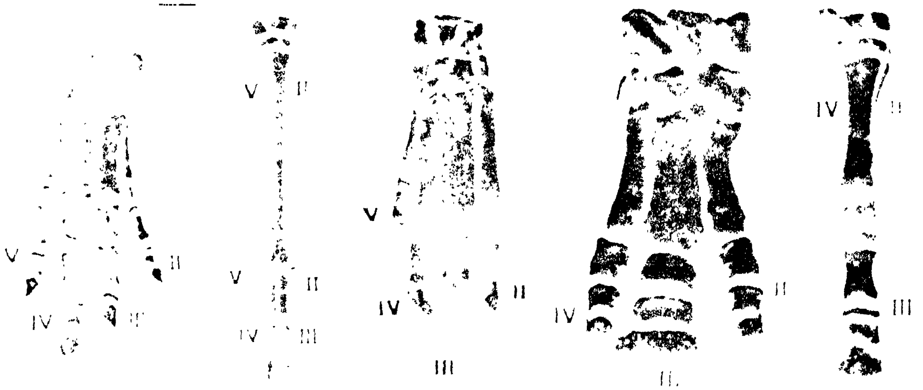
We have now to consider means of progression. The Hoofed Mammals (*Ungulata*) best illustrate structural arrangements which promote great speed, and also the way in which these arrangements have been evolved. As we have seen, the remote ancestors of this group were comparatively small animals, which lived in swamps and damp forests. Their limbs were not particularly long, they were flat-footed (plantigrade), and possessed the full number—*i.e.*, five—of fingers and toes. Such spreading extremities, presenting a large surface, were very well adapted for progression on spongy soil, but not for great speed on a firm surface.

Fleet Mammals. For such rapid progression length of limb is a primary essential, and this has been partly attained in all hoofed forms by abandonment of the old flat footed attitude for a tiptoe or *digitigrade* one. At the same time there was a gradual elongation of the different sections of the limbs, especially the hands and feet, thus converting them into jointed levers of great efficiency, as may be typically seen in deer and horses. Running, the most rapid kind of progression, differs from walking and the like in that the body actually leaves the ground altogether at regular intervals. This is chiefly the result of sudden straightening of the hind limbs, which by a strong backward push propel the body into the air, to come down again on the fore limbs.

Abolition of the Collar-bone. One result of evolution in the direction indicated has been the abolition of the collar-bones, which would be only a source of weakness in running, as the sudden descent of the body on the fore limbs means a very considerable shock. And the collar-bones are, so to speak, "struts" extending between the breast-bone and shoulder, and ill-suited to resist such sudden impacts.

Spreading extremities, with the full number of digits, suitable for swamp conditions, would "give" too much to render them efficient when employed for rapid movement in a tiptoe attitude on firm surfaces. In the course of evolution this difficulty has been got over by more or less reduction in the number of digits, with increasing size and specialisation in those remaining. To make matters clear, it is necessary to mention here that the digits are numbered 1, 2, 3, 4, and 5, No. 1 being the thumb or great toe, as the case may be. In all hoofed mammals the digits have developed broad hoofs, presenting a firm and sufficiently broad surface for application to the ground. But there have been two lines of evolution, represented by the *even-toed* and *odd-toed* forms respectively, and these require separate consideration.

The Hand of the Pig. In *even-toed* forms digits 3 and 4 have become more or less dominant, and the axis of symmetry runs between them. If we examine the hand of a pig [246] we shall find that the thumb has disappeared altogether, while digits 2 and 5 (the outer ones) are much smaller than 3 and 4, which are the chief agents of progression. But as these creatures have not altogether weaned themselves from the old swamp life, the smaller, outer digits come in handy upon soft ground, preventing their owner from sinking in too far. The palm bones (*metacarpals*) which come between the small, irregular bones of the wrist and the finger



246. Pig 247. Deer 248. Tapir 249. Rhinoceros 250.

SKELETONS SHOWING DEVELOPMENTS OF HANDS

raphed by Professor

bones [246] are moderately elongated. The peccaries of South America are faster runners than ordinary pigs, and we find that their limbs are somewhat longer and more specialised. The hippopotamus, which has to climb the muddy banks of its native rivers, is practically constructed on the pig-type. In this and the subsequent examples the fore limb is taken, but, except where specially mentioned, the hind limb is fashioned in much the same way.

The Hand of the Deer. Turning now to deer, the embodiment of swift progression, we shall find the limbs slender and much elongated, while the hand [247] presents great specialisations as compared with a pig. The outer digits (2 and 5) are reduced to insignificant vestiges, evidently on the way to complete disappearance. And the palm bones of 3 and 4 are much elongated and fused together into a "cannon bone," which gives greater firmness than if they remained separate. There is not nearly so much specialisation in the pigmy swamp deer (tragulines) native to West Africa and South-East Asia.

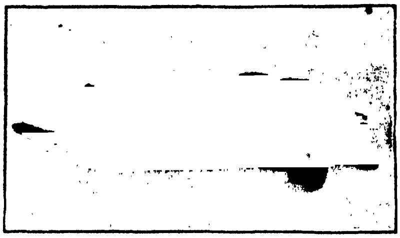
252. ORANG-UTAN

Dando

Ruminants that Climb. Among ruminants a place of security in which to chew the cud is a matter of considerable importance, and we find that the even-toed foot lends itself to this end by proving an admirable climbing organ. In illustration of this, some antelopes—*e.g.*, the Alpine chamois, wild sheep, and wild goats may be taken.

The camel presents a further point of interest in the modification of its extremities to fit them for progression on hot desert sands. Only the two central digits, 3 and 4, are present and these diverge somewhat, so as to give a firm support to a rounded elastic pad on the underside of the foot.

In *odd-toed* forms the middle digit, 3, is more or less dominant, and the axis of symmetry runs down its centre. Examination of the hand of a tapir [248], the most primitive existing type of the group, will show that the thumb has entirely disappeared, while the central digit is the largest and most important. The foot is still more modified, for it has lost the little toe, 5, as well.



251. MOLE

Medland

Spreading Toes. The hand of a rhinoceros [249] shows further reduction, for not only has it lost the thumb, but also the little finger, and the foot is on the same model. Just as the two spreading toes of a wild goat are advantageous for climbing, so are the three spreading toes of the rhinoceros of use for rapid progression on an irregular stony surface.

The Long Hand of the Horse. The horse and its allies constitute the last term in the perfecting of the odd-toed type of foot for rapid progression on a firm surface. In the hand we find the central digit, 3, practically the only one, is of very large size, and its palm bone is much elongated [250]. On either side of this we note, on dissection, however, a narrow "splint bone." The two splint bones are no other than the remains of digits 2 and 4, which have almost disappeared. The elongation of hand and foot is very noteworthy, and the so-called "knee" of a horse is really its wrist, while the "hock" corresponds to the ankle. Our one-toed horses were preceded in time by three-toed ones, and we can trace the descent of these, step by step, from the primeval swamp-dwellers to which reference has so often been made.

Leaping Mammals. Members of several orders of mammals chiefly progress by means

Dando

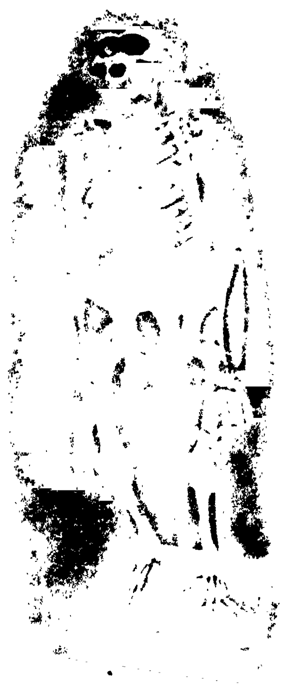
254. RED-FRONTED LEMUR

of the hind limbs only, which are of quite disproportionate length, and used for the execution of a series of long leaps. The kangaroo is the best known example, and its long thick tail is employed as a balancing organ, useful also as a support in the intervals of rest [**240**, page 1493]. Some of the African desert types have evolved on somewhat similar lines—*e.g.*, the jerboas, which belong to the order of Gnawers (*Rodentia*), and, the jumping-shrews, which are classed with the Insect-eaters (*Insectivora*).

Digging Mammals. Mammals which have taken to pursue underground prey have naturally evolved on lines which have made them efficient diggers. Of this no better example could be taken than that of our native mole [**251**], a member of the Insect-eaters (*Insectivora*). The general shape of the body is adapted to a subterranean life, and the short, strong limbs are scooping organs of great efficiency, provided with powerful digging claws. This applies more particularly to the hands, which serve as spades. There are no external ears, the eyes are very minute, and the short hairs are implanted vertically in the skin, so that there is no particular "set" to the velvety fur, which presents no obstacle to progression either forwards or backwards.

It is of particular interest in this connexion to note that the pouched mole (*Notoryctes*) of the Australian deserts, though belonging to a totally different order (*Marsupialia*), is not unlike a common mole in appearance, being adapted in much the same way to life underground.

There are also diggers among other orders of Mammalia, as rabbits and prairie "dogs" among the Gnawers (*Rodentia*), and armadillos among the Mammals Poor in Teeth (*Edentata*). In all such cases there are at least powerful digging claws.



253. SKELETON OF GORILLA

Climbing Mammals. Since a tree life offers abundant food of both vegetable and animal nature, with fewer dangers than life on the ground, it is not surprising to find that it has been adopted by a large number of mammals belonging to different orders. More or less mobility of limb is here an advantage, and this involves, among other things little, if any, reduction in the number of fingers and toes.

Among the Pouched Mammals (*Marsupialia*) we find the phalangers of Australia and the opossums of America are arboreal, their extremities being adapted for grasping, while in some of the latter there is a prehensile tail, serving as a sort of fifth hand. Of Mammals Poor in Teeth (*Edentata*) the leaf-eating sloths of South America live entirely among the trees, progressing head downwards with complete security, for their long curved claws give a firm hold. In this case, it is true, the digits have been reduced, but a few efficient claws are better than a larger number of smaller size. In the same order some of the smaller South American ant-eaters also affect an arboreal life, as do some species of their Old World relatives, the pangolins, which use the overlapping scales on the under side of the tail as climbing irons.

Caudal Climbing. Among climbing Insect-eaters (*Insectivora*) we find the squirrel-like tree-shrews of South-east Asia with their bushy balancing tails, and our common squirrel illustrates the same habit among the Gnawers (*Rodentia*). In the "flying" squirrels of West Africa there are climbing scales on the under side of the base of the tail. Aided by their sharp claws a number of the Flesh-eaters (*Carnivora*), from leopards, pumas, and cats, down to civets and some of the weasel tribe, are able to climb with facility. Some of the bears, too, can climb effectively if clumsily.

The Monkeys (*Primates*), however, constitute the most notable climbing order of mammals [**258**], both hands and feet being able to grasp branches, as, for instance, in the orang-utan [**252**]. This is mainly due to the fact that the thumb and great toe can be opposed or placed opposite to the remaining digits. Some of the American monkeys possess a prehensile tail.

Our Tree-dwelling Ancestors. There is no doubt that man himself has descended from arboreal ancestors, and in a young baby the mobility of the toes and the inturned soles of the feet are very noticeable. The power is also possessed of supporting the entire weight of the body by grasping a stick in the hands, though readers will find that there are formidable obstacles in the way of pursuing researches in these matters on very juvenile members of the human species. It has also been plausibly suggested that the fatal instinct of throwing up the arms noticeable in drowning persons may be regarded as an involuntary attempt to grasp the branches of the original tree-home of mankind.

The Lemurs (*Lemuroidea*) [**254**], sometimes grouped with the monkeys, but in reality decidedly lower in the scale, possess climbing arrangements similar to those just described

COOKERY RECIPES

Ingredients for, and Methods of Cooking, Meat Puddings, Pies, and Croquettes. Various Dishes of Fish, Poultry, and Game

MEATS—continued

Roast Fillet of Veal (Stuffed)

Ingredients. Five pounds of rolled fillet of veal, three tablespoonfuls of white crumbs, three tablespoonfuls of chopped suet, one large tablespoonful of chopped parsley, one teaspoonful of mixed powdered herbs, one egg, half a teaspoonful of grated lemon rind, pepper and salt.

Method. Wipe the joint and remove the centre portion of bone, if not already done by the butcher. Mix together the crumbs, suet, parsley, herbs, and lemon rind. Season the mixture well, and bind it stiffly with the beaten egg; if necessary, a little milk may be added. Place this stuffing in the space made by the removal of the bone. Tie a piece of greased paper over the meat, see the joint is tied securely in shape with tape or string, and roast it before the fire, or bake it in the oven for about two hours. Remove the paper for the last half-hour. Baste the joint frequently, as it is very lean; extra dripping must be used for this purpose. Serve with thick brown gravy poured round.

Veal Cake

Ingredients. One pound of lean veal, half a pound of fat bacon, three hard-boiled eggs, two teaspoonfuls of grated lemon rind, two teaspoonfuls of chopped parsley, one teaspoonful of salt, a quarter of a teaspoonful of pepper.

Method. Chop the parsley and grate the lemon rind finely, mix them together with the salt and pepper. Boil the eggs for fifteen minutes, then shell them, and leave them in cold water till they are wanted. Cut the veal and ham into neat cubes. Have ready a plain mould, which holds one pint; rinse it out with cold water. Cut the eggs into slices, and arrange some of them in any pretty device on the bottom and sides of the mould. Now fill in the mould with alternate layers of meat, seasoning, and the remains of the eggs coarsely chopped. Pour in one gill of stock, twist a piece of buttered paper over the top, and cook it in a slow oven for four hours. Then take off the paper, and fill the mould up with stock in which a quarter of an ounce of leaf gelatine has been melted. Leave it till it is cold and quite set. Then dip the entire mould in tepid water, and the cake will easily slip out on to a dish.

Mutton may be treated in the same way, but should be rather strongly seasoned, otherwise it will be tasteless.

Veal and Ham Pie

Ingredients. One and a half pounds of lean veal, half a pound of lean ham (or bacon), three hard-boiled eggs, salt and pepper, some lemon juice, one teaspoonful of chopped parsley, one teaspoonful of chopped sweet herbs, stock to half fill the pie-dish. For the flaky pastry, one pound of flour, three-quarters of a pound of butter, lard, or dripping, cold water.

Method. Divide the butter into four equal parts. Sieve together the flour and the salt. Take one-fourth of the butter and rub it into the flour in the same way as for short crust, and mix it to a paste with cold water. Then roll it out in a long, narrow strip. Spread the second quantity of butter in small lumps over the strip. Shake over a little flour, then fold it evenly in three, pressing the edges together with a rolling-pin; then roll it out again, and proceed as before. Repeat this process till the four divisions of butter have been used. Then roll out to the required thickness. To make the pie, cut the meat and bacon into neat pieces, and put a layer of the veal in a pie-dish. Shake over it some chopped parsley and herbs, lemon juice, and seasoning. Next put in a layer of ham, then a layer of veal, and so on till the dish is full. The last layer should be ham. Then half fill the dish with the stock—or water, if you have no stock. Wet the edge of the pie-dish and put round it a strip of pastry. Then cover the top of the pie-dish with pastry, of which leaves can be made to ornament it. Brush over the top with beaten egg. Put the pie in a quick oven, and bake it for about two hours.

All meat pies are made in the same way, but omit the lemon when making steak, or steak and kidney pie.

Steak and Kidney Pudding

Ingredients. One and a half pounds of buttock steak, half a pound of beef kidney, pepper and salt, one pound of flour, six ounces of suet, cold water, one teaspoonful of baking-powder.

Method. Cut the steak and kidney into thin slices. Mix together about an ounce of flour and a good dust of salt and pepper; dip each piece of meat and kidney into this. Chop the suet finely. Sieve together the flour, baking-powder, and a pinch of salt; add to them the chopped suet and, lastly, enough cold water to mix the whole into a soft paste. Roll it out on a floured board, having first put aside a piece to form the lid of the pudding. Grease a pudding basin, and line it with the pastry. Place the beef and kidney in alternate layers in the basin, then fill up with water. Wet the edges of the pastry, put on the lid, pressing the edges together. Scald and flour a pudding-cloth, tie it over the basin, taking care to have a pleat across the top, and tie the opposite corners of the cloth across to keep it in place. Put it in a pan of fast-boiling water, and let it boil steadily for two hours. Then either turn it on to a hot dish or serve it in the basin, with a folded serviette pinned round it. The latter method ensures it being really hot, an important matter in the case of a suet pudding. If preferred, the kidney may be omitted, and half a pound more beef used in its place. All boiled meat or fruit puddings are made in this way.

Croquettes

INGREDIENTS. Half a pound of any cold meat, poultry or game, one ounce of butter or good beef dripping, one ounce of flour, one gill of water or stock or gravy, two teaspoonfuls of chopped parsley, one teaspoonful of chopped shallot, nutmeg, pepper and salt, one egg, breadcrumbs.

Method. Remove all skin and bone from the meat, and chop it finely. Melt the butter or dripping in a saucepan, stir in the flour smoothly, then add the stock, or if poultry or rabbit is being used, use milk. Stir the sauce over the fire till it boils and thickens, then add it to the meat, parsley, onion, salt, pepper, and a dust of nutmeg. Mix all well together, then turn it on to a plate, and spread it evenly over. When cold, mark it into equal divisions. Form them into neat balls. Brush each over with beaten egg, then cover it with crumbs. When all are coated, have ready a pan of deep frying fat; when a faint bluish smoke rises from it put in the balls, two or three at a time, and fry them a pretty golden brown. Drain them well on kitchen paper. Arrange them on a lace paper, and garnish with fried parsley. These croquettes may be made of any kind of meat, poultry or game, or a mixture of any. If using veal, a little grated lemon-rind is an improvement. They may be reheated either by refrying them for a few seconds, or by putting them in a hot oven.

FISH

Dressed Crab

INGREDIENTS. A good-sized crab, oil and vinegar, salt and pepper, a tablespoonful of white crumbs.

Method. The crab should feel heavy for its size and have large claws. Remove all the meat from the body, carefully picking it out from the claws and the bony part in the middle. Scrape out and save all the soft meat as well. Throw away all bony and finny pieces. You will notice the flesh is of two kinds—a dark, soft kind (which is the liver), and the rest firm and white. Separate the latter into little shreds with a fork or skewer. When the shell is quite empty, wash it well, and rub it with a little warm butter to polish it. Also chip off the under portion so as to leave a neat edge. Mix the soft substance with oil, vinegar, salt and pepper, and, if liked, the breadcrumbs. Toss the shredded meat lightly in the seasoning of salt and pepper and vinegar, but keep the light and dark meat separate. Fill the shell with the two mixtures, arranging them alternately so that they appear in stripes. Pile rather high in the centre, and if there is any coral, pound it with a little butter, and decorate tastefully with it round the shell.

Fish Pudding

INGREDIENTS. One pound of any kind of uncooked fish, three ounces of beef suet, three ounces of white breadcrumbs, one teaspoonful of chopped parsley, one teaspoonful of chopped onion, two teaspoonfuls of salt, a quarter of a teaspoonful of pepper, two eggs, half a pint of milk.

Method. Remove all skin and bone from the fish, then chop the flesh finely; chop the suet also, mixing the crumbs with it while you do so to prevent it from clogging. Put the fish, suet, parsley, onion, salt, and pepper in a basin. Beat up the eggs and the milk, then stir these into the other ingredients, mixing all well together. Thickly grease a pudding-basin, put in the mixture, pressing it down well. Cover the top with a piece of greased paper, and steam the pudding for one hour. Turn it out on to a hot dish, and pour egg sauce all over it.

Tinned salmon is excellent treated in this way.

Fried Fish

INGREDIENTS. One medium-sized sole or plaice one egg, breadcrumbs, a little flour, salt, pepper, and oil.

Method. Wash, dry, and fillet the fish carefully; there will be two fillets from each side. Add to the flour a good dust of salt and pepper; dip each fillet in this, and shake off all loose particles. Beat up the egg on a plate, brush the fish over with it, then cover with breadcrumbs, pressing them firmly on with a knife. Have ready a pan of deep frying fat; when a faint bluish smoke rises from it put in one or two pieces of fish and let them fry till they are a delicate golden brown. Lift them on to a baking-tin lined with kitchen paper, and let them drain well. Arrange them on a lace paper, and garnish them with fried parsley.

Any kind of fish may be treated in this way. Whiting are usually curled round, their tails stuck through the eyeholes, egg-and-breadcrumbed, and fried whole. Cod is generally cut into steaks about an inch thick, then egg-and-crumbed.

Fresh haddock may be filleted, or merely cut in thick steaks.

If preferred, the fish may be coated in batter instead of egg and crumbs.

For the batter, mix together a quarter of a teaspoonful of salt and a quarter of a pound of flour; stir to these smoothly a quarter of a pint of tepid water, and one tablespoonful of oil or melted dripping. Beat the white of an egg very stiffly, then add it lightly to the batter, and it is ready.

Grilled Salmon Steaks

INGREDIENTS. Salmon steaks, medium oatmeal, two ounces of butter, salt and pepper. For the sauce, two teaspoonfuls of horseradish, two ounces of fresh butter, two teaspoonfuls of lemon juice, cayenne.

Method. The steaks should be quite an inch thick. Brush them all over with warmed butter. Roll them in the oatmeal. Heat and well butter a gridiron, lay on the steaks, and grill them over a clear, sharp fire for ten to fifteen minutes; use a fish slice and knife to turn them unless you have one of the double gridirons. When they are a tempting brown, slip them on to a hot dish. Dust with salt and pepper. Put a lump of butter on the top. Serve at once, handing them with Dutch sauce.

To make the sauce, put the butter in a saucepan, and add a little salt. Stir over a slow fire till about three-quarters of it is melted. Draw it to the side of the fire to finish melting. This prevents overheating, which ruins the flavour. Add a dust of cayenne, the lemon juice, and, for this special dish, the grated horseradish. Serve in a hot sauce-boat.

Cod, hake, white salmon, or haddock may all be treated in the same way, while herrings, whiting, and mackerel could be split open and grilled as directed.

Boiled Halibut

INGREDIENTS. About two pounds of halibut, milk and water, lemon and salt.

Method. Rub the halibut all over with salt, then lay it in cold water for an hour. Take it out and rub it well over with a piece of lemon. Put enough milk and water in a fish-kettle to cover the fish; add a little salt—about one level teaspoonful to each quart of water. When the water boils put in the fish. Bring it to the boil, skim well, and boil for three minutes. Then move it to a cooler place, and let it simmer till done. It should take from twenty to thirty minutes, according to the thickness of the fish. When done, the flesh should easily part from the bone. Then lift the fish out of the water, and let it drain. Rub it over with a little butter. Serve on a hot dish on a fancy paper. Garnish with slices of lemon and fresh parsley. Serve shrimp sauce or any nice fish sauce in a hot sauce tureen.

Cod, fresh haddocks, hake, turbot, and brill may be treated in the same way.

Lobster Cutlets

INGREDIENTS. One lobster (fresh or tinned), one ounce of flour, one ounce of butter, one egg, breadcrumbs.

Method. Take out all the flesh from the shell, and chop it finely. Melt the butter in a saucepan, stir in the flour smoothly; then add the water, and stir the mixture in the pan over the fire till it will leave the sides of the pan quite clean. Now add to it the chopped lobster, and if there is any lobster coral add it also, with a good dust of salt and pepper. Mix all well together, then spread the mixture on a plate to cool. Beat up the egg on a plate and make the breadcrumbs; to do this, rub some stale bread through a wire sieve. When the mixture is cool, mark it out in even sized divisions, and form each division into a pear-shaped cutlet; do this with a knife dipped in flour, and on a slightly floured board. When all the cutlets are shaped, brush them over with the beaten egg and cover them with crumbs. Have ready a deep pan of frying fat; when a faint bluish smoke rises from it put in the cutlets, one or two at a time, and fry them a pretty golden brown. Drain them well on kitchen paper; into the end of each put a piece of the feeler cut about an inch long. Arrange the cutlets in a circle on a lace paper.

The remains of cold cod, haddock, or whiting are excellent treated in this manner.

POULTRY

Spatchcock

INGREDIENTS. One fowl, salt and pepper, a little chopped onion, parsley and herbs, browned crumbs, an ounce of butter.

Method. Cut the fowl straight down through the backbone, but not through the breast. Dust it well inside and out with the onion, parsley, herbs, pepper, and salt. Skewer the fowl so that it lies quite flat, and brush it all over with some melted butter. Rub the gridiron over with a piece of butter or suet, put on the fowl, and grill it till it is half cooked; then cover it with browned crumbs, and finish cooking it. It will take about twenty minutes altogether. Take out the skewer. Serve the bird very hot, with some good sharp sauce.

Game of all kinds may be cooked in this way.

Boiled Turkey with Celery Sauce

INGREDIENTS. A medium-sized turkey, one pound of pork sausages, salt, pepper, nutmeg, flour, milk, and two heads of celery.

Method. Skin the sausages, then season the meat with salt, pepper and nutmeg. Fill the bird through the neck with this stuffing. Truss it neatly into shape. Put it in a saucepan with nearly boiling stock or water to cover it, bring it to the boil, then skim it well and let it simmer gently about two hours. Meanwhile, wash and prepare two heads of celery, and cut them into thin slices. Melt three ounces of butter in a saucepan, put in the celery, and let it cook slowly for a quarter of an hour—it must not get at all brown. Now stir in the flour, then add one and a half pints of milk. Stir over the fire till the sauce boils and thickens. Season it carefully. Let it simmer gently from ten to fifteen minutes, then rub it through a sieve. When the turkey is done, put it on a hot dish, coat it nicely over with some of the sauce, and serve the rest in a hot tureen.

Chicken and pheasant may be served in this way, but they are not usually stuffed, though sometimes the latter is stuffed with oysters.

Roast Duck

INGREDIENTS. A couple of ducks, two large onions, three ounces of breadcrumbs, six sage leaves, one egg, one ounce of chopped suet, salt and pepper, a little dripping.

Method. First prepare the stuffing. Peel the onions, cut them in quarters, and boil them till tender in salted water. Dip the sage leaves into boiling water for a few seconds, then dry them in the oven till they can be powdered between the thumb and finger. When the onions are tender, drain off the water, and chop them finely; add to them the powdered sage, the breadcrumbs, salt, pepper, and chopped suet. Beat up the egg, and bind the ingredients together with it. The stuffing is now ready.

Pluck and draw the ducks, and wipe them inside with a cloth dipped in hot water. Singe the birds thoroughly. With a spoon put the stuffing into the birds; draw the flap of skin over the opening, and keep it in place with a skewer or string. Truss the birds into shape. All but the last joint is cut off from the legs and wings; the wing joint should be firmly stretched out till it almost touches the thigh joint, which must be pushed back a little to meet it. Then either stitch or skewer the limbs in shape. Put them in a baking tin, with the dripping on the breasts, in a quick oven for ten minutes, then move them to a cooler part. They will probably take an hour. Serve them with a tureen of good gravy and one of apple sauce. It is a wise plan to stuff one duck only, as so many people object to sage-and-onion stuffing.

Goose and turkey may be stuffed in the same way, but in the case of the latter the stuffing is put in at the neck end of the bird.

Ducklings, like chickens, are never stuffed, but merely trussed, and put in the baking tin, with a little dripping, and roasted.

Chaudfroid of Chicken

INGREDIENTS. Two fowls, two large onions, one large carrot, two pieces of celery, a bunch of herbs, two quarts of stock or water. For the sauce, three ounces of butter, three ounces of flour, one and a half pints of broth, one ounce of leaf gelatine, a dessertspoonful of cream, salt and pepper.

Method. Truss the fowls for boiling, roll them up in a buttered paper, and tie it up like a parcel. Put them in a pan with the stock and vegetables. Cook slowly till the birds are tender, probably for three-quarters of an hour. Take them out and let them get cold. Melt the butter in a pan, stir in the flour, mixing it in smoothly. Cook these for a few minutes without letting the flour brown. Now stir in one and a half pints of the stock in which the fowls were cooked. Stir over the fire till it boils. Dissolve the gelatine in a little stock, and strain it into the sauce; also add the cream. Place the fowls on a dish, and when the sauce has slightly cooled pour it very smoothly over every part of them. Garnish with two lines of roughly chopped aspic jelly down the breasts of the birds, and make a border round the dish.

GAME

Roast Grouse

INGREDIENTS. A brace of grouse, two slices of bacon, an ounce of butter, two squares of toast.

Method. Pluck and singe the birds, and wipe them inside with a cloth dipped in hot water. Truss them, and tie a slice of fat bacon over the breast of each. Wrap each bird in a piece of greased paper, and put them in a baking-tin, with the butter, in a hot oven. Baste them frequently. After ten minutes take off the paper and bacon, and continue to roast the birds for another ten minutes, but care must be taken not to overcook them. They should be rather under than over done. Put two neat squares of buttered toast under the birds for the last ten minutes of cooking them. Put the toast on a hot dish, and place a bird on each. Serve them accompanied by bread sauce, gravy, and fried crumbs.

All game may be treated in this manner, but woodcock and snipe should not be "drawn."

Salmis of Game

INGREDIENTS. Two or more grouse or partridges, woodcock, or any other game, a quarter of a pound of ham, two shallots or onions, a bunch of parsley and herbs, four cloves, four peppercorns, a bay leaf, a dessertspoonful of rowan jelly, a piece of glaze the size of a pigeon's egg, salt and pepper, one ounce of flour, half a lemon.

Method. Cut the birds, which should be only half roasted, into large joints and the ham into dice. Put these in a stewpan with the shallot, herbs, bay leaf, peppercorns, and cloves, and stir them over the fire till they are a pale brown. Then shake in the flour, and brown that also; now add the stock, and stir it over the fire till it boils. Season it carefully with salt, pepper, and lemon juice and add the glaze and rowan jelly; then simmer the whole very gently for half an hour, adding, if liked, a glass of red wine. Arrange the joints on a hot dish, and strain the sauce over.

Jugged Hare

INGREDIENTS. One hare, one onion, two cloves of garlic, two ounces of good beef dripping, eight cloves, pepper and salt, one blade of mace, two ounces of flour, a bunch of herbs, a small carrot.

Method. Skin and paunch the hare carefully. Cut it up into small joints. Mix together the salt, pepper, and one ounce of flour. Dust each joint over with this mixture. Peel the onion, stick the cloves into it, and tie the herbs together. Put the onion into a brown stew-jar with the herbs, mace, and garlic. Then pour in enough stock or water to cover all. Put on a tight-fitting lid, put the jar in the oven or at the side of the stove, and let its contents simmer gently for two or more hours. Melt the butter in a small pan, stir in about two ounces of flour smoothly, add a little of the liquid from the hare gradually to this flour, then pour the mixture slowly into the stew-jar, and stir it over the fire till it cooks and thickens. Season it nicely to taste with the salt and pepper. Take out the herbs, garlic, and onion. Tie a clean serviette round the jar, and send it to the table. It is a matter of individual taste whether you use the blood of the hare or not; it of course greatly adds to the flavour. It is best to remove the head before serving. Cook the heart and liver separately in a little stock, then rub them through a sieve or chop them finely, and add them to the gravy. Red currant or rowan jelly should be served with this dish.

By Louis A. Barbé, B.A.

INDEFINITE ADJECTIVES

The indefinite adjectives are *aucun*, no ; *nul*, no ; *chaque*, each ; *même*, same, self ; *tout*, all ; *quelque*, some ; *plusieurs*, several ; *tel*, such, such a ; *maint*, many a ; *quel*, what.

(*a*) *Aucun* and *nul*, no, are negative, and therefore require *ne* before the verb of which they are either subjects or objects.

They are both singular :

Aucun chemin de fleurs ne conduit à la gloire, no path of flowers leads to glory.

Il n'a aucun emploi, he has no employment.

Nul homme n'est exempt de la mort, no man is exempted from death.

Je n'ai nulle autorité, I have no authority.

(*b*) *Chaque*, each, can only be used in the singular :

Chaque âge a ses plaisirs, each age has its pleasures.

(*c*) *Même* means "same" when it precedes a noun. It means "self" when it follows a pronoun, and is joined to it by a hyphen :

Ils ont les mêmes droits, they have the same rights.

Vous êtes contents de vous-mêmes, you are pleased with yourselves.

(*d*) *Tout*, all, has a feminine form, *toute*, and the plural forms *tous*, for the masculine, and *toutes* for the feminine. It takes the definite article, and is the only adjective that precedes it. A possessive may take the place of the article :

Tout son pouvoir, toute sa capacité, toutes ses forces, tous ses efforts, all his power, all his capacity, all his strength, all his efforts.

In the plural it has the meaning of "every" :

Tous les jours, every day.

When used in the singular, and without the article, it has the same meaning :

Tout citoyen a des devoirs aussi bien que des droits, every citizen has duties as well as rights.

Tout, *tous*, *toutes*, may not, like the English *all*, immediately precede a relative pronoun. The singular must be followed by ce, and the plural by *ceux* or *celles* : *Tout ce qui reluit n'est pas or*, all that glitters is not gold ; *tous ceux qui le connaissent le respectent*, all who know him respect him. *Tous* may not come immediately after a personal pronoun : We all know him, *nous le connaissons tous*.

(*e*) *Quelque*, and its plural, *quelques*, mean "some," but are more restricted in sense than the partitive :

Nous avons eu quelque difficulté, we have had some (a little) difficulty.

J'ai quelques bons livres, I have some (a few) good books.

(*f*) *Plusieurs*, several, has only one form for both masculine and feminine :

Plusieurs historiens, plusieurs histoires, several historians, several histories.

(*g*) *Tel*, *telle*, such, are usually preceded by *un*, or *une*, and their plurals, *tels*, *telles*, by *de* :

Un homme d'un tel orgueil est insupportable, a man of such pride is unbearable.

Il n'y a pas de tels animaux, there are no such animals.

The indefinite article never comes after *tel*, as it does after "such" in English :

Un tel homme est insupportable, such a man is unbearable.

"Such" before an adjective is *si*, used in connection with *un*, *une*, for the singular, and with *de* for the plural :

Un homme si intelligent, such an intelligent man.

Une si belle maison, such a fine house.

Des hommes si courageux, such brave men.

De si gentils enfants, such nice children.

Tel repeated before two nouns, and used without an article, means "like" :

Tel maître, tel valet, like master, like man.

(*h*) *Maint*, *mainte* is equivalent to the English "many a," but may be used in the plural :

Avec quelques vertus il a maint et maint défaut together with a few virtues he has many and many a defect.

Maintes fois, or *mainte fois*, many a time.

Quel, what, is used in both direct and indirect questions :

Quel livre lisez-vous ? What book are you reading ?

Quelle heure est-il ? What time (hour) is it ?

Je ne sais pas quelle heure il est, I do not know what time it is.

The names of countries take the definite article except after the preposition *en*, and after the preposition *de* when, with its aid, they form adjectival expressions : *la France; en France*, but *du cuir de Russie*, Russian leather. Before feminine names of countries *in* is rendered by *en* ; before names of towns it is rendered by *à* ; *je demeure à Paris*, I live in Paris ; *Paris est en France*, Paris is in France.

EXERCISE XIV.

VOCABULARY.

âge (m.), age
an (m.), year
argent (m.), silver
armée (f.), army
Ascension (f.), Ascension
Assomption (f.), Assumption

la Bastille, Bastille
la Belgique, Belgium
la capitale, capital
la chute de pluie, rainfall
le centime, centime
le centimètre, centimetre
le chemin de fer, railway

le climat, climate
le commerce, commerce

c'est-à-dire, that is to say
pour, for
ensemble, together
Lyon, Lyons
Marseille, Marseilles

TRANSLATE INTO FRENCH.

The territory of the French Republic is about 536,500 square kilometres. Its area is nearly thirteen times the area of Switzerland, and more than thirteen times the area of Belgium. Its population is 38,600,000 inhabitants. Each square kilometre has about 72 inhabitants. There are in France 60,000 Jews and 650,000 Protestants. It has 86 departments. Its climate is temperate; its mean yearly temperature is 60 degrees. Its rainfall is 80 centimetres. France forms a republic. At the head of the executive power is placed the President of the Republic. He is elected for a period of seven years. Military service is compulsory in France from the age of 20. The duration of the service is 25 years: three years in the active army, 10 years in the reserve of the active army, six years in the territorial army, and six years in the reserve of the territorial army. In time of peace the effective strength is about 560,000 men. The French navy comprises 450 ships of war. They are manned by about 100,000 sailors and marines. There are five great military ports. Paris, the capital of France, has a population of about 2 millions and a half. Lyons and Marseilles are also two of the largest towns in France. In Marseilles there are 404,000 inhabitants; in Lyons there are 420,000. Paris has more than 900,000 inhabitants more than those two towns together. By its industries and its commerce Paris is one of the first towns in the world. Marseilles is the first harbour in all the Mediterranean, and one of the 10 or 12 most important commercial places of the globe. The commerce of France is very considerable. The average value of its foreign trade is 7,500,000,000 or 7½ "milliards": 4 of importation and 3½ of exportation. The longest river in France is the Loire. The length of the Loire is 1,020 kilometres. The railway lines of France have a total length of 40,000 kilometres. The English measure distances by miles; the French by kilometres. The English mile is 1,609 metres. The French indicate value by francs and centimes. The franc is worth a little less than 10 English "pence." The centime is the 100th part of the franc. There are pieces of silver of 50 centimes and gold pieces of 10 francs. The largest silver piece is the 5-franc piece. In France the feast days are: the 1st of January, or New Year's day, Easter, the Ascension, Pentecost, the Assumption, All Saints, and Christmas Day. All Saints is always the 1st of November, and Christmas the 25th of December. Easter falls between the 21st of March and the 26th of April. The Ascension is also a movable feast. It falls 40 days after Easter. Pentecost falls 10 days later—that is to say, 50 days after Easter. The French celebrate their national feast (on) the 14th of July, in memory of the taking of the Bastille in 1789.

KEY TO EXERCISE XIII.

1. Nous avons passé une quinzaine de jours à Londres.
2. J'ai acheté une demi-livre de beurre et une demi-douzaine d'œufs.
3. Dans quatre-vingt-dix-sept il y a neuf dizaines et sept unités.
4. Il y a une centaine de pages dans le cahier.
5. Quelle heure est-il? Il est quatre heures dix; dans cinq minutes il sera quatre heures et quart, et dans vingt minutes il sera quatre heures et demie.

6. Cette rue a un demi-mille de longueur (long) et cinquante pieds de largeur (large).

7. Notre maison a plus de quarante pieds de hauteur (haut).

8. Cette table a deux mètres de long sur un mètre soixante-quinze centimètres de large.

9. Vous avez trois fautes ; je n'en ai qu'une.

10. Douvres est à environ vingt et un milles de Calais.

11. Le Pas de Calais a plus de vingt milles de large.

12. Vous avez gagné plus de cinquante francs de plus que nous.

GERMAN

Continued from page 1776

By P. G. Konody and Dr. Osten

XXVII. If the Possessive Pronoun [see XVII.] is not directly connected with its substantive by preceding it, it either takes (*a*) the definite article and follows the *weak* declension of the adjectives [see XXVI., 1], or (*b*) it remains without article and takes the inflections of the *strong* declension [see XXVI., 2].

Examples. Preceding the substantive: mein Hut (*m.*), my hat; meine Weſte, (*f.*), my waistcoat; mein Hemd (*n.*), my shirt. (*a*) The pronoun takes the article and follows the substantive: Der Hut iſt der mein-e, the hat is mine; die Weſte iſt die mein-e; das Hemd iſt das mein-e. [There is also a lengthened form with the inserted suffix ig: der mein-ig-e, die mein-ig-e, das mein-ig-e.] (*b*) Without article: dieſer Hut iſt mein-er, dieſe Weſte iſt mein-e, dieſes Hemd iſt mein-es.

1. This declension of the adjectives (*a*) the weak, and (*b*) the strong, is applied to all disjoined possessive pronouns: mein, dein, ſein, ihr, unſer, euer, ihr—*e.g.*: dieſer Hut iſt der ſein-e, der ſein-ig-e, and dieſer Hut iſt ſein-er; dieſes Buch iſt das unſ(e)r-e, das unſ(e)r-ig-e, and dieſes Buch iſt unſer-es. The *strong* inflection is sometimes dropped after the auxiliary verb ſein: dieſer Hut iſt mein-er, and dieſer Hut iſt mein(er).

2. The possessive pronoun used with the definite article takes a capital when used substantively: Ich habe das Meine (or das Meinige) getan, I have done [the] mine (my duty, all I could do). Jedem das Seine (or Seinige), to everyone [the] his (his due); etc.

XXVIII. The prefix ge (see XIV.) cannot be used for the formation of the past participle of verbs with *unstressed* first syllables, such as the verbs with the unstressed prefixes be, emp, ent, er, ge, ver, and zer. These unstressed particles which, detached from the verb, convey no meaning, cannot therefore be disjoined, and are called inseparable prefixes, to distinguish them from the separable prefixes, to which belong the prepositions and adverbs which have also an independent existence. When joined to the verb these separable prefixes are *stressed*. They can be detached from the verb and displaced in the course of conjugation.

1. Verbs with separable stressed prefixes ab, an, auf, aus, bei, hin, mit, um, etc., form their past participle by insertion of the conjugational prefix ge between the stressed prefix and the stem, and by the addition of et or t to the stem of weak verbs [see XIV.], and en or n to the stem of strong verbs, with unchanged or changed vowels [see XVIII.]—*e.g.*: the *weak* verb ſtell-en (to put, to place), joined to the separable *stressed* prefix aus (out) aus′-ſtell-en (to exhibit, expose), forms the past participle: aus′-ge-ſtell-t. The verb entſtel′len (to disfigure, to deform) with the *unstressed* prefix ent, forms the past participle: entſtellt′ without the prefix ge. The *strong* verb ſchreib-en, to write (imperfect: ſchrieb, with change of vowel; past participle: ge-ſchrieb-en [see XVIII.]), when joined to the *stressed* separable prefix ab (off, from) = ab′-ſchreib-en (to copy), forms the past participle: ab-ge-ſchrieb-en. On the other hand, beſchrei′ben, to describe, with the *unstressed* inseparable prefix be, forms the past participle: be-ſchrie′b-en. The past participle always forms *one* word: aus′geſtellt, entſtellt′, geſchrie′ben, ab′geſchrieben, beſchrie′ben.

2. In the *present*, *imperfect*, and *imperative* the stressed separable prefixes are completely detached from, and placed behind, their verbs: ab′ſchreiben, present indicative: ich ſchreib-e ab, etc.; present conjunctive: ich ſchrieb-e ab, etc.; imperfect indicative: ich ſchrieb ab, etc.; imperfect conjunctive: ich ſchrieb-e ab; imperative, singular 2: ſchreib[illegible] ab! ſchreib-en Sie ab! plural 2: ſchreib-et ab! In the present and imperfect the prefix is placed at the end of the clause or sentence; present: Ich ſchreib-e den Brief ab, I copy the letter; imperfect: ich ſchrieb den Brief ab, I copied the letter; but perfect: ich habe den Brief ab′-ge-ſchrieb-en; pluperfect: ich hatte den Brief ab′-ge-ſchrieb-en; first future: ich werde den Brief ab′ſchreiben, I shall copy the letter; second future: ich werde den Brief ab′geſchrieben haben, I shall have copied the letter.

3. In principal clauses like the above the *constant forms* (past participle and infinitive of the verbs [see XXIV.]) are placed at the end and are separated from the *finite forms* by the objects of the actions, etc. Where both constant forms are used, the infinitive is placed at the end. Examples: Der Lehrer lobte den Schüler, the teacher praised the pupil; der Lehrer hat [finite verb] den Schüler gelobt [past participle], the teacher has praised the pupil; and der Lehrer wird [finite verb] den Schüler gelobt [past participle] haben [infinitive], the teacher will have praised the pupil. Note the difference in the position of the words in the two languages. Literally translated, the German sentence would run: the teacher will the pupil praised have.

XXIX. The Strong Declension of Substantives. Refer to Table VI., page 748.

1. The unaltered plural (first case) [see Table VI., 2, 5] is only formed by *masculine* and *neuter* substantives.

2. The plural with modification of the vowel and no other change [see Table VI., 8] is formed

chiefly by *masculines*, by the feminines die Mutter and die Tochter, and the neuter das Kloſter, the cloister, convent (plural: die Mütter, die Töchter, die Klöſter). The plural of the neuter das Waſſer, the water, is die Wäſſer or die Waſſer, the latter being preferable.

3. The e in the plural, without modification of the vowel [see Table VI., 6] is chiefly taken (*a*) by *masculines* and *neuters*, and only by such *feminines* as end in ſal and nis, and substantives of foreign origin ending in an unstressed as, is, nis, os, us. The latter and all substantives ending in nis double the final s. Examples: die Trübſal (the affliction), die Trübſal-e; die Wild'nis (the wilderness), die Wildniſſ-e; die A'nanas (the pineapple), die A'nanaſſ-e; der Fir'nis (the varnish), die Firniſſ-e; der Iltis (the polecat), die Iltiſſ-e; das Rhino'zeros (the rhinoceros), die Rhino'zeroſſ-e; der Re'bus (picture-puzzle), die Re'buſſ-e.

(*b*) Substantives with a final (round) s change it in the plural (with suffix e) into the long *soft* form (ſ), pronounced as in Roſe. Examples: der Greis (the old man, greybeard), die Greiſ-e; das Los (the lot, lottery-ticket), die Loſ-e.

(*c*) Substantives ending in ß preceded by a long vowel retain both in the plural: das Maß (the measure), die Maß-e; der Schweiß (the sweat), die Schweiß-e. In those with short vowels the ß changes in the plural into ſſ: das Roß (the horse), die Roſſe, etc.; the same change occurs with nouns of foreign derivation ending in an *unstressed* syllable with a final ß: der Kom'paß (the compass), die Kom'paſſ-e; der Kü'raß (the cuirass), die Kü'raſſ-e, etc.

4. The plural with the suffix e and modification of the vowel [see table VI., 7] is formed mainly by *masculines*, and by most of the feminines belonging to the strong declension [chiefly monosyllabics]. The only neuters that take this plural are das Chor (the choir), die Chör-e, and das Floß (the float), die Flöß-e; but it must be remembered that the masculine gender is optional for these two nouns.

5. The plural er [see table VI., 4] is formed chiefly by *neuters*, and by a few *masculines*, never by feminines. The modifiable vowels are modified. Examples: der Geiſt (the spirit), die Geiſt-er; das Neſt (the nest), die Neſt-er; das Gemüt' (the soul), die Gemüt-er; das Ei (the egg), die Ei-er; das Bild (the picture), die Bild-er; der Wald (the forest), die Wäld-er; der Rand (the border), die Ränd-er; das Loch (the hole), die Löch-er; das Buch (the book), die Büch-er; das Haupt (the head, chief), die Häupt-er; etc.

6. The plural with s [see table VI., 9] is formed by substantives of foreign origin (French, English, etc). Examples: der Chef (the chief), die-Chef-s; der Salon (the drawing-room), die Salon-s; der Jockey, die Jockey-s; der Papa, die Papa-s; etc. A few German words take the same plural in vernacular: der Junge (the boy, youth), die Jungen-s [correct form: die Jungen]; der Kerl (the fellow), die Kerl-s [correct: die Kerle]; das Mädel (the lass), die Mädel-s [correct: die Mädel]; das Fräulein (the young lady), die Fräulein-s [correct: die Fräulein].

XXX. The rules of paragraph XXIX., 3*b*, *c*, are also applicable to the declension of the singular (strong genitive with es or s, etc.).

EXAMPLES:

1. der Greis, 2. des Greiſ-es, 3. dem Greiſ-e, etc.
1. das Los, 2. des Loſ-es, 3. dem Loſ-e, etc.
1. das Maß, 2. des Maß-es, 3. dem Maß-e, etc.
1. das Roß, 2. des Roſſ-es, 3. dem Roſſ-e, etc.
1. das Geheim'nis (the secret), 2. des Geheim'niſſ-es, 3. dem Geheim'niſſ-e, etc.
1. der Il'tis, 2. des Iltiſſ-es, etc.
1. der Kompaß, 2. des Kompaſſ-es, etc.
1. der Küraß, 2. des Küraſſ-es, etc.

EXAMINATION PAPER VIII.

1. Which declension is followed by the possessive pronoun not directly preceding the qualified substantive?
2. What classes of prefixes are known in German verbs, and how do they differ as regards stress and meaning?
3. To which class of nouns do some of the separable prefixes belong?
4. How do verbs with stressed prefixes form the past participle?
5. In which tenses are the stressed prefixes detached from their stems, and where are they placed?
6. What is the arrangement of the constituent of a compound tense (finite verb, past participle, and infinitive) in a German sentence?
7. Of which gender are the strong substantives which undergo no alteration in the nominative plural, and how can the plural be distinguished from the singular?
8. To which gender belong most of the substantives which modify their stem-vowel in the plural without taking a suffix?
9. Which feminine nouns take in the plural the suffix e with, and which without, modification of the stem vowel?
10. Of which gender are the nouns that form the plural by the suffix er without, and with, modification of the stem vowel?
11. How is the plural sounded in nouns with a final (round) s in the singular [das Los], and what alteration does the final ß undergo in the plural, when preceded by a long or by a short vowel?
12. Which nouns take the suffix s in the plural?

EXERCISE 1. Insert the missing declensive inflections:

(*a*) Der Griff meines Stockes (*m.*) iſt ſchön;
The handle of my stick is beautiful;
ich gab mein... Freunde (*m.*) dein.. Stock (*m*):
I gave to my friend thy stick.
ſie brach ihr.. Uhr (*f.*); der Deckel (*m*) ihr... Uhr (*f*)
she broke her watch; the cover of her watch
iſt zerbrochen; er fuhr mit (3) ſein... und mit (3) ihr.
is broken; he drove with his and with her
Pferden (*n.*); ich ging zu (3) Ihr... Arzte (*m*); ſie
horses; I went to your physician; they
gingen mit (3) ihr.. Eltern in (4) unſer... Garten (*m*)
went with their parents into our garden
und bewunderten die Schönheit (*f.*) unſer.. Blumen (*f*)
and admired the beauty of our flowers.
Eu(e)r... Freunde (*m.*) und die Brüder (*m.*) eu(e)r...
Your (*pl.*) friends and the brothers of your

Freunde (*m.*) waren in (3) eu(e)r... Garten (*m.*) und
friends were in your garden and
pflückten eu(e)r.. Blumen (*f.*)
gathered your flowers.

(*b*) Ihr Freund (*m.*) iſt auch der mein.. (*or* unſer..);
Your (*sing*) friend is also mine (*or* ours);
er brach nicht blos ſein.. Uhr (*f.*), ſondern auch
he broke not only his watch but also
die dein.., die ihr.., die unſ(e)r.., die eu(e)r.., die ihr..
thine, hers, ours, yours, theirs,
und die Ihr..; die Schnelligkeit dein.. Hengſtes
and yours; the speed of thy stallion
iſt größer als die des mein.., des ſein.., des ihr..,
is greater than that of mine, of his, of hers,
des unſ(e)r.., des eu(e)r.., des ihr.. des Ihr...;
of ours, of yours, of theirs, of yours;
ſeine Dogge (*f.*) lief hinter (3) der mein.., der dein..,
his bulldog ran behind mine, thine,
der ihr.., der unſ(e)r.., der eu(e)r.., der ihr.., der Ihr..;
hers, ours, yours, theirs, yours;
mein Pferd ſchlägt das dein.., das ſein.., das ihr..,
my horse beats thine, his, hers,
das eu(e)r.., das ihr.., das Ihr..; deine Freundinnen (*f.*)
yours, theirs, yours; your friends (*f.*)
ſind auch die unſ(e)r.., die ihr... Die Wolle mein..
are also ours, theirs. The wool of my
Schirmes (*m.*) iſt beſſer als die Seide des dein..,
umbrella is better than the silk of thine,
des ſein.., des ihr.., des unſ(e)r.., des eu(e)r..,
of his, of hers, of ours, of yours,
des ihr.., des Ihr..; ich glaube dein... Freunde (*m.*)
of theirs, of yours: I believe (to) thy friend (3)
mehr als dem mein.., dem ſein.., dem ihr..,
more than mine, his, hers,
dem unſ(e)r.., dem eu(e)r.., dem ihr.., dem Ihr..;
ours, yours, theirs, yours;
er liebt ſein.. Freund (*m.*) mehr als den mein..,
he loves his friend more than mine,
den dein.., den ihr.., den unſ(e)r.., den eu(e)r..,
thine, hers, ours, yours,
den ihr.., den Ihr.. etc.
theirs, yours, etc.

(*c*) der Stock (*m.*), die Dogge (*f.*), das Pferd (*n.*) iſt
the stick, the bulldog, the horse is
mein.., dein.., ſein.., ihr.., unſ(e)r.., eu(e)r..,
mine, thine, his, hers, ours, yours,
ihr.., Ihr..
theirs, yours.

(*d*) Replace the possessive pronouns in (*b*) by their lengthened form, whenever this form is applicable.

EXERCISE 2. (*a*) Form the present indicative in all persons and both numbers of the following verbs with *stressed separable* prefixes: aufſtehen, to rise; anbieten, to offer; ausgeben, to spend; beiſchließen, to enclose; einſchlafen, to fall asleep; hinkommen, to get there; mitnehmen, to take along with; umfallen, to fall [down].

(*b*) Form the *present* tense of the following *strong* verbs with *unstressed* inseparable and *stressed* separable prefixes, the stress marked by an apostrophe *behind* the stressed syllable: ver·ſte'hen, to understand; bei·'ſtehen, to assist; ver·bie'ten, to forbid; auf·'bieten, to call up, to summon; aus·'ſchließen, to exclude; be·ſchlie'ßen, to resolve, (finish); ge·fal'len, to please; auf·'fallen, to fall upon (also in the sense of: "to be conspicuous").

(*c*) Form the *imperative* singular and plural in the ordinary and civil form of address of the verbs enumerated in (*a*) and (*b*).

EXERCISE 3. Change the *present* tense of the following *weak* verbs [see XXIV. and Exercise 5*a*] for the *perfect* and *pluperfect* in the arrangement explained in XXVIII., 3; [the verbs conjugated with the auxiliary verb of tense ſein (to be) are made prominent in print, all others are conjugated with haben (to have)]:

Der Schüler lernt; der Lehrer öffnet das Fenſter;
The pupil learns; the teacher opens the window;
der Künſtler zeichnet ein Bild; das Mädchen lächelt;
the artist draws a picture; the girl smiles;
der Gärtner arbeitet im (3) Garten; das Schiff ſegelt;
the gardener works in the garden; the ship sails;
die Kinder ſpielen; die Mädchen erröten; ich liebe
the children play; the girls blush; I love
meine Eltern; er redet Unſinn; du rauchſt eine
my parents; he talks nonsense; thou smokest a
Cigarre; ihr badet im (3) Fluſſe; ſie läuten die Glocke;
cigar; you bathe in the river; they ring the bell;
die Kinder zerſtören ihr Spielzeug; er lauſcht an (3) der
the children destroy their toys; he listens at the
Türe, du begrüßeſt den Vater.
door; you greet the father.

EXERCISE 4. Form the *plural* (*a*) [without Inflection] of the following substantives, of which those with *modifiable* vowels in the stressed syllable are modified: der Va'ter (*m.*), the father; der Löf'fel (*m.*), the spoon; der Ap'fel (*m.*), the apple; das Fen'ſter (*n.*), the window; der E'ſel, the donkey; der Bru'der, the brother; der On'kel, the uncle; der Vo'gel, the bird; der Rei'ter, the horseman; der Fa'den, the thread; das Veil'chen, the violet; der Käſe, the cheese; der Sattel, the saddle; (*b*) of the following substantives (following XXIX., 3): der Berg, the mountain; der Hund, the dog; das Jahr, the year; die Kennt'nis, the knowledge; der Hirſch, the stag; die Bewandt'nis, the condition, state; das Pferd, the horse; das Haar, the hair; der Kür'bis, the pumpkin; das Lab'ſal, the refreshment; der A'bend, the evening; der Preis, the prize; das Moos, the moss; das Fließ, the fleece; der Schuh, the shoe; der Sproß, the offspring; das Geheim'nis, the secret; (*c*) of the substantives following the rules of XXIX., 4: der Arzt, the physician; die Gans, the goose; der Kopf, the head; die Braut, the bride; die Hand, the hand; der Zahn, the tooth; der Topf, the pot; die Fauſt, the fist; der Fuchs, the fox; die Bruſt, the breast; der Strom, the stream; die Wurſt, the sausage; der Krug, the jug; (*d*) of the substantives following XXIX., 5: das Tuch, the cloth; das Land, the country; das Kind, the child; das Gewand, the garment; das Weib, the woman; das Kraut, the cabbage; das Lied, the song; das Faß, the barrel; das Dorf, the village; das Glied, the limb; der Wurm, the worm; das Geſpenſt', the ghost (spectre); das Volk, the people. (*e*) Decline the substantives das Roß, the horse (steed); das Los, the lot; das Hindernis, the hindrance (impediment, obstacle).

EYES AND NO EYES

The Faculty of Observation. How to Acquire it. Training Children to See. The Value of Observation in Practical Life. The Mystery of Vision. What to Observe

By HAROLD BEGBIE

GEORGE MEREDITH has described observation as, perhaps, the most lasting of human pleasures. The man who enjoys the art of seeing beyond all question employs life in a far fuller degree than the man who notes but little as he journeys through the world. But the art of seeing endows its possessor with something more than pleasure; it enables him to attain success in his undertakings with greater ease than is possible for the unseeing man, and it also leads to a more permanent and a far pleasanter development of character.

A Faculty which can be Cultivated. It may be said, indeed, that success in any walk of life depends in no small measure on the degree of observational powers enjoyed by the prize seekers. Thousands of astronomers had looked at the planet Uranus before William Herschel looked and observed that it was not a star. It was another genius of science—John Kepler—who remarked that "God has waited six thousand years for an observer." The man whose trained and patient eyes see everything conquers all things. There is no doubt that many men are born into the world with this gift of observation, but it is a mistake to suppose that the faculty cannot be cultivated and developed by those whose eyes have been altogether untouched by the good fairies. It is a thing to be learned—essentially a thing to be taught to children—and it is furthermore one of the very first and one of the most important mental exercises for developing the creative and inventive faculties of the brain.

Comparison. If you doubt the value of observation, enter into conversation with two travellers, one of whom has the gift and one who has not. The one has nothing to tell you of his travels beyond the baldest and most uninteresting commonplaces of the road; while the other, you will find, can scarcely find words enough to express the pleasure he has derived from a thousand and one experiences of his journey. The one can tell you that he passed along a road, that there were trees by the side of it, a river under the trees, and a few fields sloping upward from beyond the river. The other will make a romance of the very dust along the highway, will tell you the names and describe the colours of the wild flowers growing in the grass beside the stream, will make so actual a picture of the river's curving way that you will persuade yourself you must have visited the scene.

It may be said that the difference between these two men is rather one of expression than of observation, that the eloquent traveller has learned the use and graces of languages, while the dumb traveller has merely put himself to no pains to learn the art of description. But to this we object that all the eloquence in the world does not teach a man to observe interesting things, whereas the art of observation does in the very nature of things urge the mind to suitable and suggestive language. The eloquent man who has no faculty of observation can make you an interesting essay on a broomstick, but he cannot make vividly interesting a description of a journey, however beautiful and inspiring.

The Practical Value of Observation. And just as the faculty of observation renders the one traveller a far more welcome guest at the fireside than his fellow who sees nothing at all, so the same faculty puts into the possession of the mind a plentiful store of material—useful, and in some cases needful—for success in the stern and practical battle of life. It not only makes a journey interesting to its possessor, and not only makes popular him who has it, it is a weapon of the first order in the great struggle of humanity for fuller life and fuller consciousness. The engineer and the poet must both be close observers to be great in their work.

It is possible to teach children the art of observation even in their games. One of the indoor amusements of childhood which never seems to lose its freshness and attraction is known as "Eyes and No Eyes," and consists of seeking for an object which is hidden—but not out of sight—in a room from which the seekers have been momentarily excluded. On their admittance to the room each child is aware that no amount of cupboard opening, lid removing, or lifting and shifting of bric-à-brac, will suffice to discover the object. Everything depends upon sight, and sight alone. The object has been placed in some position in the room which renders it difficult of discernment, while it remains perfectly visible to those who have thus placed it.

Mental Blindness. Another excellent practice is to make children write a description of their bed-room or their father's study, or, indeed, any room in the house with which they are daily familiar. It will be found in many instances that the child is even unable to name the colour of the wall-paper in his own bed-room, while the pattern of the carpet or the shape of the fireplace will present to his mind the most insoluble of problems. Things which his eyes have seen every day for years have been so little observed that he is utterly unable to afford you even the crudest and barest description of them.

But this which is true of most children is likewise true of most adults. Not born to realise the endless pleasure of observation, and never having been encouraged or trained to develop the faculty, the average person passes through life seeing everything and observing nothing. Life presents to these unhappy ones a confused kaleidoscope of form and colour, a jumble of shapes and lines, with no clear and distinct picture of its meaning or its mystery, with no definite and vivid impression of its reality. Their commonplace book is as empty when they reach the grave as it was when they first handled it in their cradles.

The Mystery of Vision. To comprehend the law of observation, it is necessary to consider something of the mystery of vision. If you consider within yourself, it will probably seem to you that in writing a letter with your eyes fixed upon the paper you see absolutely nothing else but the writing which you thus so assiduously observe. But if you make the experiment, you will find that even while your eyes are following the flowing strokes of the pen you are conscious of many other things than the mere writing. You will be aware of the ink-pot in front of you, of the ash-tray on your right, of the penholders scattered upon the blotting-paper, of the stick of red sealing-wax in the tray beside the ink-pot, of the pile of books and papers on the left of your manuscript, and of several other details of your immediate environment. It is true that you do not see these things with any distinctness, but it is also true that the rays of light which make these things conscious to you as surely enter your eyes and are photographed upon the retina as perfectly and as certainly as is the writing over which you exercise such close and exclusive pains. The difference is that you see and observe the writing, while you only see the surrounding objects of your work.

You will also find in conversation with a person that while your eyes remain fixed on his, and while you may think you see only his face, yet you do in reality see a very great deal of the scene about you. Without removing your eyes from his, you may yet be conscious of the pattern of the window curtains, of the trees out on the lawn, of the dog lying asleep in the sun on the gravel path, of the pictures over your friend's head, of the colour and pattern of the carpet under his feet, of the chairs and tables and sofas in his neighbourhood, and of the clock on the mantelpiece behind him. But while that clock is absolutely real to you, you will find nevertheless that you are unable to tell the time it records so long as your eyes remain faithfully fixed on the face of your friend. You see the clock, but you do not observe it. The rays of light from the dial and the hands enter your eyes and impress themselves upon the retina, but consciousness is not there to record the impression.

The Really Great Man. It may be, as some suppose, that every ray of light which enters the eye, and every vibration of sound which enters the ear, are as tenaciously and as fully retained in that larger memory of which our normal and limited consciousness knows such a very little, as are the vibrations and waves of which we are intelligently conscious; and that some day—as is said to happen to drowning men—we shall re-live in a blinding flash of that memory every single incident and every passing instant of our lives. But, be this as it may, certain it is that we can make more use of the things we consciously and intelligently observe than of the things which we merely see because they happen to be in the line of vision.

Just as in art Michael Angelo could have made better use of a housemaid's mop than a savage could have made of the finest camel-hair brushes, so may defective sight, with a keen consciousness behind it, see more of the world, and see the world far better, than is possible to the finest-sighted eyes among mankind with a stupid and unintelligent consciousness behind them. But while the eyes cannot be changed it is possible to change and develop the consciousness with every fresh experience of life, and one of the very best means for so training and developing the mind is by the eyes, by the education of this very observational faculty of which we have been speaking. This is why we place it first among those mental exercises which make for the happy use of learning; it is, more than all other exercises, a direct and most certain influence in the enlarging of consciousness and the enriching of personality.

The really great man is he to whom the words of Shakespeare are applicable:

> In his brain
> . . . he hath strange places cramm'd
> with observation.

Genius the Fruit of Observation. Genius, indeed, is very largely the fruit of observation. The beauty of the breathing world, the actions and the thoughts of humanity, the moving of the seasons over the earth, and all the change and interchange of daily life—these are the colours with which the great artist covers the canvas of his consciousness, and the closer and the more affectionate his observation of them the nobler and sublimer is the picture. There is no education so thorough as that which has observation for its schoolmaster. To observe a thing puts one into possession of that thing, and every fact profoundly considered becomes in some sense the actual property of the observer. I can persuade myself that Shakespeare had so observed mankind as to feel that he had almost created humanity, and that Wordsworth had so observed the face of Nature as to feel that he had well-nigh fashioned the earth.

This god-like sensation of the true observer is adumbrated by Emerson and contrasted with the slavelike sensation of the man who sees nothing:

"The making a fact the subject of thought raises it. All that mass of mental and moral phenomena which we do not make objects of voluntary thought come within the power of fortune; they constitute the circumstances of daily life; they are subject to change, to fear, and hope. Every man beholds his human condition with a degree of melancholy. As a ship aground is battered by the waves, so man, imprisoned in mortal life, lies open to the mercy of coming events. But a truth separated by the intellect is no longer a subject of destiny. We behold it as a god upraised above care and fear. And so any fact in our life, or any record of our fancies or reflections, disentangled from the web of our unconsciousness, becomes an object impersonal and immortal. It is the past restored, but embalmed. A better art than that of Egypt has taken fear and corruption out of it. It is eviscerated of care. It is offered for science. What is addressed to us for contemplation does not threaten us, but makes us intellectual beings."

To observe a thing, then, is to think about it, and it is thought that makes us gods. It is the business of the man striving to get the best out of himself, striving to make the utmost of all that he learns and all that he experiences, to observe things, which means to see things as they really are—in a word, to think about things.

How the Faculty may be Acquired. There are many ways of practising the faculty of observation. It is a good method to spend a few minutes at the end of each day in recounting to yourself, or in recording in your diary, the events of the day, with some account of the things you have actually observed. Practise, especially at first, to be perfect in your details. To say that at twelve o'clock you spoke to a man named Brown is not enough; you should be able to say what clothes he was wearing, what is the colour of his eyes, in what fashion he brushes his hair, and something of any peculiarity in his speech or manners. To say that you saw Brown in the hall of an hotel is, likewise, not enough; you should be able to describe the furniture of the place, the hangings of the walls and windows, and the people you notice there.

If you read any of the great novelists you will discover that they have all been careful observers of such details. Balzac, perhaps more than any other writer of fiction, was the scrupulous observer of every detail of environment; he realised more than any other writer the immense importance of giving actuality to the rooms and raiment of his characters, and the success with which he has attained this endeavour proclaims eloquently the indefatigable observation with which he studied the world about him.

Some Great Observers. To read Balzac is to acquire at least the appetite for observation, if not actually the thing itself. We may learn from such authors something of the method of observation. Dickens was a wonderful observer. Thomas Hardy and George Meredith are both observers of a high order, and Guy de Maupassant observed everything that he saw. Read the works of these men, and see how they took note of salient and eternal things, how the smallest and most trivial of human habits—rescued from the web of our unconsciousness—becomes by their observation and thought about them habits that as eloquently declare character and impress personality as the biggest and most universal of things. Notice how they observed. The small thing, if it be the salient thing in a character, is insisted upon; the big thing, if it have little to do with personality, is disregarded. You will find lesser writers insisting with weariness on some gigantic peculiarity of their character, quite ignorant of the fact that such peculiarity does not in any manner help to impress the personality upon the mind. Pere Grandet's eternal "Tut, tut! We will see about it!" is an exclamation illuminating the innermost recesses of that cunning and miserly mind; and the fact that Falstaff plucked at the sheets as he lay a-dying is a thing that makes us almost believe we shed tears for him with Bardolph.

Importance of Discrimination. It is of central importance in this cultivation of the art of seeing to learn to observe salient things. You can by practice quicken the activity of your consciousness into observing many things which you did not see before; but it is essential to remember that the burden of remembrance must not be overloaded with negligible details. Even if it were possible to remember the smallest details, it were wise not to do so, for observation becomes in this fashion an unintelligent and mechanical recorder. But by learning to observe salient things, essential things, things that give startling reality and eternal actuality to remembrance, you cultivate within yourself at the same time a discrimination and a conscious direction of your intellect, which will prove of infinite value through all the days of your life.

Learn first to see, then to see wisely.

Begin by taking note of your own immediate surroundings: the room, for instance, in which you spend the most familiar hours of your day. Note all there is to be seen there; every detail of furniture and ornament, every arrangement of your possessions. Then close the eyes and build up the picture out of remembrance from the mind's eye. Gradually you will perceive that there are some few things which give the character of the apartment—it may be a vase of flowers, a picture, a certain disorder of a small table, and not at all a big piece of furniture, or curtains, or carpet; seize upon these few things and write them on the tablets of your memory. Make no effort to remember the things which have no effect upon the character of the room, but be very sure you have seen all there is to be seen in the room.

What to Observe. In the same way, when you take a walk, do not busy your thoughts with personal troubles and individual anxieties, but study to see all that is to be seen of the street's life. Notice the horses, the windows, the doors, the roofs, and the chimneys. Notice the people, their faces, their clothes, their walk, their manners. And then, on your return home, reconstruct the scene so as to give it, in remembrance, the very reality with which it appeared in your eyes. You will recollect many things which had no real meaning for the scene; do not trouble to remember them. But you will recall a few things which gave the walk its character and its tone; remember these few things, and think about them till they become almost a part of yourself.

I knew a man who once, as a young medical student, took a walk with Dickens, in order to reveal to the great novelist a method he had for observing people in the street. The method had to do with the science of the physician, and person after person passed in whom the medical student was able to point out the symptoms of some physical irregularity. But presently one passed of whom the medical student had nothing to say, and Dickens immediately discarded the theory. It was, he said, not universal. And then he pointed out to his companion how every man and woman and child, if you looked close enough, has some peculiarity of countenance or gait which differentiates each one completely from the rest; and it was for this peculiarity, he said, that the eyes of the observer should always accustom himself to look. The other method was interesting and clever, but it was not universal. Observation must be catholic.

Development of the Faculty. One of the pleasures of training the mind to observe lies in the swift development of the faculty. Every day one is flattered by an increase of power. The faculty grows with every exercise, and not only in this way does the mind acquire fresh pleasure, but it will be found that in setting oneself to any fresh task one is able to master it with greater ease. For the mind which has learned to observe becomes quick in all its perceptions. It sees almost by instinct the thing that matters, and does not have to blunder through a tangle till the knot is presently discovered. The mind of the practised observer is a quick and an acute mind. It is free from heaviness, is not slow in its judgments, does not begin a task half-heartedly, is not clumsy. The power which it has acquired by patient and contemplative observation is a directing power, a power of mastery. It is no longer a machine working at random, but an engine directed to a conscious end by a vigorous and intelligent overlord.

And this is really what lies at the back of observation, and is, too, the only intelligent reason for education. We have to make ourselves brighter and intenser beings; we have to possess ourselves of a fuller and a deeper life.

The True End of Education. The quickening of consciousness, the vivifying of the personality—this is the end of education, and this is the first fruits of observation. Without the seeing eye, life is but a shapeless and a colourless thing, a blurred impression of a chaotic picture. But with the seeing eye life becomes every day a page of more and more entrancing interest, a book the hours of the sun do not afford sufficient time for reading. I have never yet met a person who was a keen and earnest observer who was also a pessimist. I have never yet encountered a pessimist who was not also a person of no observation.

And as for success in life, you will surely find that no man has yet climbed by his own ladder into fortune and fame who was not in some measure an observer of humanity. It is said that a certain Midland firm made their fortune by the observation of one of its members that the Germans like to buy screws in certain coloured paper packets. A millionaire grocer has narrated how, as a shopman, he studied to see what poor people bought, and, getting his own business, provided only such things, and in such vast quantities, that his windows were the magic spell of all the working-classes in that neighbourhood. In the same way the amazing advances made by mechanical invention have all flowed from the patient observation of engineers. James Watt, observing the steam and the kettle-lid, was doing the same work as the engineer who now observes an engine day after day, and week after week, till he discovers a fresh improvement.

It often strikes the unthinking as strange that improvement should be so slow in mechanical invention. If an engine at all, why not a proper engine from the first? If a bicycle at all, why not a perfect bicycle at the beginning? But man can neither create nor perfect without having something to observe. It needs for the children of men a copy before they can begin to write. And so it happens that inventions come as a surprise even to mechanicians, because there are so few profound observers among their number.

Science and Observation. Long before Darwin men of science had the theory of evolution, and even while he was perfecting his observations, another man of science—Alfred Russel Wallace—was writing a treatise on similar lines. To the generality of mankind this new era in science came as a staggering revolution; by the whole realm of science—the trained observers of nature—it was more or less expected.

I have been told by manufacturers and merchants that they have old clerks in their businesses who have been with them since boyhood, and who are yet as ignorant of the general working of the undertaking at the end of their lives as they were at the beginning. On the other hand, a boy enters the office in a humble capacity, who, while he is addressing envelopes and licking stamps, so observes the methods and the management of the business that in a few years he is able to start a similar business on his own behalf. It is not enough to be assiduous and thorough in one's particular branch of labour; one must also be a close and earnest observer of the entire machinery of the whole undertaking.

The mind must always be roused out of dozing, must always be kept from nodding over life. It is not living to accept the facts of existence in a semi-conscious manner. It is not reading to receive a story in a half-sleepy frame of mind. The intellect should always be braced to receive every effect of life vividly and clearly. The mirror of consciousness must be kept polished.

The mind can never be overworked in this mission of observation. To observe one thing alone, and for a great stretch of time, is more or less injurious; but to observe all things thoroughly is to strengthen the fibres of the mind, and to endow it with a strong and robust constitution.

.TOW AND JUTE CARDING

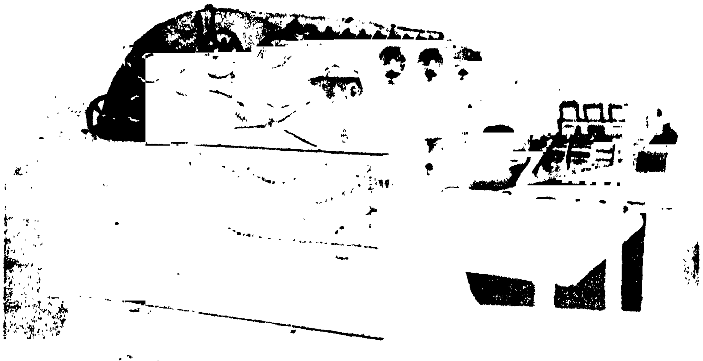
Tow Carding. Hempen Slivers. Lapping and Lapping Machines. The Special Requirements of Jute Carding

Continued from page 1737

By W. S. MURPHY

IN principle, tow carding is the same as cotton or wool carding; but it would be altogether misleading to say that the operations are in all respects the same. Every kind of fibre, if it is to be treated to the best advantage, requires its own special carder. The flax manufacturers are right who insist on modifying to their own customs the tools they take from other trades. Tow can be carded on an ordinary cotton-carding engine without the flats; but the best results are obtained from the engine designed on the lines of the spreader. Here, also, we should perhaps make another preliminary remark. Most persons outside the linen trade have the notion that tow is a kind of waste; it is nothing of the kind. Its fibres, it is true, have been eliminated from the longer flax, but that may possibly mean a finer quality rather than a lower grade of material.

Special Carder. The tow is gathered into bins and placed near the carding engine [70]. From the bins the workers take the fibre and weigh it. According to the weight of the sliver designed, the weight of tow is spread on the marked area of the feed-sheet. The area is 36 in. and the given weight must be spread evenly on that space. The sheet having been spread, it moves on and up to the feed-roller, which draws in the fibre. The action of this part of the carding engine is the same as in those we have studied, the workers and strippers acting and reacting on the cylinder. Not till we come to the back of the cylinder do we find much difference. Here, instead of the doffing apparatus of the wool and cotton carders, or the delivering rollers of the spreader, we have spiral brush-rollers, which separate the carded tow into three different heads, and deliver them through heavy calender rollers in the shape of flat sliver bands. By the simple device of changing the delivery of the slivers, and sending them all in one direction, they are combined into one thick, filmy rope. On this engine, as on the spread-board, a bell gives warning of the length of sliver paid out into the cans. As may be expected, there is a considerable amount of refuse and rubbish dropped from the tow in the process of carding. This falls into a receptacle placed in the bottom of the carder, and is generally sold to the paper-maker.



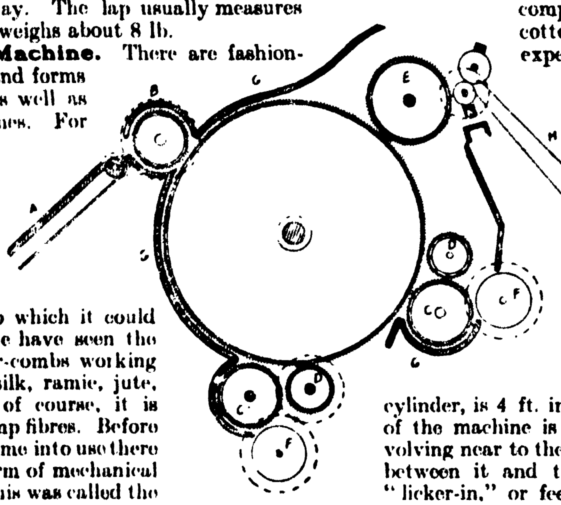
70. TOW CARDER (Taylor, Wordsworth & Co., Leeds)

Hempen Rope Slivers. We take strong exception to the free-and-easy way of passing over the differences between closely-related fibres which even expert teachers sometimes adopt. It is misleading and unfair. Having been led to think he knows all about one fibre because he has studied another nearly resembling it, the student, on entering into practical work, finds himself confronted by machines and processes which seem to him utterly unlike anything he has been taught to expect. The experienced worker, of course, knows that the difference is not essential; but it is the superficial difference that strikes a beginner. Hemp and flax offer a case in point at this stage. For the most part, hemp is prepared in the same way, and on the same machines as flax; but, as we have seen, there are many kinds of hempen fibres, and all do not lend themselves to similar treatment. Moreover, certain advances made in the utilisation of hemp in recent years call for notice.

Lapping. When our aim in rope-spinning is quick production, we try to obtain the longest fibre possible at the soonest moment. In many of the leading roperies of this country lapping has been discarded, but in America it has been developed, and a return to it is gradually coming among ourselves. The student is now familiar with the spreader and its screw gills;

but suppose that, instead of the drawing rollers, doubling plate, and sliver rollers, we have a wide cylinder studded with rows of spikes, what would be the effect? As the faller-combs advance to the end of their career, the long spikes of the revolving cylinder take hold of the fibres and drag them round its huge bulk. When the cylinder has fully clothed itself, the fibres are taken from it, and laid out in what is called a lap. Manilla and sisal hemp fibres are treated in this way. The lap usually measures 19 ft long, and weighs about 8 lb.

A Special Machine. There are fashionable machines and forms of machinery as well as fashionable clothes. For about forty years it was the fashion among textile machinists to use the screw-gill for every conceivable purpose to which it could be applied. We have seen the screw-gill faller-combs working in wool, spun silk, ramie, jute, and flax, and, of course, it is also used on hemp fibres. Before the screw-gill came into use there was another form of mechanical comb used. This was called the sheet gill, an endless band of rods holding upright combs and moving in a horizontal direction.



71. DIAGRAM OF JUTE CARDER

Though out of fashion, the sheet-gill was never wholly forgotten, and it occurred to an ingenious hemp-spinner to try what improving the sheet-gill would do in adding to his machinery. He had, moreover, another end in view. Hemp had not, in his opinion, attained the position in the textile world to which it is entitled. It is well known that the position of jute was very much improved by the oiling of the fibre, and this idea occurred to our friend. A combined hemp spreading and oiling machine was accordingly constructed on the sheet-gill principle. But mark the advance.

In the fore end of the machine we have the usual feeding apparatus, with the endless band and feed-rollers; but above the feed-rollers is set the oil-spraying apparatus, Leach's ingenious invention being the one most commonly adopted.

Next is the first sheet-gill, an endless band of bars set with combing teeth. At this point the older form of sheet-gill stopped; but our new machine goes farther. Another sheet-gill, with finer teeth and running at higher speed, is geared over the bed of the machine. On this second sheet the fibres are drawn out finer and longer. Thence the fine fibres are delivered to the sliver-forming apparatus. One can easily see that a very good and high class fibre can be produced on these machines. Fig. 72 illustrates the hemp-gilling department in a modern factory.

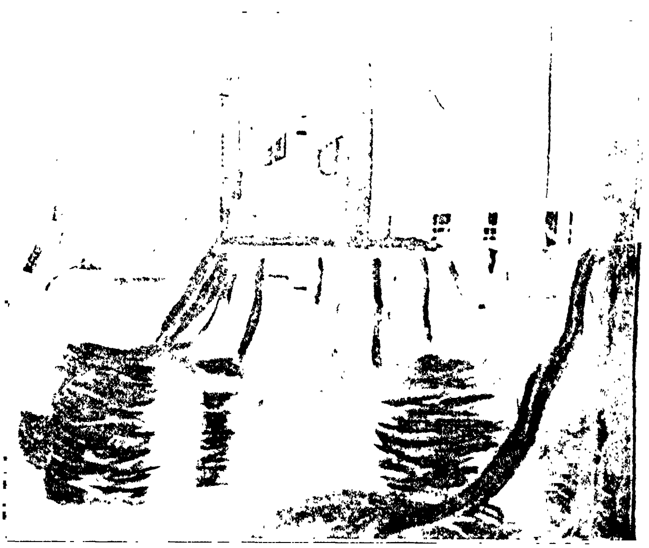
Jute Slivers. When the jute fibre comes from the softener, it is about 6 to 8 ft long. Such a length of fibre cannot be handled by the spinner. Cutting might be resorted to, but that involves a special operation, and adds to the cost of working. The jute spinner has found a simpler way out of the difficulty, and combines the carding of the fibre with the reduction of its length. The first, or breaker card, reduces the length of the jute to about 12 inches. Even this length is great when compared with the 2 in. of the cotton staple, and we therefore expect to find in the jute-carding engine special modifications to suit the length of the fibre.

Jute Carders. The largest machine of the carder class, the jute carding engine, possesses features special to itself. Let us look first at the general structure. The centre, or breast cylinder, is 4 ft. in diameter. At the front of the machine is the feed lattice A. Revolving near to the head of the cylinder and between it and the feed lattice, sits the "licker-in," or feed-roller B, clothed with spiky points. On the lower circumference of the cylinder, we find a pair of tooth-covered rollers; these are the first worker D, and stripper C. The second worker D and stripper C are placed further round on the cylinder. At the point of inward curve on the back of the large cylinder, sits the doffer cylinder E, and working upon it are two small rollers which operate above the slanting channel H, at the end of which we find the delivery rollers I. Rather strange, and a feature not seen on other carders, are the curving plates G, G, G, which seem to act as guards on the cylinder and stripper rollers. Behind both stripper rollers, also, are tin rollers (F), the functions of which are not familiar to the workers of other carding engines.

Special Characteristics. Studying the jute carder, one almost sees the handiwork of the succession of able and practical men who wrought it into form suited to the special need of the jute industry. In the wool and cotton carders, the teeth of the cylinders point in the direction parallel to the circumference of the cylinder; but in the cylinder of the jute carder, the teeth point slightly outwards. Perhaps the greatest difference is in the workers and strippers. The workers are smaller than the strippers, their relative sizes being 9 in. and 13 in. in diameter respectively.

Another feature worth noting is the peculiar teeth of the workers. Long, slanted, and turned in the direction opposite to the revolution of the rollers, these teeth have great pulling power. This leads us to note a further singularity in the machine. With the exception of the feed roller, all the parts of this machine turn in one direction. Workers, strippers, and doffing cylinder run in precisely the same way as the central cylinder. Here is a great result attained by one of the simplest devices known to mechanics—*viz.*, differential speed. The relative speeds are: breast cylinder, 2,000 feet per minute; workers, 50 feet per minute; strippers, 450 feet per minute; doffing cylinder, 140 feet per minute. But the action of the workers and the doffing cylinder is taking off from the central cylinder. In ordinary cases, the carder which takes must run faster than the one taken from. To give so small cylinders such a speed as would enable them to overtake one running at the rate of 2,000 feet per minute was practically impossible. Therefore, the teeth on these rollers were reversed. Rushing past the opposed teeth, the breast cylinder gives them a great pull. Again, though strippers and workers are running in the same direction, the reversal of the teeth of the workers gives the swifter strippers an easy chance of picking off the fibres, while, because the teeth of the strippers are in the same direction as those of the swifter main cylinder, the latter gets back its own.

Saving the Long Fibres. Note that the feed lattice does not come close up to the licker-in. If it did so, the swift spiky roller would break the long fibres with the sharp curves. On the other hand, if left free, the fibres would drop between the licker-in and the feed lattice. To obviate this, the adapters of the jute carder devised a concentric plate to curve below the licker-in, with a broad flange acting as a guard on the main cylinder. This device has worked so happily that the principle has been greatly extended, and the newest carders have guard plates, as shown in our diagram, curving over the head of the main cylinder and round under the strippers. Supplementary to those plates are the tin rollers working behind the strippers. For the same reason, the jute carder has the long conductor channel between the doffers and the sliver delivery rollers. Though the jute has been considerably reduced in length, it is yet a long fibre, and the sliver is correspondingly tender.



72. PREPARATION ROOM

First process in preparing hemp for spinning

Finisher Carding. Jute, except when used for very coarse purposes, is subjected to a second or finisher carding. The finisher card is finer in the tooth, and has from one to three more sets of worker and stripper rollers. The slivers from the breaker card are weighed, and twelve cans are set along the front of the feed cloth, thus forming a lap. By this means the fibres are given an intimate mixing, to eliminate inequalities and combine differences. Here we may also take note of a principle to be exhaustively investigated in our next course, but seen working in the jute-carders to a very pronounced degree. This is the matter of draught. The feed rollers deliver a sliver weighing about, say, one pound for every half yard in length; but the doffer-rollers run fourteen times quicker than the feed-rollers, and therefore elongate the sliver to fourteen times the length. As the weight does not alter, and the length does, we have a sliver 7 yds. long, weighing only 1 lb. In the finisher card this principle is carried to even greater lengths, the weight of a yard being reduced to about one ounce.

The *gigantic fibre* has now become a sliver, and is on the way to be made into a thread.

PHRASING

Scale Playing—continued. Chromatic Scales. Rhythm. Accents. The Pedals. The Importance of Practising the Old Masters

By M. KENNEDY-FRASER

Scales in Double Thirds. Scales in double thirds can be fingered on this same principle of *two* groups to the octave, thus:

3 4 5 2 3 4 5
1 2 3 1 1 2 3

although many finger them in three groups, thus:

3 4 5 3 4 3 4
1 2 3 1 2 1 2

For such three-group system the student may be referred to Leopold Waldstein's "Scales in Double Thirds and Sixths." We had better, perhaps, omit the study of double sixths; they are dangerous for the hand, unless practised very carefully, and are not very profitable. The two-group system of double thirds as taught and formulated by Mr. Matthay is given below. Note that the groups of four begin with twice thumb or "double-thumb" position, as we shall call it.

1. All white keys, excepting F and B, like C, counting from key-note:

C
3 4 5 2 3 4 5
1 2 3 1 1 2 3
3 2 1 3 2 1 1
5 4 3 5 4 3 2

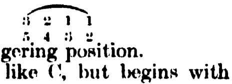
Hands *coincide* as to fingering position.

The exception, F, is like C, but begins with "double-thumb" position, instead of the "five-finger" position.

2. B has "all-black" keys position—*viz.*, index finger of both hands in the "double-thumb" position falls on the middle black key of the three, thus: ▌▌▌, whilst the combination $\left(\begin{smallmatrix}3\\5\end{smallmatrix}\right.$, which occurs *twice* in the octave, *always* falls on the two black keys with the big gaps between them, thus:

Note that the R.H. $\left(\begin{smallmatrix}5\\3\end{smallmatrix}\right.$ and L.H. $\left(\begin{smallmatrix}3\\5\end{smallmatrix}\right.$ coincide in the two hands twice in each octave. This fingering applies to the other "all-black" keys—*viz.*, F♯ and C♯, and also to the minors of B and B♭; but in the case of these minors the index finger falls on the *white* key inside the three blacks.

3. In E♭ and B♭ major the "double-thumb" position in both cases begins on the second note of the scale with its accompanying upper third. Hands coincide as in C. These are all the majors, with the exception of A♭, which we shall take with its tonic minor.



4. All minors, with the exception of G♯ minor, C♯ minor, and F♯ minor, are fingered like their tonic majors. The left hand of F minor is also an exception, and is best fingered like C:

3 2 1 3 2 1 1
5 4 3 5 4 3 2

The rule for the set of three minors is double-thumb *on* the notes of the augmented second in both hands—*i.e.*, the repeated thumb occurs in both hands on the sixth and seventh of the scale. A♭ major takes the same fingering as its enharmonic minor—*viz.*, G♯. The $\left(\begin{smallmatrix}5\\3\end{smallmatrix}\right.$ $\left(\begin{smallmatrix}3\\5\end{smallmatrix}\right.$ coincides only once in the octave now with the two hands.

Chromatic Scales. Chromatic scales in single notes are fingered normally, thus (beginning on C♯):

3 1 3 1 2 3 1 3 1 3 1 2
one octave.

or: 3 1 2 1 2 3 1 2 1 2 1 2

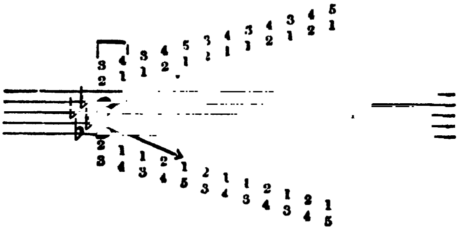
Chopin used also other methods, thus (again beginning on C♯):

3 4 3 4 5 3 4 3 4 3 4 5

and Busoni, the present-day Italian pianist, thus:

3 4 3 4 5 2 3 4 5 3 4 5

Chromatic scale in double thirds, thus:



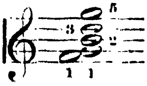
Playing them thus by contrary motion on the *keyboard*, the action of the *hands* is exactly the same, the fingering of both coincides. The inside part of both hands has thumb on all the white keys and forefinger on all the black.

In all double-note scales the legato can only be produced at the finger-group junctions by *one* of the pair of notes; we must realise this, and rest gently on that particular one, gliding easily to the position of the next pair.

Chords and Arpeggi. The fingering of chords and arpeggi next claims our attention. The normal fingering for the three positions of the common chord in arpeggi is first position (root position), 1 2 3 5; second position (first inversion), 1 2 4 5; third position (second inversion), 1 2 4 5—these when the first key of the group is an ivory. The exception comes when in the second and third positions the distances on the keyboard between fourth and fifth fingers is greater than usual, as, for instance, when the interval of the third then lies between B♭ and D or E♭ and G, the middle finger may be used instead of the weaker (fourth) on the black key. But if the hands be large, and the stretch between the fingers ample, it is better to make it a rule to use the *weak* finger here. It makes for uniformity, and prevents the over use of the strong finger and under use of the weak.

When in an arpeggio the position of the chord offers us a *black* key for the starting point, it is better to postpone the use of the thumb till the first white key is reached in going away from the centre of the keyboard. When we play the arpeggi of F♯ major and E♭ minor, we are obliged to use the thumb on the black keys, as these chords consist of black keys only, the black keys here being treated as if they were all white ones. The normal fingering of chords of the seventh is: 5 4 3 2 1.

Here, again, when these are taken in arpeggio and begin with a black note, postpone the use of thumb in travelling away from the centre till the first white key after a black key is required. It will be found easier always to make the pass under take place between a black key and a white. In fingering chords which include two adjacent keys, both white or both black, the thumb should be used on the two adjacent keys, thus:



Remember, when uncertain as to the fingering of a passage, first to try to find the finger-grouping. We may also try it in the other direction—*i.e.*, if an ascending passage, finger it from the top downwards, and vice versâ, so that we may discover what is the best finger-grouping.

Fingering Sequences. When rapid passages consist of repetitions of the same figure, it is best to finger these all like the first group of the sequence, regardless of the unevenness of the keyboard caused by black and white keys; but this is not obligatory. Fingering chosen must be such as helps to make the phrasing clear, and it depends also on *how* the passage is to be played—whether by finger-movement, hand-movement, or arm-movement, staccato or legato, and so on.

Chopin is fond of playing soft chromatic *marcato* successions of notes from the arm, and for this purpose has a curious but effective fingering—all white notes with the fifth, all the black notes with the fourth finger. See, for instance, the ornamental passages in the well-known E♭ Nocturne. In playing passages thus, turn the hand laterally somewhat, wrist inwards, so that the two fingers (fourth and fifth) could be dragged along over the keys—fourth on the blacks and fifth on the whites. Again, Chopin joins his arpeggi passages occasionally by a smooth lateral movement of the forearm, instead of passing over or under the thumb. All these fingerings seem quite natural when the *muscular conditions* are correct.

Fingering in its details is a variable quantity—what suits one hand and mind may not suit another; but the main rules as to looking for *grouping* always apply. It is well to try the fingering suggested by, say, a Von Bülow in the later Beethoven sonatas, or a Klindworth in Chopin's works, before resorting to one of our own; and also to compare fingerings, and select, if we can find different editions.

Fingered Editions. In choosing fingered editions for study, we should never choose those (like Charles Halle's) that finger *every* note. Nothing is more confusing. The numbers placed above or below the notes should be applied only as guides to the groups of fingering or indications of something unexpected. One should regard them as danger-signals or finger-posts. Thus, one will welcome them as friends and not disregard them as bores. As teaching and self-teaching editions, I would recommend the German "Cotta" editions of the classics—*i.e.*, Clementi, Haydn, Mozart, Beethoven, etc.; Peters' *Kroll* edition of Bach; the Bote and Bock edition of Chopin; and Madame Schumann's edition of Schumann's works. Matthay's "Popular Teaching Pieces," a selection mostly from the earlier composers, as Scarlatti, Paradies, Bach, etc., supply material of the very best for serious students. Here I would urge that all teaching of fingering should now be based on the 1 2 3 4 5 notation and *not* on the × 1 2 3 4, for the very good reason that the cheapest and best and all foreign editions adopt the first mode. Pianoforte music when first published appears, as a rule, unfingered, but fingered editions soon appear if the works are popular; and Germer has done a good deal of the finger editing of such modern composers as Grieg and Tschaikowsky. Siloti, the Russian pianist, has done the same for many of the composers of the Russian school whose music it has been his mission to popularise.

We may have learnt to get out of the instrument all it can give; our tone-production and agility may leave nothing to be desired; yet, unless we learn to phrase well, we shall be incapable of giving musical pleasure to anyone.

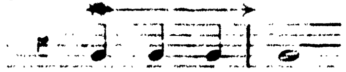
Phrasing. By phrasing we mean the conception and execution of notes as intelligent and intelligible utterances. Music is at all times an intelligent and, as a rule, also an emotional utterance, and unless we understand what we have to play, alike intellectually and emotionally, our technique will be a useless accomplishment. For the intellectual grasp of the larger forms, much study and much hearing of music is necessary. For emotional sensitiveness our own temperament must be answerable. To be a good reproducer one must be first a sensitive plate oneself—the music must have affected us strongly before we can affect others by our rendering of it.

Although using the keys with intention and intelligence, we can give expression only to what we ourselves have felt and seen. The reproduction of a work of art is such a delicate operation that *all* our attention is called for, *every* time we attempt it, for every note we play.

Artists say it is practically impossible to reproduce a "Venus de Milo" in marble, and yet this is the sort of thing we pianists attempt every time we try to play a Sonata Appassionata, for example. We may learn much of the generating causes of musical expression by reading such books, which are cheap and accessible, as Bertenshaw's "Musical Form," Riemann's "Musical Æsthetics," Lussy's "Musical Expression," and Carpé's "Rhythm and Phrasing."

Riemann, for instance, shows how music, in the *very nature of things*, expresses our feelings—that the pulse in music, for instance is analogous to our own pulse—the crescendo and accellerando the natural expression of the human body under the influence of mental excitement, the *decrescendo and diminuendo as naturally that of recurring languor*. Besides this, music can be "realistic" and imitate things outside of us—things that we see or hear.

The Importance of Rhythm. Much of this tone-painting is achieved by rhythm. We must see to it in our performance that this rhythm shall be *alive*, shall always be freshly *willed*, shall never sink into mere automaticity. We should at all times strongly picture to ourselves the intended rhythms, even in mere scraps of technical exercises, seeing to it that even such a simple scheme as this shall have an intelligible musical shape :



Out of such a fragment Beethoven made his C Minor Symphony. Let us even feel that finger exercises are possible fractions of some great whole.

Where Riemann theorises, Lussy lends immediate practical aid, and is full of examples. He treats of the various kinds of accents—the metrical, grammatical or bar accents ; the rhythmical or phrase accents ; and the rhetorical or pathetic accents.

In his "Introduction to the Elements of Music," Niecks (best known as Chopin's biographer) says : "The phrase accent sometimes modifies and even altogether sets aside and reverses the bar accent." For the phrase groups bars together, and we cannot very well *group* or unite them if we constantly disconnect them by an *equal* emphasis on the strong beat of each. To make musical shapes definite and musical utterances articulate, we may use either a complete disconnection of tones, a momentary silence (often too short to be even indicated by a rest), or a partial disconnection got by accentuation.

We must keep always before us a vivid mental picture of the phrasing, and *listen* to our own performance, that in it we may *realise* this picture. But the thing to be kept chiefly in mind is that every musical phrase *goes* somewhere, that a group of notes means nothing musically until it is, by accentuation, made to point to a climax, a phrase-object, found, as a rule, towards the end of each. "We must learn to perceive," as Matthay says in his "First Principles," "what the music does, where it is that each idea, phrase, sentence, and section has its natural climax or crises." As, for instance, the opening bars of Chopin's E♭ Nocturne :

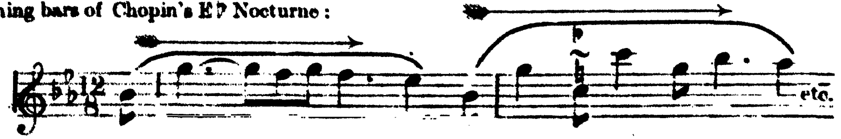
Simple melodic waltzes, with an easy, throbbing accompaniment, make excellent early studies for the purpose of acquiring such rhythmical or phrase sight, and also for the study of tone-quality and tone-quantity as contrasted in melody and accompaniment. Study such waltzes *before attempting* the art waltzes—the Chopin waltz, for instance—which get many of their effects by deviations from the normal, by the unexpected. We must learn rigidly to obey the law before we can take an artist's licence with regard to it.

Accents. In playing strongly accented notes, let our artistic and our technical judgment both be on the watch, the one seeing to it that the accent is neither stronger nor weaker than is justly due, the other that we guard against (1) using down-arm force, (2) pressing on the keyboard after we hear the sound begin.

Accents and all marcato effects are pitfalls in this respect. We must resist the natural tendency here to use down-arm force, the finger and hand must act *upwards* against the loosely lapsed arm. The unexpected should, as a rule, be well marked ; syncopated notes, therefore (deviations from the natural metrical accent), and chromatic notes (deviations from the diatonic scale), unless the latter be mere unaccented passing notes, call for an accent. Discords are intended to arrest the attention—some musically nonsensitive people play the most poignant discords as though they were as innocuous as the tonic triad. Mentally follow the resolutions of discords in harmonic progressions, and learn, in playing chords, to bring out now one note and now another to this end. To effect this, allow the finger that is to bring out a particular note of the chord to take more weight than the others.

In chord playing from the wrist, the fingers must take up the position relatively to the hand before it descends. To this end we must learn to *mentalise* all the fingers that are to be used in the performance of a chord before we fulfil the act of playing it.

Full chord playing is an important department of modern pianoforte work, and must be specially studied. We must learn to play full chords with loose-arm weight behind the fingers—a consideration which we have already studied—and, when required legato, connect them as closely as possible by beginning the lateral arm-movement while the hand and fingers are still, as it were, lazily lying on their keys, the pedal being used to make the actual tone continuation—this for the interpretation of such passages as the hymn-like chorale middle section of Chopin's Nocturne in G Minor. Here we have an invaluable study in chord phrasing. Connect the chords in groups of eights by the rhythmical balance of the accents and also by the tone.



The Use of the Pedals. This brings us to the use of the pedals. To a passage of this sort we may apply what is called the "syncopated" pedal. The general rule as to pedalling with the damper pedal (the right foot pedal) is that we may depress it, and keep it depressed, as long as the harmony of a passage does not change. When the harmony changes we must lift the foot and release the pedal, instantly re-depressing it if we wish a continuous pedal effect. For detached chords the pedal may be depressed at the same moment as the keys, but in the course of a legato passage the finger and foot must not go down simultaneously. On the contrary, the pedal must rise just as the next keys are being depressed, immediately going down again, however, to continue the new sounds. This "syncopated" pedalling *joins* the sounds without allowing them to overlap. If foot and finger rose *together* there would be a short silence between the sounds.

This syncopated pedalling may be applied to every note of a melody or every chord of a harmonic progression, such as the above-mentioned Chopin chorale. Such constant pedalling in great portions of modern music is absolutely essential, but we must not lose sight of the great importance of *omitting* the pedal at other times. Many players of to-day over-pedal, thus losing the advantage to be gained by the contrast between pedalling and its total cessation. Chopin without the damper pedal would be like a Whistler picture reproduced in the style of Sir Noel Paton. Schumann was a still greater devotee at the shrine of the damper pedal; he did not care about harmonic exclusiveness, he liked to put down the pedal and to keep the course of harmonic changes in unbroken legato—too much so very often, in fact, and the pedalling marks in many of his works require much revision. Chopin was much more refined in his use of the pedal, probably because he was a better pianist. Mendelssohn was ultra-refined, and we must bear this in mind in playing his music; let his outlines be definite, his colours pure, his rhythms free from emotional exuberance; try particularly to be "good," as he himself puts it, and refrain even from a self-indulgent rallentando at the end of a composition.

Use of the "Una Corda" Pedal. The "una corda" pedal should be used sparingly. Modern composers, as a rule, indicate the use of it, as, for instance, Grieg in his well-known Lyric pieces. Very frequently it is used in combination with the damper pedal; the two are quite independent. Use both pedals very sparingly, if at all, in performing the music of Scarlatti, Couperin, or Bach. The first two composed for the harpsichord, and even Bach's clavichord, although it did possess some sensitiveness of touch, was not much like a modern piano.

Part Playing. Much modern pianoforte music consists of a melody with accompaniment. We must listen to the *end* of each melody note as much as to its beginning, in order that we may join it perfectly to the following melody note, and that we may choose the right tone for this succeeding note. To bring out the melody also, we must be careful to *subdue very much the accompaniment*, and not let our attention to the *phrasing* of the *melody* be distracted by the accompaniment. If the melody be at the thumb side of the hand, as in Schumann's beautiful Romance in F♯, and in many popular waltzes, remember the use of the rotary relaxation there; if at the little finger side, as more frequently happens, we must see to it that the forearm rotary relaxation helps the weak fingers at that side. Have a melodic ideal over present—imagine such melodies given out by the 'cello, the violin, or the voice, and imitate these. When a note is sustained while other notes play round it, *listen to the sustained note to the end.*

It is not enough merely to keep the key down; we must connect the sustained tone intelligently with that which follows it in its own part. Practise Bach for such part playing, the playing of several melodies one above the other—his melodies are more difficult to perceive and more difficult to connect subtly than even Chopin's—and listen to all the interwoven parts.

Crescendo and Diminuendo. A perfect crescendo or diminuendo, especially if long sustained, is seldom heard, and yet they are among the most entrancing and convincing of musical effects.

The crescendo in performance was not introduced till late in the eighteenth century, in the orchestra at Mannheim; and when the audience first heard this new effect, it is said they rose from their seats like one man. Realise the emotional possibilities of *nuances* (shading). The secret of getting a good crescendo is, as Von Bülow, the cleverest and wittiest of nineteenth century pianists, puts it, "when you see the expression mark 'cres.' play softly, when you see the mark 'dim.' play loudly." This gives us something to work away from, and prevents our making the common mistake of *at once* playing louder at the beginning of a crescendo, <, or softer at the beginning of a diminuendo, >.

The same thing holds of accelerations and retardations of time. Accelerando must be gradual and continued, as must ritardando. It is different in the case of ritenuto, which is a *sudden* slackening of the tempo. It requires all our attention to keep an accellerando really accellerating to its climax, and a ritardando really slackening note by note till all animation dies out; "and we must remember," says Mr. Matthay, "that all such effects, both of tune and time, must increase with an increasing *ratio* to be effective." Reference must be made here to time accents, a most effective means of expression. Composers use them in the form of syncopations, as Chopin does in his waltzes:

Time Accents. In performances we can make a melody note *seem* accented by making it either slightly longer than is due or letting it begin just a very little too late. We may also delay a little the entry of the accompaniment *after* a melody note which we wish to make specially prominent, and then, by hurrying the time a very little, make up for this irregularity. This is the principle of the tempo rubato, which even Mozart employed in a measure, as we learn from his letters, and which must be applied to all modern music since the time of Chopin and Liszt. These two pianist composers were the great protagonists of the tempo rubato, or robbed time.

Although seemingly whimsical and wayward, it is really rooted in a strong sense of rhythmical balance, and Liszt compared it to a tree firmly rooted in the soil, whose branches were yet played upon by the wind. Only those who are anchored to a perfect feeling for rhythmical balance and symmetry can safely trust themselves to the waves of tempo rubato. It takes effect in prolonging some notes, hurrying others, dragging one part of a phrase, accellerating another, either dragging or accellerating a series of phrases and making up for it with the remainder of the period; but, whatever form it takes, it should always be so perfectly balanced that the period ends where the strict metronome beat *would have had it end* had the time never been bent from the straight line. Without the tempo rubato, the music of Chopin would be vulgarised, and much of Schumann rendered unintelligible; but we must beware of applying it to any extent to the earlier composers, as Haydn or Schubert—it would destroy the meaning and symmetry of their music.

Ornamental Notes. It is a mistake to hurry the rendering of ornaments—in cantabile music we should see that we *sing* them. Let them be *grace* notes in very truth, and let them always heighten the particular beauty, and intensify the special character, of the music they adorn.

Quick, light ornaments should be played with as little weight as possible, remembering that such are in truth agility passages of short duration, and that the touch laws for agility must therefore be obeyed in them. Do not (as so many are apt to do) lift away the weight of the hand in preparing for this. Most delicate finger-work, other than pianoforte playing, requires, possibly, that the hand should support itself by its own muscles, and so, instinctively but wrongly, the inexperienced player prepares for a delicate passage by lifting away the weight of the hand. Such a proceeding is fatal to ease, certainty, and beauty of tone. As already pointed out, we must let the hand lie on the fingers, and see that it makes no exertion of any kind in such light passages. "Prepare" such a passage with as many fingers as possible, feel the resistance of keys, let the loose, light weight of the hand *lean* against the keyboard, then imagine the whole group as one concept—not conceiving each note singly—thinking only (if it be a long passage or cadenza) of the notes that form the landmarks of the passages and the fingers that fulfil these "landmark" notes, and leave all the rest to subconscious automaticity.

See that we breathe deeply, fully, freely before starting on one of these long embroideries, such as occur, for instance, in Chopin's Berceuse, and keep the whole body passively quiet meantime, as the least thing will disturb us in the execution of such fairy-like webs of sound. *Holding* the breath through difficulties and subtleties of this kind is a bad habit to fall into. See to it that we use either what Mr. Matthay calls "passing-on touch," or first species, or perhaps second species for the louder portions, and make sure of the preliminary and continuous resting. Let no excitement and nervous tension communicate itself to the up-muscles of the hand, and so cause it to become active to the extent of lifting away its own weight. Then, with a clear mental picture of what we want to produce, "the rest shall be added unto us." To ornaments, as to melodies, the tempo rubato may be applied; shakes may be begun slowly, accelerated towards the middle, and slackened off again towards the end.

Beethoven's Influence on Technique. When sufficiently advanced, we should make not only Bach but Beethoven our daily bread. He will force us to give attention to the music, and to develop a varied tone-palette for its expression. We cannot lazily dream through a Beethoven sonata after having once mastered the art of touch-variety. He expects so much from us, and his expression is often so unexpected, that there is no moment during his music when we may cease to be acutely alert, alike musically and instrumentally. Judging the due amount and quality and time-place of every note from start to finish, and watching key-resistance to see that we realise it, we must get a fine loosely-left arm and well-braced finger and hand for his frequent sforzando staccato chords, and give them with a convincing, well-nourished tone, or sharp finger-action instead, as the case may require. We must learn to obey his characteristic crescendo followed by a sudden piano, and learn to change our technique as suddenly as *he* changes his mood, from the passionately virile to the passionately tender.

From the moment of reading out a Beethoven sonata we should try to "paint" it—that is, try to play it with the constantly changing touch-varieties required. We must not say, "I shall get the notes first and then see what they mean," but look for the meaning through the notes by obeying them in every particular from the first. We should not begin the serious study of Beethoven till we *can* proceed thus. Of course the bravura work—the difficult passages and presto movements—will require to be worked at out of focus, but try even when working at these to conceive their place in the finished scheme. Remember that we never can express all there is in such music unless we obey the laws of tone-production, but remember also that artistic reproduction is the art which conceals Art, which is the goal of all technical study.

CHINA AND GLASS DEALERS

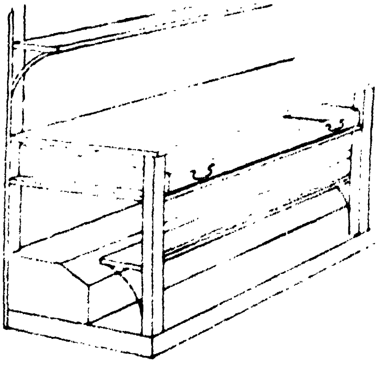
The business of retailing glass, china, and earthenware affords a fair return for the capital invested, whether as a department or as a self-contained business. From £60 to £100 laid out in "pots and pans" would purchase a stock which would make a capital display as a side line in a furniture, drapery or hardware business. Twice the latter sum—more, of course, if possible—would suffice to make a good start on independent lines as a glass and china merchant.

It is erroneous to assume that it is a business only suitable for ladies. Properly conducted, it affords sufficient scope for a smart man to make a good living and something more.

The Secrets of Success. A thorough knowledge of the markets, a capacity for salesmanship, and good window accommodation, with adequate show-rooms for displaying the best of the stock, are the qualifications and facilities required to ensure success. A good deal of glass and china can be stored in a comparatively small space, and large stock-rooms are not necessary, but a good light shop, with one or more windows, low down, and deep from back to front is essential. In looking about for a centre in which to open, the retailer must not overlook the outside baskets or boxes. A good deal of trade may be gathered by such fixtures. The public come round to buy a few odd plates or cups and saucers, and these they expect to be able to purchase after examination. They do not care to step in and ask for half a dozen odd cups, but if these be placed outside they pick them out, walk in and pay, stop to look round at better class wares, and usually leave actual or prospective customers. That this is the case has been proved over and over again. We know of one dealer who took premises in a large town for which he paid a rent as high as £300. Without a customer to start with he built up in five years a big cash business, firstly by always having plenty of cheap bargain stock on the pavement outside, secondly by utilising the windows to their utmost, and thirdly by keeping suitable stock inside. His windows were always attractively dressed, no gaps were allowed to be seen, sales from the windows were encouraged, and plenty of inexpensive but attractive stuff was kept well to the front in the shop itself.

Fittings. It is a mistake to suppose that fittings which might serve for such a business as that of a draper or grocer will suffice for the glass and china dealer. Special fixtures are necessary to store the stock conveniently, and to display it attractively.

The details which follow are those observed by a dealer who, as manager and employer, has fitted up a number of shops. Along both sides of the shop, if it be narrow and long, should run a sole not less than 2 ft. 3 in. nor more than 2 ft. 6 in. from the wall, and 4 in. above the floor. On this, next the wall, there should be on one side or both, bins, 18 in. wide by 12 in. deep, to hold the stock most in demand. To hide this stock 8 in. shelves along the front may be fixed for the reception of such wares as teapots and flowerpot vases, for which latter there is always a ready sale. Two feet above the sole is a double bench with an open front into which trays can be slipped. These last are useful for the reception of samples of tea services, trinket sets and the like. The top of the bench is available for dinner services, and above this, right up to the ceiling, should come shelves, 12 in. wide, supported on simple iron brackets secured to battens from sole to ceiling. The space between the shelves will vary, but at least one should be 17 in. clear above that immediately below, for a smaller space will not accommodate a toilet basin and jug. The general idea is illustrated in the sketch herewith. At the back and round the show-room, if there be one, plenty of 12 in. shelving, with "straight" hooks along the edges for jugs, should be provided, and it may be remarked that it is a false economy to try and make 11 in. boards, cleaned on both edges, answer this purpose. A foot is none too wide. In every case, as well as in the floor stands next described, the sole must be fixed. Its provision obviates much loss from crockery broken by the sweeping broom and the toes of assistants and customers.



A CONVENIENT CHINA-SHOP FIXTURE

Except for a short counter for packing up parcels, and perhaps a little desk, the floor ought to be reserved for show benches, 36 in. above the floor, and not less than 3 ft. wide. Under and upon these, movable tiers for the reception of stock may be devised. The great thing is to provide plenty of flat spaces upon which stock may be placed ready to the hand of customers. It is safe to state that plain figured stock that can be handled and examined freely will sell itself over and over again.

The colour scheme should be simple and severe—walls distempered, or papered with a self-colour paper—brown paper is excellent—and all the wood painted and varnished without any relief. Black takes a great deal of beating, but a dark sage green or an "invisible" blue may be tried.

Stock Fixtures. Stock fixtures, whether in the basement, warehouses, or stock-rooms, may be open framework, built up of 3 in. by ¾ in. deal, arranged with from 2 to 4 in. spaces between the battens. This saves timber, and facilitates the handling of the stock. The fixtures should be divided to about 27 in. every way—that is, equally dimensioned from back to front, top to bottom, and in width. The front of each bin ought to be protected by a batten or two, nailed along the front, if small stock such as tumblers are intended to be stored.

Salesmanship. The second point of importance is a capacity for salesmanship. This cannot be taught by book, but some remarks may help the novice. He must have a thoroughly sound knowledge of the technical details of his business, and these, although not over numerous, are peculiar. Earthenware is bought by count on a plan recognised by no other trade, and this is apt to puzzle a beginner. Take pudding-bowls as an example. A dozen does not mean twelve, but a variety of sizes between nine and forty-two to the "dozen." That is to say, the dealer buys nine, or eighteen or thirty, as the case may be, for the same price as he pays for twelve of a certain size, the nines, of course, being larger and the others smaller, than the normal or basis pattern. Knowledge of all this comes with experience born of actual contact with the goods. It is not of the kind required when dealing with purchasers. These, however, like the salesman to tell them facts about the quality of the ware—how it is decorated, and its probable utility and durability under ordinary conditions of wear; as in many other businesses, a "talking" acquaintance of one's goods greatly facilitates the sales, and the glass and china dealer needs, therefore, to learn all that he can about the novelties that are introduced to his notice from time to time.

Where to Buy. The third essential to success is a knowledge of the markets. At the beginning a novice may place himself in the hands of a reputable house handling the productions of half a dozen manufacturers. There are many such in London, mostly in the vicinity of Holborn Circus. Owing to the conditions under which the pottery trade is run, these firms have ordinarily a pull upon the sources of supply which preclude the small man from getting better terms at first hand. As a retailer's business progresses, however, manufacturers' travellers begin to find out his shop, and invitations will follow to visit their show-rooms, opened in some hotel in the place or in some neighbouring town. These displays of new wares should on no account be overlooked. A visit carries no obligation to purchase, but unless one is made competitors will step in and secure sole selling rights in the best patterns, and the most attractive novelties.

Buying Direct from Works. The next stage in the acquisition of knowledge of the markets is a periodical visit to the Potteries. At first the dealer may have some difficulty in getting what he wants on such occasions, but if he makes it clear to his wholesale people that he is bargain hunting, and that unless he gets bargains there will be no stock orders, these visits will not be in vain. Obviously, the manufacturer of pottery wants to sell his best wares at full prices. He is not proud of his failures, and unless a dealer can convince the maker that he can sell best and "seconds" side by side, he will hear little about and see less of the latter on the occasion of a visit to Staffordshire. As, however, "seconds" are always being made, the manufacturer is usually keen to meet the man who treats with him fairly in the matter of sales of his first-class productions.

Seconds. It is commonly supposed that "seconds" cannot be mixed with the best class of trade. With but few exceptions, however, there is always room in a good general shop for well bought "seconds," but they *must* be well bought, or the dealer is likely to become filled up with unsaleable stock. It should be explained here that the term "seconds" is applied to pottery which is quite sound but not perfect. Cracked and chipped wares would not be included, ordinarily, in the category; but articles with fire marks in them, of slightly irregular shape, or imperfectly decorated, would be entitled to be called "seconds." This quality is usually offered in assorted crates at £5 or £10, the selection being made by the manufacturers. At other times—and this plan is the better of the two—the dealer bids an "over-head" or "overall" price for what is shown him at the works; that is, he takes the parcel at per piece, according to the class of goods offered. Thus, he may buy a thousand cups and saucers at a penny apiece, or a hundred toilet basins and ewers, etc., at a shilling each. When he gets these home, he may find that he has to sell half the cups and saucers at just a trifle over the price he paid for them, but the rest may fetch any price between 3d. and 1s. per pair, and thus a handsome profit on the outlay is reaped.

What to Buy. The stock will, or should, consist of certain well-defined classes of ware. First there will be the common kitchen goods in stoneware, such as glazed brown bowls for bread and cake making, and washing-up dishes, foot-warmers, breadpans, cane and white bowls, and heavy ware generally. Next there will be white pudding-bowls, basins, pie-dishes, common jugs, "pheasant" or "willow" pattern plates and dishes, brown Rockingham teapots, and the like. Better than these, will be printed (decorated) earthenware jugs, teapots, cheese dishes and covers, and then come sets of toilet ware, dinner services, the latter being obtainable also in a higher grade known as semi-porcelain. This class of wares comes from the district known as the Potteries. The chief towns where this industry is carried on are Stoke-on-Trent, Hanley, Longton, and Burslem.

[illegible] Porcelain, or china, as it is commonly called, comes also from these districts. Tea services and fancy table dishes and appointments naturally come under this head, and in this department the Potteries are unbeaten for style, quality, or price. Curiously enough, trinket sets for the toilet table are made only in limited quantities in Staffordshire. Large quantities are imported from Germany, and these have to be sought for in the London stock-rooms already mentioned, for most of the agents also represent one or more Continental houses, while others are to be found in and about Fore Street, E.C.

Glass. Fancy glass ware, and, indeed, most of the fancy goods retailed in a china and glass warehouse, come from the Potteries. Stourbridge is the centre of the glass-making trade, and much of the best crystal table glass comes from that quarter, as, for example, wine-glasses, tumblers, finger-bowls, table decorative glass, salt cellars, water jugs, carafes, and ups, either plain or cut. Moulded glass also comes from Staffordshire, but Belgium and the Continent compete for this class of trade, and the United States also has made a bid for a share of the business. The firms competing with the British makers are almost all represented in London by sole agents or wholesale houses.

Profits and Expenses. The profits on the sale of china, glass, and earthenware vary largely. Some of the common stock carries barely 20 per cent. profit on the cost prices. Better classes of earthenware, toilet sets, dinner services, and the like, show about 30 per cent. China and fancy glass carry 40 or 50 per cent. margin, and good utility glass in good class districts about the same. Moulded glass varies between 25 and 30 per cent. Seconds well bought often run to from 50 to 70 per cent. profit on the outlay, and many of the fancy ornaments can be bought to show a cent. per cent. profit on cost. On the aggregate an average gross profit of 30 per cent. on the turnover, may be expected. Against this, expenses have to be set off. Rent is undoubtedly the heaviest, and ought to be. Success cannot be won in a back street, and the first thing a dealer must face is a stiff rent, with its concomitant of heavy rates and taxes. Other than this, the expenses are comparatively small. The assistants required in the shop will be young women, earning from four to possibly twenty shillings per week. Something must be allowed for breakages, and carriage and packing are important items which will require close watching.

Advertising. The question of advertising is being dealt with at the end of this course. Here it is necessary only to emphasise its importance in the glass and china trade, and, whatever plan is adopted, it should be systematically pursued. How much of the profits should be located to this purpose each man must decide for himself. Probably 5 per cent. of the turnover is not too much to set apart. Without doubt, £50 out of every £1,000 taken could be profitably spent in circularising the town areas and bill-posting the outlying country district, besides which the local press must on no account be neglected. In the last case, however, patterns and prices ought to be given in detail, and different matter ought to appear each week.

A good plan in this connection is to advertise every time one has special bargains to offer, and to make a point of having special lines for the purpose at least two or three times a year. A reputation for real bargains is the best advertisement a dealer can have, and bargains cannot be offered without vigilance and a first-hand touch with the manufacturers or their accredited agents. It always pays to cultivate personal friendship with the manufacturers and their agents and travellers.

CHIROPODISTS

Chiropody is sometimes classed with "pedicure," and pedicure has been described as doing for the foot what manicure does for the hand. But chiropody, in its complete and proper application, embraces more than either. Chiropody should not be confined, nor allowed to degenerate into mere decortication, or corn-cutting. It should be approached through the portals of preliminary study of the anatomy of the foot—its proper functions and their abuse, its proper clothing and the results of improper clothing, its peculiar maladies and the causes of them. There should also be a real mastery of the remedial treatment required. All available technical literature should be carefully studied, particularly those works which treat reliably of excrescences, suppurations, ingrowing nails, etc. A knowledge of chemistry in its relation to asceptics, antiseptics, and curatives, together with local anæsthetics for deadening pain in the more complicated and difficult operations, is also an essential to success.

Scope of Chiropody. The true status of chiropody is that of a specialised form of minor surgery. It is extensively linked on to the ancillary qualifications of the hairdresser's saloon, and no doubt it affords a platform from which the barber, by proper study and skill, may regain something of that nobler position which was once held by the members of that trade, as barber-surgeons, before the surgeons divorced themselves in the time of Henry VIII. In practising chiropody, the barbers are, in fact, merely continuing a form of minor surgery left to them by the surgeons at the time of their separation from their former coadjutors. It may be true to-day that a patient suffering from foot troubles may obtain superior medical advice from a doctor; but it is equally true that the patient would get a more dexterous use of the knife for painful corns and callosities from the expert chiropodist. Few people, nowadays, would hie them to a surgeon to extract a painful corn, or foot wart; and it follows that chiropodists, or hairdresser-chiropodists, have a fair field of this minor surgery open to those of them who approach it from a scientific standpoint.

Instruction. There is no system of apprenticeship, or its equivalent, in the chiropodist's calling. Nor are there any recognised teaching institutes. The usual procedure is for an aspirant to take a course of lessons from a practical and experienced practitioner, whose fee is generally about 10s. 6d. per lesson. Half a dozen such attendances, with interim practice on acquaintances and friends, should qualify a pupil to deal with ordinary corn-cutting. The lessons are at first directed to guiding the student with regard to what he should not attempt; in other words, to keep him well within a circumscribed area of primary treatment until his own intelligent interest in his work, combined with full practice, and the necessary experience, should make him competent to undertake the cure of the more advanced and complicated disorders of the feet. For a course of six or ten lessons at, say, 10s. 6d. each, there is usually an understanding between pupil and teacher that the former can keep in touch with the latter, in order to ask questions and seek advice in any cases with which he may come into contact, and which present some difficulty or possess some uncommon feature.

Nature of the Work. A qualified chiropodist should be capable of tending all the maladies indigenous to the foot—chilblains, bunions, malformed toes, freakish and ingrowing nails, callosities resultant from walking, or other cause, soft and hard corns, etc. That is the bona-fide standard to which a genuine chiropodist should aspire, and it is perhaps to be regretted that in Great Britain there is no recognised Board of Examiners to sift quacks from qualified operators, and certificate them accordingly. But this may come.

Where Chiropodists Practise. Taking the majority of chiropodists, it may be said that they were barbers first; and it is generally found that Turkish baths present the best opportunities for acquiring practice and proficiency. In the few cases in which chiropodists are employed exclusively, the pay is £2 per week, and commission, which averages a similar amount. Hairdresser-chiropodists do not actually command any more, but they often get it in the form of commission, which in many instances is arranged on the basis of an allocation of half the fees charged. Some chiropodists only obtain 25 per cent., but a man who "knows the ropes" insists on, and secures, the higher proportion of his earnings.

Charges for the Work. The charge for ordinary corn treatment, to state an average, is 2s. per foot, but this is raised to 2s. 6d. in some instances, and by the best practitioners to 3s. 6d. For difficult cases, demanding more advanced skill and experience, the fee fluctuates between 10s. 6d. and £1 1s., according to the nature and the extent of the treatment involved. An outfit of instruments—supplied by the chiropodist himself—costs from 25s. to £3. Specially adapted chairs and stools are employed by the foremost men, at varying prices.

Legal Status of Chiropodists. In the matter of safeguarding the profession and ensuring that only properly trained and efficient chiropodists are permitted to practise America is well ahead of Great Britain. A society of chiropodists exists, for example, in the State of New York, under the name of the Pedic Society. Organised in June of 1895, members are admitted to this society only by examination, and no one may practise within the confines of New York State until he has shown himself to be fully conversant with the anatomy and physiology of the feet, therapeutics, chemistry, minor surgery, and bandaging. If the student can show an average proficiency of seventy-five per. cent. in these subjects, he is granted the certificate of the Pedic Society, which entitles him to practise the art of chiropody within the State. The examiners adopt a high standard of examination, and to secure the required percentage of points the candidate must be really competent and have studied deeply and thoroughly.

The chiropodists of the State of Illinois are similarly supplied with their representative institutions, and have a Bill before the Legislature at Springfield, seeking powers to enforce examination and registration of all chiropodists practising within the State. The membership fees of this society are as follows: Initiation, one dollar; assessment, 10 dollars; monthly dues, 50 cents. The assessment fee was required from all members at the time of the society's formation, to supply the necessary finances, and all new-comers are now required to contribute a similar sum.

CLOTHIERS

To many young men engaged in the clothing trade the all important question is, What capital is necessary in order to start in business and achieve success? The answer to this query must depend on the inquirer's idea of success. If he be content to make only as much as he would in a situation, then the answer is fairly easy; but as many young men get the notion that to be in business for themselves warrants their living in a far more extravagant way than formerly, the problem becomes more complex.

Let us assume the case of a man who would consider himself successful if his returns reached from £1,200 to £1,500 per annum. It may be taken for granted that he will not turn over his stock more than two and a half times a year, which means that he will want a stock of about £500, and to hold this and take his discounts he should have a capital of from £200 to £250. Taking it for granted that such is forthcoming, his first step should be to go to some firm of repute with whom he intends to do a fair share of business and state his case with the view of opening an account with them on the usual trade terms, and asking them to act as his reference house. Needless to say, the best possible firm should be chosen for this purpose, as their standing will influence the opening of other accounts.

Taking a Shop. The acquisition of premises will be the next thing, and in doing this many points should be considered. The position should be as commanding as possible, and in proximity to other shops patronised by the class of customers for whom he intends to cater. The fact that the business of other clothiers is carried on near by is often an advantage, as it creates a market for goods of this class.

It is always advantageous to have a corner shop if possible, and under any circumstances it is essential to have good windows for display. A double-fronted shop is very suitable for clothiers, as one side can be devoted to ready-made clothing and the other to hats and ties, hosiery, etc. The rent should not exceed 3 to 4 per cent. of the anticipated returns—thus, anticipated turnover, £1,500; rent, from £45 to £60 per annum. The shop should, if possible, be taken for a year, with the option of a lease for seven, fourteen, or twenty-one years. Fronts are often put in to suit tenants, especially in new premises; but if a new front has to be put in, and extensive alterations made by the tenant, the rent should be correspondingly lower. The tendency of the times is to go in for very elaborate shop-fronts, name-boards, and fittings, but we would advise caution. It is certainly most desirable to make a good start, but most essential that in doing so the starter should not cripple his finances.

Fittings. The fittings of a clothier's shop need not be very costly. Plain shelving of sufficient width and depth to take the stock will suffice, and the shelves should not be carried too high.

One or two mirrors are essential, and they can often be arranged very effectively at certain angles, so that, while they serve the purpose of letting customers judge the suitability of the articles tried on, they also add to the appearance of the size of the shop. The fittings for a clothing window need not be elaborate. A few shoulder busts, a few planks and boxes on which to stand them, and a supply of neat but effective tickets, will suffice; but for the outfitting window a supply of brass rods and brackets, hat-stands, etc., will be necessary. We have seen many cheaper substitutes used for brass fittings for this purpose, but in the long run the brass ones are the most effective and the most economical. Tickets are, of course, an essential, but their style must be in harmony with the class of trade catered for, and should always be refined rather than gaudy, as the former invariably suggests a better quality of goods than the latter. Many business men have the leading features of their businesses indicated by enamel letters on the upper part of their windows, and this helps to make the premises attractive. The question of light must be to a certain extent decided by local conditions. Electric light is clean and very effective, but it is a mistake to have very powerful arc lamps for illuminating purposes; they are trying to the eyes of customers, and give an unnatural appearance to the goods. Gas has many advantages, especially when the most up-to-date fittings are used. To sum up the question of fittings, let them be selected with taste, and with the view of making the window one of the best possible advertising agencies.

Buying the Stock. Before starting to buy, the beginner should carefully plan his expenditure out. Let us suppose that he feels justified in purchasing a stock to the value of £500. He must decide how much of this will be spent on ready-mades, how much on hats, hosiery, shirts and collars, ties, mufflers, bags, rugs, jewellery, and sundries. Assuming that he intends making the sale of ready-made clothing the mainstay of his business, the larger portion must be devoted to goods of that class.

Some men specialise in certain departments, such, for instance, as juvenile clothing, trousers, or any other line they may fancy; but in any case the speciality chosen should be an article for which there is a good demand, and which can be done really well. Having decided the various proportions of the stock, the details must be decided on—such as sizes, prices, etc.—and in both cases it will be safe to anticipate a larger sale of medium sizes and medium prices. In the men's department, sizes 4 and 5 are the best sellers, as they fit men of 36 to 38 in. chest measurement. The larger and smaller sizes must, of course, be stocked, but only in about half the quantity. Some of the cross sizes are exceedingly useful, and enable the clothier to fit the tall and thin, or the short and stout types, so that a selection should be kept.

Stock must be Representative. Generally speaking, the stock should be of as representative a character as possible; the patterns of the cloth and the styles of the garments such as will find favour with the inhabitants of the neighbourhood. Exceptional requirements can always be met by the aid of a pattern-book supplied by one of the wholesale bespoke houses who cater for the clothiers in this department. In hat stock, the best selling sizes are 6¾, 6⅞, and 7, it being the usual thing to assort them up in half-dozens, as follows:

One 6¾, two 6⅞, two 7, one 7⅛; or
One 6⅝, two 6¾, two 6⅞, one 7.

The same rule applies to collars and shirts. The best selling sizes are 15 and 15½ neck; but it is usual to stock from 14 to 17. This must be the plan to work upon, aiming at a representative stock rather than a heavy one, as in these days of quick conveyance goods can easily be replaced as they are sold out week by week.

Terms of Trading. It is usual for wholesale houses to date opening and season parcels forward for from two to four months, after which they give one clear month's credit (and sometimes two months), and allow 2½ per cent. discount. This means that the tradesman gets from three to six months' credit for his season's parcels; but for his ordinary purchases and sorting-up lines the terms are one clear month only, if discount is to be taken, so that goods purchased during February have to be paid for in the beginning of April, the latest date for taking the discount being the 10th.

Credit. It is, of course, essential that the young tradesman should take advantage of this credit as far as possible, but there is a temptation to overbuy when long dates are offered, and this all too often results in bad stock, so that while it is a great mistake to starve the stock, yet it is far worse to get it choked with unsaleable goods, which not only depreciate in value but lock up the capital in a very unprofitable manner. The young tradesman should carefully watch in these directions, for he can hope to get the best terms only when he keeps his financial engagements with the utmost punctuality. The usual terms for prompt cash are 3¾ per cent., though some of the best houses only allow 3 per cent. discount.

Readers may be advised to study the kindred articles in this course, particularly those on DRAPERS, GLOVERS AND HOSIERS, OUTFITTERS AND TAILORS.

Advertising. Assuming that the shop has been taken, and the stock purchased, the opening day comes in due course, and here let us warn against undue haste. Do not try to start before you are ready, for it often makes a bad impression that it is difficult to remove. The advertisements sent out should state clearly the class of business you cater for; they should have the address of the premises prominently brought out, while any special qualifications the tradesman may possess and which are calculated to enhance his prospects should be modestly mentioned. Do not spoil your advertising by claiming too much, but let it be marked by common-sense, as well as smartness, modesty and up-to-dateness. A study of some of the advertisements of some of the well-known houses of the trade is very instructive and helpful by way of suggestion.

Working Expenses and Profits. The working expenses of a clothing business ought not to exceed 12 to 14 per cent. of the turnover, and to meet this, a minimum of 25 per cent. profit must be made on the returns, which will necessitate the addition of 33⅓ to the cost (thus, cost 9d., sell 1s.,) with a higher rate on goods that are risky.

This will mean a careful watch on all outgoings, for it is only by keeping the expenses down that the tradesman can hope to succeed, and, as will be easily seen on the above estimate, he will make about 10 per cent. on his turnover for himself, which on a business doing £1,500 a year is only £150. Still, that is probably better than he would be doing as an assistant, and there is always the prospect that by energy and enterprise he may increase his business and eventually make a much more handsome income. This, however, will be possible only by constant attention to business, a careful study of the local requirements, and a courteous and obliging manner towards even the most inconsiderate customers.

THE PHYSICS OF THE WEATHER

Humidity and its Measurement. Wet and Dry Bulb Thermometer. Humidity and Health. Formation of Dew. Clouds and Rain

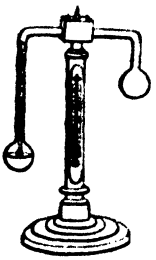
Group 24
PHYSICS
13

Continued from page 1742

By Dr. C. W. SALEEBY

IN a previous section [page 1139], when discussing the atmospheric pressure, we described the barometer, and showed how it may be used as a weather glass, the inference being that the state of the atmospheric pressure at any given time and place is the most important fact in determining the kind of weather experienced there.

But it is also very necessary, in order to understand the weather, to recognise the part played by water vapour in the air in affecting our sensations, and the obvious characters of the weather. This subject may appear to be a mere digression from the great subject of heat which we are discussing, but we must remember that temperature is one of the conditions which determine the amount of water vapour in the air, and also that the difference between such water vapour and the liquid water which we know as rain depends upon the latent heat, so-called, which is contained in the former.



DANIELL'S HYGROMETER

Water and Air. Water vapour is a constant constituent of the air, but its amount varies within very wide limits, and its amount may be expressed by the term, *the humidity of the air*. So long as the air is not saturated, it has a drying power, as everyone knows, and we have already noted that the motion of the air aids this drying power simply because it interferes with the tendency towards saturation. What we constantly appreciate by our senses is not the absolute humidity of the air—that is to say, the actual quantity of water vapour which it contains—but its relative humidity; which may be defined as the ratio of the actual density of the water vapour in the air to the possible density at that temperature—that is to say, the density of saturated vapour. Hence, on a hot day we would call air dry which really contained much more water vapour than the air which, on a colder day, we would call damp, the reason being that, in the first case, the air was much further from saturation-point than in the second case, and thus was, though absolutely much more humid, relatively less humid, and so possessed of much greater drying power.

We have already seen that in a mixture of vapours and gases each constituent exerts its own pressure independently of the others. The pressure of the water vapour in the air is thus exerted just as if nothing but water vapour were present. It depends upon its quantity and upon the temperature. When the temperature is lowered beyond a certain point some of the water vapour in the air is condensed in the form of dew, and that point is called the *dew-point*. This depends upon the pressure of the water vapour, and we have already seen upon what conditions this pressure depends.

Hygrometers. The *hygrometer* (from Greek *Hygros*, damp), must carefully be distinguished by the student from the *hydrometer*, which we have already described as an instrument for measuring the specific gravity of a liquid. The object of the hygrometer is to determine the humidity or dampness of the air, and this is usually done by determining the dew-point. The best-known hygrometer is named after Daniell. It consists of a bent-glass tube with a bulb at each end, one of which is half full of ether that has been boiled, so that the whole apparatus contains nothing but ether and ether vapour. The bulb containing the liquid ether also contains the thermometer, and is blackened. The other bulb is covered with cotton-wool, upon which a little ether is poured. This rapidly evaporates, and in order to obtain its latent heat of evaporation, as we have seen, it is bound to condense the ether vapour within the bulb. This permits further evaporation of the liquid ether in the other bulb, which, for the reason we are now familiar with, is also lowered in temperature. When the temperature falls to a certain point, dew appears on the blackened surface of the ether bulb. Thus, the dew-point can be ascertained. But the most accurate way of using the hygrometer is not to be content with one reading, but to note it, stop the cooling process, and then carefully note the temperature at which the dew disappears. The mean of the two readings may be taken as the dew-point.

Wet and Dry Bulb Thermometer. This is a thoroughly useful device so long as one remembers to keep it supplied with water. In the first place, there is an ordinary ("dry bulb") thermometer, which ascertains the temperature of the air. Beside it, there is another, the bulb of which is covered with muslin, which is kept wet. (This is usually done by attaching a piece of lamp wick to the muslin, along which, by capillarity, water travels from a reservoir.) The rate at which the moisture evaporates from the muslin is an index to the relative humidity of the air—that is to say, to its drying power—and can itself be measured by the extent to which it lowers the reading of the wet bulb as compared with that of the dry bulb thermometer.

Needless to say, there are simpler methods than any of these for ascertaining, very roughly, not the absolute amount of moisture in the air but its relative humidity. For instance, there is the *hygroscope*, the essential part of which is simply a human hair, which is longer when moist and shorter when dry. A piece of seaweed, also, containing a quantity of salt, acts as a hygroscope, since when the air is near saturation-point it becomes soft, whereas when the relative humidity of the air is low it becomes stiff and hard.

Relative Humidity and Health. The relative humidity of the atmosphere is a very important factor in our bodily comfort and health. The temperature of the warm-blooded animal body must be kept constant at all costs, and this is effected by a balance between the rate at which heat is produced within the body and the rate at which it is parted with to the environment. Now, we lose heat to the environment in two ways; in the first place, by direct *radiation*—a term to be later explained; and in the second place, as has been already hinted, by supplying the latent heat of evaporation to the *perspiration*, sensible and insensible, which is incessantly leaving the body. The possibility of controlling the temperature in the latter fashion entirely depends upon the relative humidity or drying power of the air, which is thus a far more important factor in our comfort than its mere temperature. Indeed, the temperature is more important in so far as it helps to determine the amount of water vapour which the atmosphere can hold than in any other way. When the amount of water vapour in the atmosphere is nearly at saturation-point, the evaporation of the perspiration becomes very slow, and hence our discomfort.

High temperatures, such as those of the tropics or a Turkish bath, can be endured with impunity only when the air is so dry, or rather when its relative humidity is so low, that we are able to part with abundance of sensible heat to the perspiration, in which it takes the form of latent heat of evaporation.

Dew. When we spoke of the hygrometer, we observed that the commonest means of ascertaining the relative humidity of the air consists in an observation of the dew-point. It is commonly stated that the natural formation of dew takes place in a precisely similar fashion to the formation of dew on the ether bulb of Daniell's hygrometer. At night, the warm earth rapidly radiates into the atmosphere the heat that it has received from the sun during the day, and blades of grass and the like, standing slightly apart from the earth, become especially cool, and cool the air in their neighbourhood, so that it can no longer hold the moisture which it could hold when it was at a higher temperature—in other words, it is cooled below its saturation temperature, and deposits its moisture. One of the most important factors in determining the amount of dew that falls is the rapidity of the radiation that occurs when the sun goes down, and this is favoured on a clear dry night, while, if the night be also still, the formation of dew is still further favoured, the lower layers of air having time to deposit their moisture before they are blown away. No doubt this is substantially true, but the botanists tell us [see NATURAL HISTORY] that plants constantly perspire (though the technical term used is *transpiration*, which is the French equivalent for our word *perspiration*), and it seems more than probable that a large portion, at any rate, of the dew does not consist of moisture deposited on the leaves of grass from the air, but consists of the water which has passed out from the leaves themselves, and the evaporation of which is prevented, owing to the cooling of the surrounding air below its saturation temperature, in the fashion we have explained. There is probably a large amount of truth in this, but, of course, the old explanation still holds entirely true for the formation of dew elsewhere than on plants. When dew freezes, it produces hoar-frost.

Fog and "Smog." In some parts of the world, where the radiation at sundown is extremely rapid, and where the air contains a very large amount of moisture, as, for instance, in tropical forests, where the dew is formed above the tree-tops, it falls like a shower of rain. This introduces us to a new subject. We have already seen that there is always a certain amount of water vapour in the atmosphere. A cloud also consists of water, but it is liquid water, formed by a lowering of the temperature of a mass of vapour-laden air, and thus having the same essential causes as dew. If the cloud be near the ground, we do not call it a cloud, but a mist, and if this be at all dense, we call it a fog. The present writer, however, strongly objects to the use of the one word *fog* to describe a dense mist, consisting merely of droplets of water, and also to describe the filth-laden products, full of smoke, particles of solid matter and sulphurous gases, which are called fogs in cities. The excellent suggestion has been made that this last should be called *smog*, in order to distinguish it from fog, which is relatively innocuous, and is essentially identical with a cloud.

Raindrops. When the very fine drops of water of a cloud join with one another, they form raindrops. Now it has been shown that, other things being equal, the smallest drops have no tendency to lose their individuality; they are protected by their surface-tension. The cause which makes them form raindrops appears to be some kind of electrical change in the atmosphere, so that the falling of rain must be regarded as a consequence of changes in those electrical conditions of the atmosphere, a complete knowledge of which will enable us, one day, perhaps, to understand the weather, and will rescue meteorology from its present position as the "Cinderella of the sciences." Already we are able to register the dew-point, to describe clouds and thunderstorms, to study the temperature, pressure, and humidity of the atmosphere, and in large measure to comprehend the causes of winds, which depend upon inequalities in the atmospheric pressure; and it has long been known that a certain series of changes in the sun affect the magnetic needle on the earth. But, as everyone well knows, there is much yet to be learnt before we can predict to-morrow's weather with a thousandth part of the accuracy of which astronomers can boast when they predict the return of a comet in a century.

EIGHTEENTH CENTURY PROSE

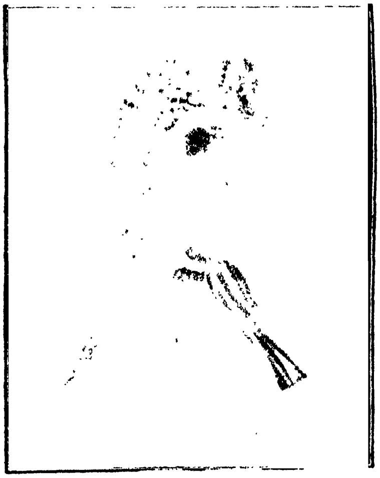
1. Being Short Studies of Defoe, Swift, Steele, and Addison, together with Illustrative Examples of their Writings

Continued from page [illegible]

By J. A. HAMMERTON

WHAT the prose of the eighteenth century may lack in colour and warmth as compared with the prose of the seventeenth century it gains in general smoothness, perspicacity, and correctness. It set the standard of the prose of the present day. It has been styled "aristocratic"; and this description is in the main a true one. But at the period with which we are now to deal the "aristocracy of intellect" was to a great extent employed to the furtherance of ends more practical, or at least more partisan, than literary. These ends were in part political, in part ecclesiastical, in part ethical. Thus the literature of the time must be studied in connection with its political, religious, and social history. Journalism, which, as we have seen, had its rise in the controversial pamphlets of Elizabethan and Jacobean times, received in the eighteenth century a new and forceful impetus, and the English novel assumed a more definite shape.

Daniel Defoe. To DANIEL DEFOE (b. 1661?; d. 1731) must be assigned distinction as the first of English journalists, and as the forerunner of Richardson and Fielding. To-day, save as the author of two or three books, one of them of world-wide repute, Defoe is half forgotten. In his lifetime, however, he played many parts, and over 250 distinct works bear his name. His "Robinson Crusoe" is as immortal as "The Pilgrim's Progress" or "Don Quixote." Like these two works and one other that we shall have to mention almost immediately, "Robinson Crusoe" may be read by the young on account of the narrative alone, and by elder readers as an allegory. Of the many pamphlets that flowed from Defoe's busy pen the most remarkable, perhaps, is that bearing the title, "The Shortest Way with the Dissenters," a Whig production, the plausible realism rather than the satire of which, if it was really intended as a satire, secured its author a cell in Newgate and a place in the pillory.



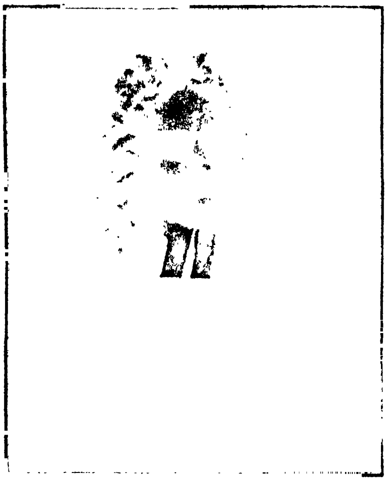
DANIEL DEFOE

As the author of "Captain Singleton," "Moll Flanders," "Colonel Jack," and other works of a kindred character, Defoe stood sponsor to the novel of crime. In 1704 he started a "Review" which was the forerunner of "The Tatler," "The Spectator," and "The Rambler." "Robinson Crusoe" and the fictitious "Journal of the Plague Year" are enough to secure for Defoe pre-eminence as a master of the art of literary illusion. "To him," says Leslie Stephen, "was given a tongue to which no one could listen without believing every word he uttered." He had defects. He was curiously heedless of chronology; he was weak, on the whole, as a delineator of character. But he was an essential "realist," and if his readers would study the didactic side of his writings more, and the "Serious Reflections" of his inimitable hero in particular, the character of Defoe himself would escape in the future some at least of the aspersions that are still cast upon it. "With Defoe," says Professor Walter Raleigh, "the art of fiction came to be the art of grave imperturbable lying, in which art the best instructor is the truth. And it was to no reputed masters of romance, but to recorders of fact, biographers, writers of voyages and travels, historians, and annalists, that Defoe served his apprenticeship."

No one need be counselled to read "Robinson Crusoe." The reading of this immortal fiction is in the birthright of every Englishman, though not so many are familiar with its sequel, which, not lacking in interest, is yet greatly inferior to the first and ever popular story. "Moll Flanders" ought certainly to be read and "The Journal of the Plague," but we would also urge the claims of "Colonel Jack," which, despite many inequalities, contains some of Defoe's most brilliant writing.

Jonathan Swift. As a pamphleteer JONATHAN SWIFT (b. 1667; d. 1745) affords an interesting companion study to Daniel Defoe. Swift was, however, by far the greater man. His power as a pamphleteer may be gauged by a consideration of the famous "Letters," signed "M.B., Drapier," and familiarly known as "Drapier's Letters." In these compositions he attacked the iniquitous "job" by which, in 1722, a certain William Wood, a hardwareman and a bankrupt, was granted a patent for supplying Ireland with copper coin. The "Drapier Letters" defeated this project, and though it is often said that the ensuing popularity of their author amongst the Irish people was unpalatable to him. his bequests to Irish charities seem to negative the idea that he had no sympathy for the people amidst whom his lot was for a long time cast. Swift, it is to be feared, is largely misunderstood. Though he became a keen Tory, his indignant passion against wrongdoing raised him so much above party feeling that he offended both friends and enemies. What he scorned to do for the sake of party or for the sake of his own preferment, he scorned to do for the sake of being thought conventional in his language. The result has been misunderstanding and the keeping of admiration at arm's length. The "Tale of a Tub" is the most comprehensive example of all that is characteristic of his prose style. As sailors were supposed to throw out a tub to a whale to prevent it from colliding with their ship, so Swift thought by his "Tale" to afford such temporary diversion to the wits and freethinkers of his day as to prevent them from injuring the State by the propagation of wild theories respecting religion and politics. But his satiric genius, his fiery imagination, and his keen eye for "the seamy side" imparted to the "Tale of a Tub" qualities that disguised his avowed object and at the very outset placed an insurmountable obstacle in the way of his ecclesiastical preferment.

Satire and Self-revelation. "The Battle of the Books," which, with the "Tale of a Tub," helped to make Swift famous, takes a witty part in a controversy that was raging over the respective claims of modern and ancient literature. Something like one-fourth of Swift's most remarkable work, "Gulliver's Travels," and a great part of his other writings are debarred from general circulation on account of their coarseness. But of "Gulliver's Travels" enough is so delightful as romance as to rival both "Robinson Crusoe" and "The Pilgrim's Progress" in the estimation of young and old. Important as a satire, "Gulliver's Travels" has a distinct value as autobiography. While Defoe excelled in the art of making fiction read like fact, Swift, with the finest skill, cultivated a drastic simplicity and homeliness of style the accumulated effect of which is so formidable as to afford a permanent object lesson in the art that conceals art where the writing of nervous English prose is concerned. But the fact must not be ignored that with all its carefully calculated simplicity the English of Jonathan Swift is never pedestrian or devoid of sparkle or variety. We select as an illustration of Swift's style his "Meditation upon a Broomstick," in which he imitated the manner of the "Reflections" of the philosopher Robert Boyle. It was written for a lady who greatly admired these meditations:



JONATHAN SWIFT

Specimen of Swift's Prose. "This single stick, which you now behold ingloriously lying in that neglected corner, I once knew in a flourishing state in a forest. It was full of sap, full of leaves, and full of boughs. But now in vain does the busy art of man pretend to vie with Nature by tying that withered bundle of twigs to its sapless trunk! 'Tis now at best but the reverse of what it was, a tree turned upside down, the branches on the earth, and the root in the air. 'Tis now handled by every dirty wench, condemned to do her drudgery, and, by a capricious kind of fate, destined to make other things clean, and to be nasty itself. At length, worn to the stumps in the service of the maids, 'tis either thrown out of doors or condemned to the last use of kindling a fire. When I beheld this I sighed, and said to myself, *Surely mortal man is a broomstick.* Nature sent him into the world strong and lusty, in a thriving condition, wearing his own hair on his head, the proper branches of this reasoning vegetable, till the axe of intemperance has lopped off his green boughs and left him a withered trunk. He then flies to art, and puts on a periwig, valuing himself upon an unnatural bundle of hairs, all covered with powder, that never grew on his head. But now should this our broomstick pretend to enter the scene, proud of those birchen spoils it never bore, and all covered with dust, though the sweepings of the finest lady's chamber, we should be apt to ridicule and despise its vanity. Partial judges that we are of our own excellencies, and other men's defaults! But a broomstick, perhaps you will say, is an emblem of a tree standing on its head; and pray what is man but a topsy-turvy creature, his animal faculties perpetually mounted on his rational, his head where his heels should be, grovelling on the earth! And yet, with all his faults, he sets up to be a universal reformer and corrector of abuses, a remover of grievances, rakes into every slut's corner of nature, bringing hidden corruptions to the light, and raises a mighty dust where there was none before, sharing deeply all the while in the very same pollutions he pretends to sweep away. His last days are spent in slavery of women, and generally the least deserving; till worn to the stumps, like his brother besom, he is either kicked out of doors or made use of to kindle flames for others to warm themselves by."

Students of Swift's life will find in his work much that reflects the shadows of his unhappy experiences. They will be especially indebted to the "Journal of Stella" (Esther Johnson, whose tutor he was) for many valuable pages of autobiography and for many sidelights on the manners of the time.

Steele and Addison. SIR RICHARD STEELE (b. 1672; d. 1729), the friend and schoolfellow of JOSEPH ADDISON (b. 1672; d. 1709), was, like Swift, born in Ireland; but in this fact lies the sole resemblance between the saturnine Dean of St. Patrick's and the genial "scallywag" who originated "The Tatler," wrote part of "The Spectator," founded "The Guardian" and other ephemeral periodicals, and worshipped Addison as a hero. In 1709, Steele started "The Tatler" anonymously. It was a small sheet, sold for a penny, appearing three times a week, and designed to expose "the false arts of life, to pull off the disguises of cunning, vanity, and affectation, and to recommend a general simplicity in our dress, our discourse, and our behaviour." Part of "The Tatler" was devoted to news. When his pen-name of Isaac Bickerstaff, which he borrowed from a diverting pamphlet by Swift, became useless as a disguise, Steele founded "The Spectator." "The Tatler" extended to 271 numbers, of which Steele wrote 188; his friend Addison contributed 42, and they were jointly responsible for 36. "The Spectator," which was published daily, ran to 635 numbers, of which Addison wrote 274 and Steele 240. The wholesome effect of these publications on the manners and morals of the eighteenth century can hardly be exaggerated. Both the style of writing and the tone of conversation were improved as a result of their influence. It is generally conceded that while Addison's style is the more finished, Steele's is more marked by liveliness of invention. Addison usually wrote at leisure, Steele often in a "white heat." The papers took the form sometimes of moral and critical discourses, sometimes of short stories of domestic life, in the writing of which Steele excelled.

JOSEPH ADDISON

SIR RICHARD STEELE

Influence of Steele and Addison. Both "The Tatler" and "The Spectator" are remarkable for the respectful tone adopted in referring to women, though Steele was more chivalrous and less patronising than his friend. It was in "The Tatler" that, as Mr. G. A. Aitken reminds us, Steele wrote, "As charity is esteemed a conjunction of the good qualities necessary to a virtuous man, so love is the happy composition of all the accomplishments that make a fine gentleman." And in the same paper he paid his memorable tribute to Lady Elizabeth Hastings (b. 1682; d. 1739), a philanthropist and beauty, immortalised as "Aspasia" by both Steele and Congreve: "Though her mien carries much more invitation than command, to behold her is an immediate check to loose behaviour, and to love her is a liberal education." The plan of "The Spectator" was laid at a club, and in the second number, which was written by Steele, we are given the first sketches of the members. It is, as Mr. Aitken observes, a remarkable testimony to the skill of Steele's work that the characters stand out so clearly before us. The immortal baronet, Sir Roger de Coverley, is understood to be Addison's invention. "The great work of Addison and Steele was to form public opinion on matters respecting which it can hardly be said to have existed before, and to cause their readers, at a critical time in our history, to consider moral and social questions from a higher standpoint than had been their wont." As a short example of Steele's style, we may select the following passage on a theme that is of universal interest:

Example of Steele's Style. "The first sense of sorrow I ever knew was upon the death of my father, at which time I was not quite five years of age; but I was rather amazed at what all the house meant than possessed of a real understanding why nobody was willing to play with me. I remember I went into the room where his body lay, and my mother sat weeping alone by it. I had my battledore in my hand, and fell a-beating the coffin, and calling Papa; for, I know not how, I had some slight idea that he was locked up there. My mother caught me in her arms, and, transported beyond all patience of the silent grief she was before in, she almost smothered me in her embrace, and told me, in a flood of tears, papa could not hear me, and would play with me no more, for they were going to put him underground, whence he could never come to us again. She was a very beautiful woman, of a noble spirit, and there was a dignity in her grief amidst all the wildness of her transport, which, methought, struck me with an instinct of sorrow, which, before I was sensible of what it was to grieve, seized my very soul, and has made pity the weakness of my heart ever since. The mind in infancy is, methinks, like the body in embryo, and receives impressions so forcible that they are as hard to be removed by reason as any mark with which a child is born is to be taken away by any future application. Hence it is that good nature in me is no merit; but having been as frequently overwhelmed with her tears before I knew the cause of my affliction, or could draw defences from my own judgment, I imbibed commiseration, remorse, and an unmanly gentleness of mind, which has since ensnared me into ten thousand calamities, and whence I can reap no advantage, except it be that, in such a humour as I am now in, I can better indulge myself in the softness of humanity, and enjoy that sweet anxiety which arises from the memory of past afflictions."

Steele and Addison Compared. Steele, as Hazlitt remarked, seems to have gone into his study chiefly to set down what he observed out of doors. Addison, on the other hand, drew most of his inspiration from books. But whatever the cause may be, and however much our heart may go out to "Dick" Steele, the verdict of such good critics as Johnson and Macaulay must be accepted concerning the high qualities of Addison's limpid style. Addison's sentences, according to Johnson, have neither studied amplitude nor affected brevity; his periods, though not diligently rounded, are voluble and easy. "Never," said Macaulay, "had the English language been written with such sweetness, grace, and facility." Steele excelled in sympathy, Addison was a master of irony. Not the least of Addison's services to literature was the attention he gave in "The Spectator" to Milton. These papers should be studied by all who desire to appreciate the style and value of literary criticism in Addison's time. On the whole, we read Addison to-day not so much for the value of what he has to say as for the way in which he says it. One of the most noteworthy of his contributions to "The Spectator" is the allegory entitled "The Vision of Mirza," which the writer professes to have translated from an Oriental manuscript. It tells of one who went up to the high hills of Bagdat to pray. There he met the Genius of a certain rock who opened his eyes to the vision of a great valley with a prodigious tide flowing through it. The valley is the Vale of Misery, the tide part of the great Tide of Eternity. In the midst is a Bridge—Human Life—over which multitudes are passing, and which, like the valley, is shrouded at both ends by darkness. The fairway is studded with trap doors through which passengers fall into the flowing tide beneath. The narrative proceeds:

Short Specimen of Addison's Style. "The Genius, being moved with compassion towards me, bid me quit so uncomfortable a prospect. Look no more, said he, on man in the First Stage of his Existence, in his setting out for Eternity; but cast thine eye into that thick Mist into which the Tide bears the several generations of mortals that fall into it. I directed my sight as I was ordered, and (whether or no the good Genius strengthened it with any supernatural force, or dissipated part of the Mist that was before too thick for the eye to penetrate) I saw the Valley opening at the farther end, and spreading forth into an immense Ocean that had a huge Rock of Adamant running through the midst of it, and dividing it into two equal parts. The Clouds still rested on one half of it, inasmuch that I could discover nothing in it; but the other appeared to me a vast Ocean planted with innumerable Islands, that were covered with fruits and flowers, and interwoven with a thousand little Shining Seas that ran among them. I could see Persons dressed in glorious habits, with garlands upon their heads, passing among the trees, lying down by the side of fountains, or resting in beds of flowers; and could hear a confused harmony of singing birds, falling waters, human voices, and musical instruments. Gladness grew in me upon the discovery of so delightful a scene. I wished for the wings of an eagle that I might fly away to those happy seats; but the Genius told me there was no passage to them, except through the Gates of Death, that I saw opening every moment upon the Bridge."

Addison's Merits and Defects. This is no bad specimen of Addison's style, illustrating its defects as well as its merits. He sacrificed everything to elegance; that is, to rhythm or melody of phrase. The supple movement and cadence of the above, its colour, will be at once apparent to the critical reader, but equally will the student detect such a tautological passage as in the second sentence, where "into that," "into which" and "into it" form six of a sequence of eighteen words. Addison not only shows a somewhat limited vocabulary at times, but is very apt to repeat unnecessarily his ideas and his images. The allegory from which we have quoted will furnish examples of this, and also of what is not always a fault, though usually stigmatised as such by the partisans of the pompous, rhetorical style of prose,—his looseness of construction. In the essay, this has its advantages, and helps to lightness of touch, which is scarcely possible where the writer aims at "rounded periods" or stately, slow-moving sentences. But we are inclined to think that Addison has long been something of a fetish with writers on literary style,—"Read an essay of Addison's every day" has been the reiteration of all our mentors for generations,—and that in the not very distant future, his chief interest will be historic, his influence less immediate on individual students, though there is no gainsaying its effect on eighteenth century prose.

THREE-PHASE

The Three-Phase Plan of Working. Combination of Three Currents to Produce Revolving Magnetic Flux. Induction Motors. Stator and Rotor

Group 10
ELECTRICITY
13

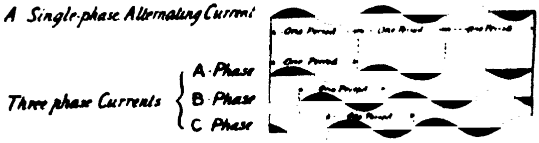
Continued from page 1061

By Professor SILVANUS P. THOMPSON

WITHIN about fifteen years a system of electric supply has come into use under the name of *Three-phase electric currents*, having certain special features and properties which have proved of great value.

Essential Features of Three-phase. In describing, on page 1357, the properties of the alternating current, it was pointed out that in the periodic changes that recur the alternating current is of zero value twice in each period. Thus an alternating current of fifty periods per second dies down to zero a hundred times a second, between the pulsations of the current. It follows that the flow of energy conveyed by such a current is pulsatory, not steady. This is analogous to that which occurs mechanically in any single-cylinder engine. There are two dead-points in each revolution—where the crank has no leverage and the piston can exert no turning effort. Engineers get over this trouble by designing engines with two or three cylinders, requiring two or three cranks.

The three-phase system of currents consists in the employment of three electric currents, which are each alternating with the same frequency, and are of equal amplitude, but which, like the pistons of a three-cylinder engine, are arranged not to be in step one with the other, but to follow one another in regular succession. The reader already knows how the pulsations of an ordinary or single-phase alternating current may be depicted graphically as on page 1362.



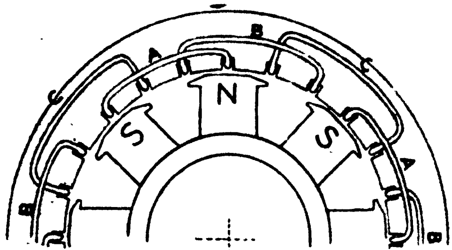
109. DIAGRAM OF PULSATIONS OF ALTERNATING CURRENTS

First Half-period.

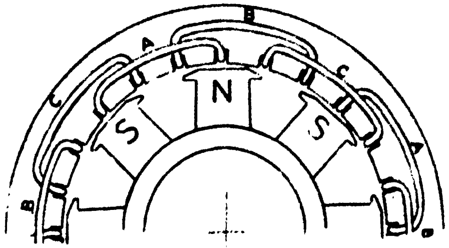
$$0\ \underset{+}{26}\ \underset{+}{50}\ \underset{+}{71}\ \underset{+}{87}\ \underset{+}{97}\ \underset{+}{100}\ \underset{+}{97}\ \underset{+}{87}\ \underset{+}{71}\ \underset{+}{50}\ \underset{+}{26}\ 0\ \overset{-}{26}\ \overset{-}{50}\ \overset{-}{71}\ \overset{-}{87}\ \overset{-}{97}\ \overset{-}{100}\ \overset{-}{97}\ \overset{-}{87}\ \overset{-}{71}\ \overset{-}{50}\ \overset{-}{26}\ 0$$

Second Half-period.

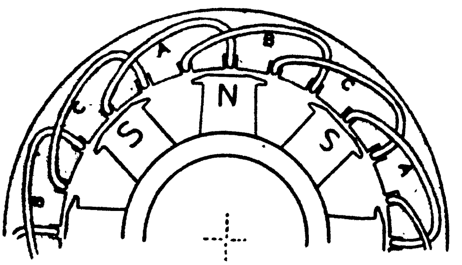
The values during the second half-period are negative, the minus sign being printed above the figures that represent the successive values.



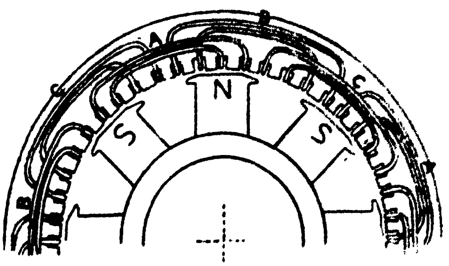
110. THREE-PHASE GENERATOR. THREE-RANGE WINDING



111. TWO-RANGE WINDING OF ARMATURE



112. THREE-PHASE ARMATURE WITH "BASKET" WINDING



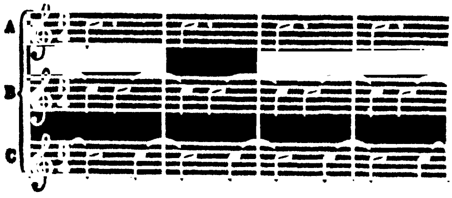
113. WINDING IN TWO SLOTS PER PHASE PER POLE

Numerical Illustration. As on page 1361, so here we may represent these alternating fluctuations numerically. Suppose a current that varies between a maximum of + 100 amperes and a negative maximum of − 100 amperes: then, if we consider the period as divided into twenty-four intervals, we may represent its successive changes during the period (lasting, say, $\frac{1}{50}$ of a second) by the numbers on the preceding page, a plan like that adopted on page 1361.

Now, in the three-phase plan, we have three alternating currents, their relations as to time being depicted in 109. In this diagram the three currents are named A, B, and C; and inspection of the diagram will show that if time be represented by horizontal distances, each *period* being represented by an inch, since the zero of the current that is in the B-phase is $\frac{1}{3}$ of an inch to the right of the zero of that in the A-phase, it follows that the B-current is $\frac{1}{3}$ of a period out of step (and later) than the A-current.

Similarly the current in the C-phase is another $\frac{1}{3}$ of a period behind the current in the B-phase, or $\frac{2}{3}$ of a period behind that in the A-phase. But if we look a little further on in the A line we see that the next period in the A-phase begins at $\frac{1}{3}$ of an inch further to the right than the point at which the C-phase began. So the pulsations of the three currents come in regular succession, at times $\frac{1}{3}$ of a period apart (like the recurrences of the three cranks of a three-crank engine or those of a three-throw pump), in the order, A, B, C—A, B, C—A, B, C, etc.

Musical readers will perhaps better grasp the idea of the way the three "phases" of the alternations overlap one another by an illustration attempted in musical notation with three simultaneous lines of notes in three-four time, as under:



Numerically this is represented by taking the previous series of numbers, repeated three times, but each time shifted on by $\frac{1}{3}$ of a whole "period" as shown in accompanying table.

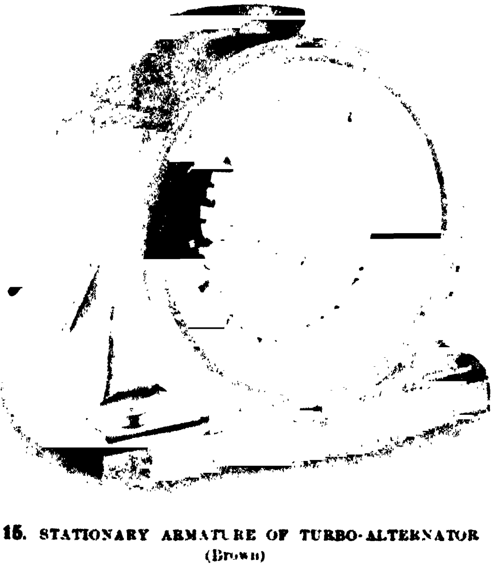
TABLE OF VALUES OF THREE-PHASE CURRENTS, ALTERNATING BETWEEN MAXIMA OF + 100 AND − 100 AMPERES

	Instant.	A-phase.	B-phase.	C-phase.
	0	0	− 87	+ 87
First Half-period.	1	+ 26	− 97	+ 71
	2	+ 50	− 100	+ 50
	3	+ 71	− 97	+ 26
	4	+ 87	− 87	0
	5	+ 97	− 71	− 26
	6	+ 100	− 50	− 50
	7	+ 97	− 26	− 71
	8	+ 87	0	− 87
	9	+ 71	+ 26	− 97
	10	+ 50	+ 50	− 100
	11	+ 26	+ 71	− 97
	12	0	+ 87	− 87
Second Half-period.	13	− 26	+ 97	− 71
	14	− 50	+ 100	− 50
	15	− 71	+ 97	− 26
	16	− 87	+ 87	0
	17	− 97	+ 71	+ 26
	18	− 100	+ 50	+ 50
	19	− 97	+ 26	+ 71
	20	− 87	0	+ 87
	21	− 71	− 26	+ 97
	22	− 50	− 50	+ 100
	23	− 26	− 71	+ 97
	24	0	− 87	+ 87

Three-phase Generators. To generate the three currents in these phasal relations to one another is quite simple. An alternator such as is described on page 1358 must have its armature wound with three independent set of coils, an A set, a B set, and a C set, and they must be spaced out in the slots along the periphery of the armature at distances apart equal successively to $\frac{1}{3}$ of the pitch from one north pole to the next north pole. Now, there are several ways of arranging the coils, according to the form given to the projecting end-bends. These are sometimes arranged, as in 110, in three ranges; sometimes, as in 111, in two ranges (one set projecting nearly straight out, while the other set is bent up); sometimes, as in 112, where the bends overlap like wickerwork. They must, of course, be properly insulated from one another, and from the iron parts. The coils of the A-phase will all be joined up together to make the A-circuit, those of the B-phase will be joined up to form the B-circuit, and so forth. Sometimes the coils of each group are distributed in more than one slot per pole. Fig. 113 illustrates a two-slot winding, in which there are therefore six slots per pole. The large stationary armature [82, page 1361] has a winding of this kind.

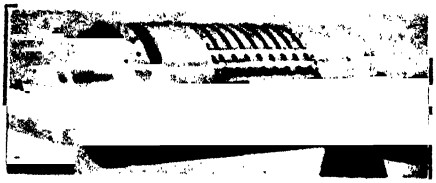
Almost all the alternators used in large generating stations are three-phase, and nowadays they are nearly always driven either by water-turbines where there is water-power available, or by steam-turbines where coal must be burned to raise steam. Figs. 114 and 115 relate to large turbo-alternators. Fig. 114 is the stationary armature of a machine, built for a Parsons' steam turbine set by Messrs. Brown, Boveri & Co., which generates three currents of 1,560 amperes each at 370 volts from line to line, or 213 volts generated in each phase. It is therefore of 1,000 kilowatts, taking 1,450 horse-power to drive it. It runs at 1,500 revolutions per minute, and has 4 poles. Fig. 115 represents the very solid revolving field-magnet used in machines of this type, the exciting windings being sunk in grooves milled out in a cylinder of solid steel. The actual field-magnet shown in **115** belongs to a smaller machine of 200 kilowatts, running at 2,400 revolutions per minute. It has only two poles, one being along the top of the cylindrical magnet, the other along its under side.

The Three Lines. From the generator there will go three lines to the place where the electricity is to be used, and every motor suitable for service on this system will have three terminals to be connected to the three lines. Lamps also may be used, and these (with due regard to voltages concerned), may be connected across either from line to line, or from each line to a common junction J as in **116**. No earth return or return line is needed, and if equal numbers of lamps are used in each phase, the three currents will be of equal virtual value. The reason why no return line is needed is because each line in turn acts as a return line to the others. This is seen by reference to the table, which is drawn up for the case where each of the three currents is of the maximum value of 100 amperes, and where, therefore, the virtual value [see page 1361] of each of the three currents is 70·7 (or say 71) amperes. Looking, for example, at line 6 of the table, we see that at the instant when 100 amperes are going out along line A, the value in B is − 50, and in C is also − 50 amperes, so that the lines B and C are, at that moment, each bringing 50 amperes back to the generator. A moment later, when the A current has dropped to 97 amperes, 26 amperes will be coming back by the B line, and 71 by the C line; while at the next moment (instant No. 8) the 87 amperes are going out along the A line, the whole 87 coming back by the C line, and so forth.



115. STATIONARY ARMATURE OF TURBO-ALTERNATOR (Brown)

Connecting up Three-phase Windings. There are two principal ways of connecting up the three windings. In the way called Y-grouping, or *star-grouping*, the three circuits start from a common junction J, as in **117**, and their three ends go to the three lines. In this case, the voltage between any two of the lines is equal to $\sqrt{3}$ (*i.e.*, to 1·732) times the voltage generated in any one of the three circuits of the generator, and the current in each line is the same as the current in each circuit. In the other way, called Δ-grouping (delta-grouping), or *mesh-grouping*, the three circuits are joined up with the beginning of one coil to the end of the next, as indicated diagrammatically in **118**, and the three lines are joined to the three meeting-points. In this case, the three voltages between the lines are the same as the voltages generated in the three circuits, but the line currents are now each 1·732 times as great as the current in each circuit. Thus, suppose a machine to be designed with so many turns in each armature circuit as to generate 1,000 virtual volts, and of such a thickness of copper conductor as to carry 100 virtual amperes at full load, then, if the Y-grouping were adopted, the lines would receive 100 amperes each, with 1·732 volts from line to line; while if Δ-grouping were adopted, the lines would receive 173·2 amperes each, with 1,000 volts between the lines. In both cases the output will be 1,000 × 100, that is, 100,000 volt-amperes, or 100 kilo-volt amperes for each phase, that is, 300 kilowatts [p. 1363], if the currents do not lag.



114. ROTATING FIELD-MAGNET OF TURBO-ALTERNATOR (Brown)

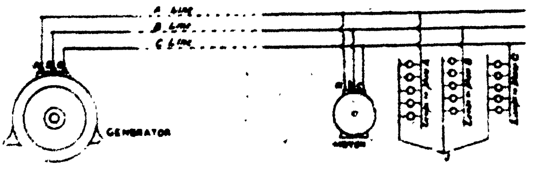
Three-phase Conductors. Where the lines are carried overhead for transmission of the current, it is usual to carry them on three insulators mounted on poles or iron standards, as in **119**, the insulators being arranged as at the corners of an equilateral triangle. For underground conductors, cables are used, having three separately insulated cores, as shown in section in **120**.

Three-phase Transformers. To transform three-phase currents from a high voltage down to the low voltage needed for lamps or motors, one may employ either three similar transformers—one in each phase—or else a special three-phase transformer having three sets of primary windings, and three sets of secondary windings. Such a three-phase transformer is shown in **121**.

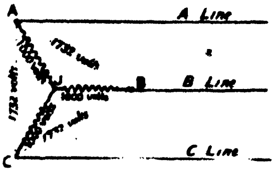
The three windings of each side may be connected, as desired, in either Y or Δ-grouping.

Three-phase Motors. The great reason for adopting the three-phase system is its suitability for driving three-phase motors; for by suitably combining coils in an armature or stator the interaction of the three currents produces a rotating or progressive magnetic field, and a suitable rotor placed in this field is set powerfully into revolution without the need of connecting it in any way into the circuit. We shall be helped to understand how this comes about if we regard 122 to 124, and compare them with the table of values given above.

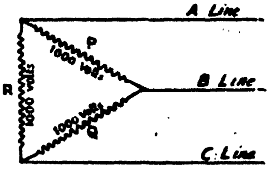
Revolving Magnetic Field. Suppose an armature wound with three sets of coils laid in slots, just as shown in 112, those coils being in three phases, A, B, and C. Now, suppose that at the moment under consideration the current is at its maximum—say, 100 amperes—in the A coils. At that moment, as seen from the tables, the currents in the B and C coils will each be − 50. The arrows [122] show the direction, + being a circulation to the right, − to the left. Then, the circulations of these currents will conspire to produce a magnetic field which will be strongest right under the middle of the A coils. An instant later, the A-current will have died down to + 97, while the B-current will have become − 26, and the C-current − 71. This will have the effect of shifting the resulting magnetic field a little to the right.



116. A THREE-PHASE GENERATOR SUPPLYING MOTOR AND LAMPS



117. THREE-PHASE Y-GROUPING



118. THREE-PHASE Δ GROUPING

After another instant, A will have died down to + 87, B will have become 0, and C will be − 87, and the magnetic field will have shifted a little further. This is shown in 123. At the next stage, A will have become + 50, B will be + 50, and C − 100, and the flux, which at first was under the middle of A, will now be a whole tooth to the right, as in 124 When A has reversed to 50, B will be + 100, and C will be − 50, and by that time the magnetic field will have shifted so that the strongest part of it will be under the middle of the B coil.

The Stator. In this way, though the stator and its coils stand still, the effect is produced of a revolving multipolar magnet. The magnetism revolves, though the metal framework stands

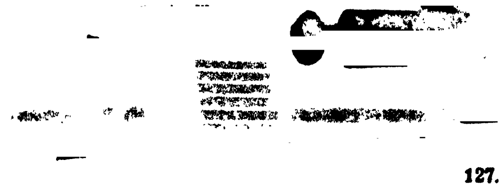
still. Such a field is sometimes called a *Ferraris field*, in honour of Galileo Ferraris, who first showed how, in such a field, rotation is produced. Fig. 125 depicts the stator of an 8-pole three-phase motor. Any mass of metal placed in a revolving magnetic field tends to revolve round after the field by reason of the electric currents induced in it by the invisible magnetic lines as they sweep round it. Hence if a rotor or revolving part be provided, consisting of an iron core having closed coils embedded in its periphery, it will, if inserted in this revolving field, be driven by the currents induced in it. As the revolving part of such motors receives its currents by *induction* instead of conduction, and is entirely disconnected from the primary circuit, such motors are often called *induction motors*.

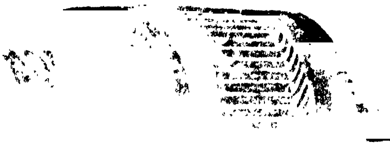
125. STATOR OF 8-POLE INDUCTION MOTOR
(Dick, Kerr & Co.)

The Rotor. For small motors, the suitable rotor to put into such a field is such as that depicted in 126. On a simple shaft is mounted an iron cylinder, built up of discs of sheet iron, in the periphery of which are embedded a number of copper rods or conductors, all joined together at each end. Such a construction is described as a *squirrel-cage* rotor. It needs no connection to the outside circuit, but receives its currents wholly by induction. In fact, the action is much like that of a transformer, the stator coils acting as a primary winding, and the bars of the squirrel-cage acting like the secondary coils. The squirrel-cage runs round, always trying to overtake the revolving magnetism, but never succeeding. In fact, it runs some 3 or 4 per cent. slower. This difference of speed, expressed in percentage, is called *the slip*. At no-load, the slip is less than 1 per cent. As the load on the motor is increased, the slip increases, the driving forces being proportional to the slip. Motors with squirrel cages, though so very simple, do not exert any great torque, or turning effort, at starting.



126. ROTOR OF INDUCTION MOTOR
(Witting, Eborall & Co.)

Wound Rotors. For all cases, therefore, where a motor is required to exert a great starting effort, the rotor is of a different kind. The iron core is provided with slots in which is wound another three-phase winding, the ends of which are connected to three slip-rings mounted on the shaft, as in 127. On each slip-ring a brush makes a sliding contact, so that connection is made with three sets of resistance-circuits. The effect of thus introducing resistance into the rotor is to increase the starting effort. But as the resistance wastes some power by growing hot, arrangements are made to cut it out as soon as the motor has started, and in running on load the rotor circuits are simply closed on themselves.



127. WOUND ROTOR OF INDUCTION MOTOR
(Witting, Eborall & Co.)

Motor Stampings. The bodies of three-phase motors are constructed of stampings [128] of thin sheet iron or mild steel about $\frac{1}{50}$ in. thick. The slots for the windings are stamped out at their peripheries.

ARCHITECTURE

Branches of Knowledge Essential to the Architect. "Taking Out the Quantities." Tenders. Cubing. The Architect's Scale of Charges. Examinations

By GASPARD TOURNIER

THE great number of very diverse sciences and arts which the student finds are involved in the functions architects have to deal with in their daily practice generally very much bewilder him at the start.

In its supreme essence Architecture is an Art—the planning of structures with lucidity, and the clothing of them with beauty restrained by fitness and the physiognomy of type. But the process to be followed for securing effective execution entails contact with many sciences and crafts and executive business processes, including a capacity for administrative management.

Knowledge Necessary to an Architect. Thus are embraced so many opposite branches of knowledge that he is disheartened, and doubts his ability ever to become personally proficient in them all. As a matter of fact, no architect is so; and it is essential, at the outset, that the student be helped to analyse the subjects, so as to enable him to group them into three distinct divisions: (1) Those he must know thoroughly and practically; (2) those of which he need thoroughly know the radicals only; and (3) those which exclusively call for the critical faculty—*viz.*, where his function is to supervise work done by others.

For, after the first main conception of a building, most of what remains has to be left to other brains—each working out its part under his supervision and master grasp.

We have found the student is much helped in this primal analysis by a condensed history of how a building is erected, from the first inceptive scale sketch to the final completion of the structure.

It should be remembered that all architectural drawings are done to scale; the first ones usually to a scale in which ⅛ in. stands for each foot of real length. Plans of each floor are made, and, to show how they fit over each other, sections are drawn representing what would be seen if the building be cut open in vertical slices and cross slices. The elevations of all sides are also drawn to the same scale, and, to show how these combine or join on to each other, perspectives are made for the client to judge the result.

The Specification. As every detail of a building cannot have a drawing made for it, all that which is not indicated or self-evident on the drawings done is described in a document called a Specification. Speaking generally, this consists of a description of all that the contractor and his men are called on to do, or supply, for the money agreed on. It stands in the place of what the architect would verbally say if he were present all day directing the building proceedings. It should not uselessly describe what is obvious, nor what the drawings indicate, yet clearly state everything else which will be necessary for the structure finished in its integrity. For if anything is forgotten the builder will claim payment for it beyond what he has agreed upon in his contract.

Thus the architect starts with the foundations, specifying that the site must be dug out and carted away for basement, and the trenches for concrete foundations under the footings of the walls are set out at levels indicated on the drawings. The composition of the concrete required is described; and so forth for every act next involved.

This leads the specification to become divided into a set of chapters, one for each of the representatives of the trades or crafts which have to be called in as the building advances—*viz.*, excavator, bricklayer, mason, smith and founder, carpenter and joiner, slater, plasterer, plumber, glazier, ironmonger, gas-fitter, painter, paperhanger, etc.

Scheduling Materials. On the completion of the specification it is, together with the drawings, subjected to a process called "taking out the quantities." This consists in scheduling, item by item, the quantities of material and labour which will be required for the erection of the building. These are set against blank money columns for the contractor to fill in his estimated price for each item. The whole is called "The Bill of Quantities." Copies of the bill are given to each contractor who wishes to tender for the work, and thus the lowest total price for it is ascertained.

Difference in Tenders. Students, as well as clients, are often puzzled at the great difference between the highest and lowest tender which repeatedly occurs. This is due to many causes. Builders are differently circumstanced. Some occasionally give very close prices to keep their staff employed over slack times in their own case; others are in a better position to quote low prices for certain materials which they are favourably placed for buying, or have in stock. The relative power of economising machinery is also a factor, and, with many items, the uncertainty as to the cost of workmen's time.

Thus, a builder's business has always an element of speculation in it. But the more clearly everything is indicated by the architect, and the more carefully every item is noted in the bill of quantities, the more the arrival at a rational price is helped.

For a clumsily written specification and imperfect drawings lead to random records in the bill of quantities, and thence to gamble-prices on the part of the builder to cover misconceptions he may make of what may be ultimately required.

But although it is practically impossible for an architect to foretell to his client what the lowest tendered price for a building will be, he must, of course, form a reasonably near idea in the course of his planning, or his scheme will hopelessly differ from the sum the client can spend.

Method of Cubing. In small jobs the architect must go into each item of cost as the builder does, but in large works the method followed is what is called "cubing." Take any building executed within recent years, with the details of which you are familiar, to the drawings of which you have access, and the total cost of which you know. Find the number of cubic feet this entire building occupies as one block, including spaces in rooms and corridors, etc., as if it were a solid lump. Then divide the total cost of the building by the total cubic feet, and the result obtained is a safe guide, per cubic foot, for any building of the same type you may have to design. It is remarkable how nearly the two will approximate.

Thus, suppose you have to design a block of municipal offices, and you have in your mind an existing block of the same type of design which you know came out at one shilling per cubic foot. Price your new building at the same rate per cubic foot.

For a church, a business block, a country house, or any other building, cubic units are obtained in the same way.

The Quantity Surveyor. The taking out of quantities always used to be done by the architect or in his office, and this is still often done particularly in the provinces; but in modern times there has arisen a quite separate profession—that of a quantity surveyor, who devotes his whole time to it and takes the responsibility.

His general charge is 2½ per cent. on the cost of the building, the sum being usually paid to him direct by the builder, who allows for it in his estimate. In that case, the transaction not being direct to the client, vexatious litigation is liable to occur when the idea of building is abandoned before its erection. The quantity surveyor is then in a difficulty as to the person from whom he is entitled to claim payment. The architect should always protect himself by seeing that the client is made aware of the quantity surveyor's exact position.

It is a growing custom for the quantity surveyor to write the specification from notes given by the architect. Whether these two documents are written in an architect's office or not, when he has reached to any degree of professional practice he seldom does them himself, but it is essential that the student should be thoroughly familiar with them.

Bill of Quantities. When the contractor signs the agreement to execute a structure at the agreed price, he deposits with the architect the actual copy of the bill of quantities he has filled in, with the prices of every item scheduled therein, thus showing exactly how he arrived at his total figure. This is kept sealed till the end, when the quantity surveyor goes over the job and measures all the additions and omissions which may have arisen, the cost for which is decided by the rates for corresponding types of work occurring in the original bill of quantities. It is very liable for additions to exceed omissions through oversights by the architect, and when a client finds that the total cost has come to much more than he had prepared himself for, friction is caused unless the extras are due to additions for which he himself asked. There have been occasions when the exceeding of an estimate has led to the loss of a client's future goodwill—a client for whom the architect may have erected a building otherwise faultless. This shows that next to capacity for good planning, elevational designing, and construction, a student should strain his utmost to acquire ability in the business and documentary branches, so as to guard against such casualties.

To cover a reasonable number of unforeseen items, it is usual to add in the specification a provisional sum for them, and likewise sums under the head of auxiliary subjects, which cannot be specified at the outset in detail; as also sums which will later on be subjects for separate sub-contracts, such as mosaic floors, stained glass, and others.

Supervision during Building. The builder having signed the agreement the work of erection is begun.

As constant supervision by the architect on the site would be an undue claim on his time, there is, in the case of all buildings of any magnitude, a clerk of the works engaged to be always there to verify the correctness of all work and the quality of all materials. It is a position which demands very efficient practical experience. His salary is paid by the client.

During the progress of the work many further drawings are made beyond the original contract ones, such as details of sundry parts and full-size drawings of mouldings, etc. It is in doing these that the real quality of the initial drawings and documents becomes apparent in the absence of unforeseen errors to be remedied and forgotten items to be supplemented.

The contractor is paid in instalments, on the certificate of the architect, usually in drafts of about 80 per cent. of the cost of work done, the balance being retained till a stated period after completion, to verify the integrity of the structure and to give time for the quantity surveyor to measure and price the extras and omissions.

Architect's Scale of Charges. The scale of charges for an architect's services is generally recognised to be that issued by the Royal Institute of British Architects, but there is no Statute to enforce these terms. It is usual for architects, at the outset, to give a copy of this scale to a client and make it a personal agreement between them; and all architects of standing are agreed among themselves to work at no lower scale. Its main terms are 5 per cent. on the cost of the executed building and 2½ per cent. on the estimated cost of work which has reached the stage for execution, but is not executed. Certain items, such as travelling expenses, are extra. In matters of personal time—such as attendance at law courts, visiting sites for opinions thereon—his charge per day depends on his standing in the profession. The minimum is three guineas per day.

It may be mentioned that 5 per cent. is not so remunerative as the uninitiated may think, since as much as half of that is often paid out for staff expenses. And so an auctioneer is often paid more for the momentary service of selling a building under the hammer than the architect actually receives for the complex work of designing it and seeing to its erection.

An Unlicensed Profession. The public often express astonishment that a vocation involving such great risks to life through faulty construction, and loss of vast sums through ignorant designing and bungling management, is not restricted by the Government to *diplomed* men. The question of doing so has long been debated, but the difficulties of drafting such an Act are many, and, as yet, the most advanced countries for State protection in all things—*viz.*, Germany, France, and America, have not done so.

Examinations by the Royal Institute of British Architects. But meanwhile the Royal Institute of British Architects, which is the chartered and recognised head of the profession, has organised an examination, compulsory on those seeking admission as As and the curriculum for this test has become the standard guide to an architect's education.

It consists of three stages—Preliminary, Intermediate, and Final—and a scheduled digest of them is given in the Table below.

Examination by the Society of Architects. The Society of Architects also holds an examination, but its status is more recent, and does not carry with it the prestige of the Institute.

The following notes give an idea of the radius of proficiency asked for under each head:

Preliminary Examination. 1. Tests for accurate spelling and punctuation, and a clear, well-formed handwriting. No grammatical questions are asked.

2. An essay to test capacity for observation and lucidity in expressing ideas; one topic to be chosen from a set which is given, such as "A Cycling Tour," "The River Nile," "The Importance to an Architect of a Knowledge of the Principles of Hygiene," "Observations on the Work of Some Distinguished Architect of the Past."

3. Arithmetic up to decimal fractions and compound proportion.

4. Algebra up to simple equations.

5. The two first books of Euclid; to be well mastered, as questions put do not always name theorems from which they are evolved.

6. A general knowledge of the geography of Europe, and a more detailed one of the British Isles.

7. English history from the Norman Conquest to the end of the Tudor period.

SCHEDULE OF EXAMINATIONS FOR BRITISH ARCHITECTS

Age Limits.	Examining Body and Time and Place of Examinations.	Preliminary Examination.		Fees.
		Obligatory Subjects.	Alternatives at Option.	
None.	**The Royal Institute of British Architects.** June and November.	(1) Writing from dictation; (2) English composition; (3) Arithmetic; (4) Algebra; (5) Elements of Plane Geometry; (6) Geography; (7) English History; (8) Elementary Mechanics and Physics; (9) Freehand Drawing from the round	(10) One language to be selected from Latin, Italian, French, or German One from the two following subjects: (11) Geometrical Drawing and Drawing to Scale (12) Elements of Perspective	£2 2s.
		Intermediate.		
19 years or over	At 9, Conduit Street, Regent Street, W., London. And at provincial towns having architectural societies allied to the Royal Institute of British Architects when a sufficient number of candidates make it feasible	(1) Classic Ornament; (2) The Characteristic Mouldings and Ornaments of each period of English Architecture from A.D. 1000 to A.D. 1550, with their application; (3) The Orders of Greek and Roman Architecture; (4) The History of Mediæval and Renaissance Architecture in Europe; (5) Theoretical Construction and Strength of Materials; (6) Descriptive Geometry, the Projection of Solids; (7) Elementary Applied Construction; (8) The Nature and Use of Ordinary Building Materials		£3 3s.
		Final.		
21 years or over		The designing of buildings. A *competent* knowledge of the styles of Architecture and their details, and a *thorough* knowledge of a *special* style selected by candidate, the choice given being either (*a*) Classic and Renaissance, or (*b*) Mediæval. No further subdivisions are allowed. A full knowledge of the properties of Building Materials and their application to building; also Construction in all departments of building (including iron and steel work) and in relation to health, drainage, water supply, ventilation, lighting and heating; specification writing and estimating; the measurement and cost of building work; the conditions for contract; shoring, underpinning, and dealing with ruinous and dangerous structures		£4 4s.

8. The questions put here are within the sphere covered by ordinary college elementary textbooks. Nothing is asked involving advanced questions or trigonometrical calculations.

9. Drawing from the cast of an ornament given. It is not elaborate, and the two hours allowed are ample. Anyone who has done a reasonable amount of drawing at school should be able to qualify easily for this subject if he is at all fit to choose architecture as his life's work.

10. In the language chosen, the main question is a test of good *translation into English*; the grammatical questions are easy. There is no oral examination in this or any of the subjects in the Preliminary Examination.

11. Geometrical and scale drawing. A fair proficiency in rule drawing, and some knowledge of building construction, is added, such as is given in the first part of polytechnic textbooks on elementary building construction.

12. The lesson on Perspective [see page 595] fully covers this subject.

Candidates are exempted from any of the above subjects if they have already taken them successfully in the following examinations:

Matriculation examination of English or Colonial Universities, or any local examinations conducted by them; also those of the Central Welsh Board, the College of Preceptors, the Board of Education, South Kensington, or any other which the authorities at the Royal Institute of British Architects deem satisfactory.

Intermediate Examination. Before admission to sit at this examination, the student must submit drawings made on a set of nine double-elephant sheets 40 in. by 27 in.

On sheets 1 and 2, examples, one on each sheet, of any two of the orders of architecture to be selected from the Doric, Ionic, or Corinthian done in outline with the ornament filled in. Each order to show two columns, with entablature over, done to a scale in which the height of the columns shows not less than 10 in. on paper, and the details to three times that scale. On sheet 3, details of classic ornament from the round. On sheets 4 and 5, examples, one on each sheet, of any two periods selected from the following three: "Early English," "The Decorated," or "The Perpendicular," exemplified by features such as a door, a window, or an arcade, done to scale with plan elevation and section, and with details and ornaments enlarged. On sheet 6, mediæval ornament, drawn freehand from the round. A description of the aforenamed sheets must accompany them, written on foolscap. On sheet 7, a diagram of a timber-framed roof truss, 30 ft. span, with nature of the strains indicated, and the ironwork and junctions drawn to a scale of 1½ in. to the foot, in isometrical projection, and dissociated. On sheet 8, details of floors, one of framed timber, another of combined iron and timber, and a third of a fire-resisting floor; size of floor, 30 ft. by 20 ft., drawn to ¼ in. scale. On sheet 9, details of joiners' work indoors, windows, and fittings, 1 in. scale, with mouldings and framing to a larger scale.

Some of these sheets can be exempt in cases where drawings regarded as equivalent have been done for or in other institutions, and may be substituted for them; but this procedure is not to be recommended. The essential use of all such work is to acquire *thorough* skill in draughtsmanship and the *memorising* of elemental shapes, out of which personal designing afterwards evolves; and the more this is done the greater the facility acquired. As ready draughtsmanship is much to be desired, it will not do to be chary of time and energy in the attempt.

Scheduled Heads of Subjects. Coming now to the scheduled heads of subjects in the Intermediate Examination, heads 1 to 4 refer to the art of architecture; 5 to 7 touch on technical construction. Under heads 1 to 4, strictly speaking, you are not called on to "design" anything, but to show, by drawing and description, that you have memorised as well as grasped the shape, features, and historic type of each style of architecture and ornamentation of the periods named. To read history and note the differences in the physiognomy of its buildings and the origin of those differences for descriptive purposes is not so difficult, but the drawing of those buildings and the analysis of their features from memory is a work calling for very much practice. You will be asked such questions as: "In what position was statuary (as apart from low relief sculpture and ornament) used externally on classic temples? Illustrate your remarks by sketches, and give your views as to the reasons for placing it in those positions." "Sketch, in elevation, to 1 in. scale, the cap and base to columns of a nave arcade of the first half of the twelfth century (English). Ditto of the first half of the fourteenth century." "In comparing the architecture of the Renaissance period of Florence with that of Rome and Venice respectively, what difference would you remark? Give a sketch of the elevation of an Italian palace of that period." "Describe architecturally, one of the following churches: Westminster Abbey, Canterbury, or Durham Cathedral. Illustrate your description by sketches."

For these examination heads, see textbooks given at the conclusion of this course, as also for heads 5 to 7.

After the written examination, an *oral* one is held. It will not break any new ground, but be within the compass of what has preceded, including questions arising from the nine previously submitted sheets of drawings.

Many otherwise good students fail here from sheer nervousness. The faculty of expressing your thoughts before men, under all circumstances, in board rooms, law courts, and public assemblies, is one which architects are constantly called on to do, and the student cannot start too soon to acquire it by joining a debating society, and talking on some subject till fluency of expression is habitual.

THE GREAT LAWS OF CHEMISTRY

The Laws of Atomic Heat, Valency, and the Conservation of Matter. Radium: its Properties and the Modification of Physical Theories it Causes

By Dr. C. W. SALEEBY

HAVING completed, as far as possible, our study of the facts of inorganic chemistry, we are now in a position to review the great laws of chemistry, some of which have already been discussed. Very early in the course, for instance, we had to refer to the Periodic Law [page 400], which was a sort of curiosity a decade or two ago, but which the recent study of the atom, the discovery of the rare gases of the air, and other advances in chemistry have elevated to the very foremost rank amongst chemical truths.

Molecules of Gases. We have also made brief reference to certain of the laws of compounds, such, for instance, as the law of fixed proportions. In this and the course on PHYSICS, reference has already been made to Boyle's law, which states that the volume of a gas at a uniform temperature is inversely proportional to the pressure to which it is exposed, and also to the law which most commonly goes by the name of Gay-Lussac, that the volume of a gas increases, if the pressure be constant, by one two hundred and seventy third part of its volume at 0° C. for each rise of one degree centigrade. From these laws it has been possible to deduce another, which goes by the name of Avogadro, and which states that, given equal temperature and pressure, equal volumes of all gases contain equal numbers of molecules. This is one of the most remarkable and important laws in the whole of physics or chemistry. It constitutes the only possible way of explaining the laws of Boyle and Gay-Lussac. This law states nothing whatever about the size of the molecules of various gases—a size which is undoubtedly different in each case from all other cases, but merely asserts that all gaseous molecules under equal conditions of temperature and pressure occupy the same amount of space.

The Law of Atomic Heat. To these laws one more must be added, which commonly goes by the name of two French chemists, Dulong and Petit. It may be stated in several ways, as, for instance, that the atomic weight of any element multiplied by its specific heat [see PHYSICS] is the same for all elements. This figure or *constant* is known as the atomic heat. This law implies that precisely the same amount of heat is required in order to raise through one degree of temperature equal numbers of atoms of different elements in the solid state.

This law and the law of Avogadro are in entire accord with the kinetic theory of gases, which has been fully discussed in the course on PHYSICS.

We have frequently had to observe the fact that the elements unite with one another in very definite proportions, and we have employed such phrases as *one-handed* and *two-handed*, in order to explain, for instance, the fact that it requires, as we have said, two one-handed atoms of hydrogen to unite with one two-handed atom of oxygen, in order to form water (H_2O). Chemists have introduced the word *equivalents* in order to express certain of the facts of *valency*. They describe as the equivalent of an element that proportion by weight which will combine with or replace one part by weight of hydrogen. The facts of water lead us to observe, for instance, that, in the case of water, at any rate, 8 is the equivalent of oxygen.

The Laws of Valency. Now, by the word valency we describe the number of atoms of hydrogen with which any element will combine, or which the element will turn out from one of the compounds of hydrogen. This is as good as to say—as the reader will see if he thinks about it—that the valency of an element can always be ascertained if we divide its atomic weight by its equivalent. For instance, in the case of water we have seen the equivalent of oxygen to be 8, while we know its atomic weight to be 16; thus, its valency in the case of water is 2, or, to use our old metaphor, it is two-handed.

But if we remember the case of hydrogen peroxide, H_2O_2, we see that an element may have more valencies than one; sometimes it may act as if it were one-handed, but at other times as if it were two-handed. The rule, however, is that the compounds formed with one particular valency are much more stable than those formed with any other valency.

Valency and the Periodic Law. Until quite recently, only a few months ago, indeed, it was scarcely possible to say any more about valency than has already been said. We could simply observe the facts and state them. It seemed absolutely impossible to explain them in any way. One curious circumstance, however, could be observed, which was that valency seemed to be hinted at in the periodic law. Taking the groups of the elements in sequence, we found that the typical members of group one were one-handed, or monovalent; those of group two were two-handed, and so on. It was not stated that this is invariably the case, but it is too nearly the case to be without significance. Furthermore, as we have already noted, the rare gases of the air were found to fit into the table of the periodic law, constituting a zero group which, if there be anything in the group arrangement of valencies, ought to have no valency at all. And this is precisely what was found. Despite innumerable experiments, these gases are found to be incapable of entering into combination with each other or with any other element; they are *no-handed*.

The very recent work which has been done by Professor J. J. Thomson, of Cambridge, and his fellow-workers is now going far, however, to make valency intelligible, and especially to unravel the real significance of the remarkable manner in which the periodic law respects the facts of valency. To this subject we must return when we have discussed, so far as may be possible, the wonders of radium, radio-activity, and the new chemistry.

The Conservation of Matter. On page 61 we referred very briefly to the doctrine of the conservation of matter, which asserts that in all chemical transformations and combinations no matter is ever lost or annihilated, appearances to the contrary notwithstanding. This is by far the most important of all the great laws of chemistry—fundamentally important to the chemist, and of equal importance for philosophy. The assertion of the chemist is that, whatever process occurs to change the distribution of matter or its forms, no matter is ever lost. When we burn a candle, it would seem that something is annihilated, but it is not so. If we collect the products of combustion, remove from them the oxygen with which the constituents of the candle have combined during the process of combustion, and weigh them, we find that nothing has been lost. We also find—and this is of precisely equal importance—that nothing has been gained. There has been neither annihilation nor creation.

Let us see now why this proposition is so fundamental. The reason cannot be better stated than by Herbert Spencer in "First Principles": "Could it be shown, or could it with reason be supposed, that matter, either in its aggregates or in its units, ever becomes non-existent, it would be needful either to ascertain under what conditions it becomes non-existent, or else to confess that science and philosophy are impossible. For if, instead of having to deal with fixed quantities and weights, we had to deal with quantities and weights which are apt, wholly or in part, to be annihilated, there would be introduced an incalculable element, fatal to all positive conclusions."

Men once believed that things could vanish into nothing or arise out of nothing, or thought that they believed it. It is quantitative chemistry which has shown that in all chemical processes the law of the conservation, or the indestructibility, of matter is observed.

A New Statement Necessary. So far as all ordinary chemical processes are concerned, this law holds true to-day. But we cannot now close the discussion of it thus. This law it was that led Clerk-Maxwell to coin his celebrated phrase describing the atoms of matter as the foundation stones of the physical universe, which have lasted since the Creation, unbroken and unworn. No power in the universe could destroy an atom. If all the other atoms in the universe were ranged against it, it would survive their attacks. But nowadays we are all aware that Clerk-Maxwell's conception of the atom is obsolete. Of this there will be no remaining doubt when we have proceeded to the discussion of radio-activity. Atoms are not like foundation stones; they consist of systems of almost infinitely smaller units, known as corpuscles or electrons. These systems vary in stability, though those with which we are familiar are probably the most stable that have survived, while less stable atomic systems have disappeared, in accordance with the law of the survival of the fittest, which is now believed to obtain amongst atoms as amongst organisms. If we are to adhere strictly, then, to the law of the conservation of matter as a fundamental dogma of chemistry and of philosophy, we must let the atom go and must turn to consider the electron or corpuscle.

Conservation of Energy. Now, the truth appears to be, as was, indeed, long ago discerned by the genius of Spencer, that the law of the conservation of matter must be regarded as merely a convenient aspect of a much greater law—the law of the *conservation of energy*. The belief in the indestructibility, or conservation, of atoms has had to go, since radium demonstrates to our actual vision the destructibility and impermanence of atoms. Apparently no success can be hoped for the attempt to transfer our dogma to the electron. We are very far indeed from having any proof, or, indeed, from having any reason to believe, that electrons are permanent and indestructible. On the contrary, we are compelled to look upon them as essentially transient and evolving manifestations of energy. While the great revelations of the last ten years have cut the feet from under the doctrine of the conservation of matter, they have not affected in any degree the much greater doctrine of the conservation of energy; but, on the contrary, have afforded it additional support. To some aspects of this question we must return in a later section.

Radium. Everyone with a guinea to spare may become the possessor of a tiny speck of the most expensive, rare, and wonderful of all known substances. At the present rate in the rise of the value of radium, however, the makers of the remarkable toy called the *spinthariscope*, which was invented by Sir William Crookes, will soon have to raise its price. This spinthariscope is a little brass tube about an inch and a half long, which is closed at one end and has a couple of magnifying lenses at the other. On the inner surface of the blind end there is a small piece of paper which has been coated with minute crystals of zinc sulphide.

Just in front of this piece of paper there stands out a metal pointer like the hand of a watch. The end of this pointer has been dipped in a solution of a salt of radium. If, now, one takes the spinthariscope into a dark room and holds it close to the eye, one sees a shower of points of light that seem to radiate from a centre and that come from the surface of the zinc sulphide paper. This shower of sparks never ceases, night or day, year in and year out. The present writer mislaid his spinthariscope, and when he found it again after some months and saw this shower of sparks still occurring, and realised that it had never ceased throughout the intervening period, the most amazing of all the features of radium was at last brought home to him.

Estimated Duration of Radium Energy. Various calculations have been made as to the length of time during which the scanty deposit of a radium salt upon the pointer of a spinthariscope will continue to evolve the energy of which the shower of sparks is the manifestation. The least estimate runs into thousands of years. The flashes of light are believed to be due to the cracking and splintering of the crystals of zinc sulphide by means of something which flies out from the radium and strikes them. Thus, it is probable that the paper may require to be renewed after some time; but that is merely because it will cease to indicate what does not cease—the continual evolution of energy by the radium within the spinthariscope.

Sometimes the owner of a spinthariscope is annoyed to find that the shower of sparks is very inconspicuous. If the toy be slightly warmed, the shower will soon reappear. Whatever the cause of this fact be, it has certainly nothing whatever to do with the behaviour of the radium itself. For radium continues to evolve energy in liquid air or hydrogen at a temperature more than 200 degrees below zero just as well as it does at ordinary temperatures. Indeed, its behaviour seems to be unaffected by anything that we can do to it.

The New Alchemy. Now, the sight which the spinthariscope affords is really the vindication of the much-abused alchemists, who sought to turn the baser metals into gold. Later generations laughed at them and said: "Oh, no, you cannot transmute one element into another, for each element has its own kind of atom; and the atoms are the unalterable foundation-stones of the universe. They cannot be changed into one another, and so you cannot change lead into gold. Your philosopher's stone is a myth." But this supposed impossible thing is precisely what is happening in the spinthariscope. Let us consider the facts.

Radium is certainly an element—as much an element as gold or lead or any other; and, of course, it has a characteristic atomic weight of its own. This has been variously estimated during the last year or two, Madame Curie, the discoverer of radium, estimating it to be 225; while other observers, using other methods, estimated the figure to be 256. This last would constitute radium the heaviest of all known substances. Madame Curie, however, has been proved to be right, and radium is recognised as the third heaviest of known substances, the heaviest being uranium, with an atomic weight of 240, and the next thorium, with an atomic weight of 232. The fact that the atomic weight of uranium is greater than that of radium is extremely important, as we shall see when we come to discuss the evolution of radium.

The Emanation of Radium. Now, if some of this element be confined in a tube, we find, after a time, that there appears in the tube a minute quantity of a gas or *emanation* which was not there before. This is not gaseous radium, for when it is examined with the spectroscope it shows a spectrum quite different from that of radium; in fact, its spectrum is quite different from that of any known substance. But it was discovered by Sir William Ramsay that if the spectrum of this mysterious emanation be examined again after an interval of about four weeks, it is found to have changed into a familiar spectrum which is instantly recognisable as that of the rare element known as *helium*. The astonishing fact, then, is that the element radium decomposes itself and produces another element, helium. Now, the atomic weight of helium exactly corresponds to the weight of the tiny particles which are now known to be shot out from radium, constituting what are called the *Alpha* rays. These particles, flung out from the radium upon the pointer of the spinthariscope at an incredible speed of tens of thousands of miles per second, bombard the zinc sulphide paper and so produce the shower of sparks to which we have referred.

Radium and Universal Evolution. In the history of the science of radio-activity, this great discovery of Sir William Ramsay's takes a prior place, since it proves once and for all that the doctrine of universal evolution is applicable to atoms. Herbert Spencer's original definition of evolution, framed more than forty years before the discovery of radium, is applicable to the facts discovered yesterday as if it had been framed in order to describe them. Thus the most important fact about radium for the philosopher, the physicist, and the chemist alike, is that it proves the truth of atomic evolution. Not even an atom is immune from the universal law of unceasing change, and thus every spinthariscope is a lasting refutation of that memorable phrase of Clerk-Maxwell's to which we have so frequently referred. Furthermore, radium has proved that Sir John Herschel and Clerk-Maxwell were wrong when they declared that the atom bears upon itself the "stamp of the manufactured article." Atoms are not manufactured, but have evolved and are evolving.

The Evolution of Radium. Of all the elements, the last that radium suggests to the mind is lead, unless, indeed, the suggestion were by contrast. Lead has long stood as the symbol for all that is mean and worthless and dull and unremarkable; whilst we know radium to be the most brilliant, the most valuable, and incomparably the most remarkable of all the elements. Lead stands for something worse than mediocrity, radium stands for uniqueness and genius. But in recent months it has actually been discovered that lead—almost certainly—has its place in that evolutionary chain of which radium is the most remarkable link.

But before we ask what becomes of the atom of radium, let us inquire into its own origin. We know that there is extremely little radium in the world, and we find that what radium there is is constantly being decomposed into simpler elements. Indeed, we can barely understand the facts unless we assume that, while radium is itself being decomposed, it is, on the other hand, being produced in some way or other—the amount of radium actually existent at any one time being determined by the comparative rates of these two processes. We now, indeed, have every reason to believe that radium itself is the child of uranium—wherein lies the importance of the fact, upon which we have insisted, that the atomic weight of uranium is greater than that of radium. These two elements are associated with one another wherever they are found ; and not only so, they are associated in a constant ratio. This ratio is determined entirely by the relative life periods of the uranium and the radium atom.

Radium and Lead. As we have already seen, the so-called *Alpha* rays of radium are now known to consist of material particles, each of which must be regarded as an atom of helium in a state of great excitement and activity. Now it is obvious that the radium atom cannot continue to lose an indefinite number of these immature atoms of helium without itself undergoing certain changes. In fact, the radium atom is changed. When it has lost one atom of helium it is no longer a radium atom, but the atom of another element. It is now believed that each radium atom is capable of losing in succession five atoms of helium. At each stage it is a different and definite product and must receive a different and definite name. (These names have not yet been quite agreed upon, but the reader may have heard of actinium and polonium, the latter having been named by Madame Curie after her native country. It is now seen that these names must apply to various stages in the transmutation of the atom of radium.) And now we come upon the extraordinary conclusion, apparently beyond all dispute, that when five such helium atoms have left what was originally an atom of radium the atom left behind is none other than an atom of lead. Such is the ignoble end of a brilliant career.

Origin of Radium. It is obviously not correct, however, to use the phrase, "originally an atom of radium," for we know that the radium atom, large, heavy, and complicated though it be, is yet none other than a decomposition product of a heavier, larger, and still more complicated atom—that of uranium. What are we to say o this ? Is the uranium atom also only a temporary product of an element consisting of atoms yet heavier and more complex than its own ? This, indeed, seems highly probable, though no such element is known. But it is not easy to see where we are to stop in the speculations which these new discoveries have suggested. Though uranium has the heaviest atom we know, there is no conceivable reason why it should be the heaviest atom possible. Indeed, it has been suggested that we must go back in thought by successive stages to a period when the whole universe was one atom.

Yet if we have difficulties in this direction, we have difficulties no less in the other direction. The atom of lead is extremely heavy and complex. Why should it be the last stage in the process which "began" with uranium. No one, indeed, now thinks that it is the last stage, and by some it is thought that the element silver, which is so constantly found in association with lead, may represent the next most striking stage in this particular sequence of atomic evolution. But in this direction also, where does the process stop ? Are we to suppose that the universe began as one huge atom, and that its last stage will be represented by the breaking down of all atoms into what we now believe to be the common constituent of them all, the electron, or corpuscle, of negative electricity ?

Helium. However these things may be, we must at any rate study, so far as is possible, the remarkable element helium, which is so positively known to be a product of the decomposition of radium. When the spectrum of the protuberances of the sun was first studied, it was found to indicate the existence of an element with which chemists had no acquaintance. But it was subsequently discovered by Sir William Ramsay that this same element is present in a rare Norwegian mineral which has the name of clevite ; the element is now known as helium (from Greek *helios*, the sun). Thirty years elapsed between the discovery of helium in the sun by the late Sir Edward Frankland and Sir Norman Lockyer in 1868 and Sir William Ramsay's demonstration of the existence of this element upon the earth. This is the one substance which Sir James Dewar has been unable to liquefy. He writes: "It has been expanded from a pressure of 80 to 100 atmospheres at the temperature of solid hydrogen without the least indication of liquefaction being perceived, although in this connection it must be remembered that its exceedingly low refractivity would render small drops of the liquid forming in the gas near its critical point very difficult to see. It may, however, be said without much doubt that helium has been cooled to 9 or 10 degrees absolute (264 or 263 degrees below zero centigrade) without sign of liquefaction, and the inference is that its critical point is below 9 degrees absolute. This means that its boiling point is about 5 degrees absolute, or one-fourth that of liquid hydrogen."

TYPEWRITING AS A BUSINESS

The Office and its Equipment. Staff. The Prices Charged for Work. Departments and Suggestions for Enterprise

By W. B. ROBERTSON

AS a means of livelihood typewriting, usually in conjunction with stenography, is becoming almost the exclusive sphere of women. It is work for which they are particularly fitted. It demands precision, neatness, and attention to detail which seem to constitute too great a strain on the average masculine capacity. When women enter a field in force the position of man becomes gradually untenable, as it seems to be an accepted, though unjust, dictum in our commercial economy that a woman, although fitted for and doing the same work as a man, ought to be content with a very much smaller remuneration. The advent of women into the domain of commercial office work was synchronous with the introduction of the typewriting machine, and women took to the work with the facility of the duckling entering the farm pond.

Conditions of Employment. The conditions of employment of the lady stenographer and typist are almost as diverse as the offices where she is employed are numerous. The occupation is considered mechanical, and all purely mechanical employments are poorly paid. But a good general education, and the ability to exercise independent judgment in case of ambiguity in the copy, is essential in a thoroughly trustworthy typist, so that the popular conception that typewriting is easy and merely mechanical is erroneous. We have heard of girls who professed expert ability both as shorthand writers and as typists accepting positions at 6s. per week. There are certainly some thousands in

between 12s. and 16s. a week. But if the average wage of a good typist in a good office could be estimated it would probably be found to lie from 25s. to 30s. a week. To attain a higher figure a woman must have exceptional ability and a knowledge of foreign languages, apart from mere proficiency in shorthand and machine manipulation. The typist aspires to the dignity of proprietress-ship of a typewriting office. The starting of such an office is an important step, and demands caution and circumspection

SPECIMENS OF TYPE—TWO-THIRDS ACTUAL SIZE

A Typewriting Office. The typist ought to have some assured regularity of work, or should be in an exceptionally favourable position for securing it, before she takes an office. Rent and other expenses must be paid whether work comes in or not. The choice of an office is the first consideration. If she have guarantee of regular employment she will naturally instal herself in a position as convenient as possible to the offices or residences of her prospective customers. The large office buildings which in London and other large centres form hives of commercial and professional activity offer the best places for such an establishment. Proximity to possible customers is an essential to constant custom, for the best patrons may be wooed away by an opposition office if the latter be nearer and therefore more convenient.

The beginner should not consider an office at a higher rent than £50 a year. Indeed, she ought to get one for much less, say £30 to £40, which will be centrally situated and give all the necessary accommodation of two or three rooms. Also, she should not saddle herself with a lease of the office. It is usually possible to secure the premises upon month to month terms.

Equipment. The office, having been secured, must be equipped. The most expensive items are the typewriters themselves. The cash price of the best makes is £22 each. It is possible to buy cheaper machines, but the opinion of the majority of those who make their living by manipu-

as the cheaper machines may be for occasional and private use, they are not sufficiently strong and reliable to stand the hard wear of constant thumping for eight hours a day throughout 300 days in the year. But the total disbursement need not be made in one payment. All the typewriter companies are prepared to sell their machines upon the hire-purchase system, and the extra price demanded for the accommodation is only 5 per cent. The usual terms of payment on the instalment system of purchase are £2 deposit and £2 per month.

Second-hand Machines. A word may be said about second-hand typewriters. Occasionally these are more expensive than new machines owing to the imperfect state of repair. The lady who buys a second-hand typewriter is usually wise to patronise one of the typewriter manufacturing firms, or, if she buy it from an outside dealer, to have it examined and certified to be in thoroughly good order by the makers.

It is not our purpose to discriminate between the respective merits of the many typewriters put forward as the best on the market. The purchaser must decide this point from an inspection of the machines themselves or from perusal of descriptive literature, which every manufacturer is only too pleased to supply. But it is a point worthy of note by anyone purchasing a typewriter for use upon many different classes of work that machines of the type of which the Hammond is the best known afford the facility of changing from one style of lettering to another by the mere withdrawal of one type shuttle and the insertion of another, an operation of only a few seconds.

The accompanying illustration shows a representative variety of type, reduced to two-thirds actual size. With any make of typewriter the purchaser may have the design of type preferred. The particular styles shown are from the Hammond machine.

Office Furniture. Besides the typewriter each operator must be provided with a desk and a chair, the joint cost of which need not exceed 50s. A smaller sum may be made to suffice by purchasing only a couple of small tables and a few chairs, which may always be bought very cheaply second-hand. Other items of capital expenditure are a carpet or other floor covering, a stock of paper to the value of, say, 20s., some carbon duplicating paper, say, 12s., and the office stationery necessary in any business. The duplicating department, which should be pushed, will entail the purchase of apparatus. Undoubtedly the Roneo or Rotary Neostyle is the best machine for such work, but its cost is high—from £10 10s. to £17 17s., and the beginner will be satisfied with a machine like the mimeograph which, with accessories, costs £2. The office must be provided with a good dictionary, but one may be purchased for 2s. 6d. If it be found that technical or scientific work comes in regularly and in fair quantity, a technical or scientific dictionary may be required. It is essential to have books of reference to check uncertain orthography. Then, if translation and copying in foreign languages be a department, a set of English-foreign dictionaries must be bought.

Staff. The woman who opens a typewriting bureau will, unless she be fortunate enough to begin with a very good list of regular customers, find that two assistant operators are capable of overtaking all the work she is likely to secure. At least one must be a capable stenographer, as demands will occasionally be made for one to be sent out to write at someone's dictation.

Young girls are often taken into typewriting offices as learners, and the practice enables the proprietress to secure service without salary expense and in return for tuition. Indeed, it is common for learners to pay a premium of £5 5s. to £10 10s., but it is somewhat difficult for a novice in proprietorship to secure premium pupils. An intelligent learner should in six months acquire expertness in the operation of a typewriter and moderate speed in shorthand, thereby becoming entitled to a salary. She should at the same time have attained a good knowledge of secretarial and general office work. During the first two months of her tuition she will, however, prove of little practical value in regular typewriting work, where experience is essential, and it is uneconomical to trust too much to such assistance.

Copying. The copying of manuscript is usually the chief business of the office, and is the least remunerative class of work undertaken. Even at the prices given in the table which follows the profits are not large if fair wages be paid to the typists employed. Some expert operators can turn out 1,000 words an hour, but this speed can never be maintained for an entire working day. The average amount of work for an eight hours' day is from 4,000 to 5,000 words, according to the clearness of the copy and its nature. If an operator cannot do this quantity she is not entitled to claim to be a fully-qualified typist.

Mimeography. The manifolding of circulars by the aid of a mimeograph or other manifold machine is far more remunerative than ordinary copying work. An operator can easily take off 200 to 300 copies an hour after the stencil sheet has been typed, and at the prices given in the list this pays very well indeed. This department should be pushed on every possible occasion, and by impressing the advantages of mimeographed circulars upon customers, much work which would otherwise issue in printer's type may be secured for the typewriting office.

Translation. It is desirable and frequent that translations to and from French and German should be executed in the office either by the principal or by a qualified assistant. It is, however, unusual to translate other foreign languages in the office, but to send them to regular translation bureaux. Many typewriting offices whose proprietors profess to do such work in the office merely send it to a translation bureau. The usual practice is that the translation bureau allows a discount of 25 per cent. from usual retail price, and this proportion represents the profit of the typewriting office.

Shorthand Work. The shorthand department of a typewriting office is another fairly lucrative branch, if prices recognised as standard and given on next page, be maintained. The work is paid for by time, and the quantity possible in a given time depends upon the speed of the dictator rather than upon the ability of the stenographer. The assistant sent to record dictation should always be able to work up to the limit of the customer's speed of speaking, for nothing dissatisfies the latter more than a stenographer for whom he has to wait. [See SHORTHAND.]

Prices. The usual charges for the various classes of work undertaken in good offices are on the following scale:

TYPEWRITING AND SHORTHAND.

Legal and Scientific Documents, Specifications, and General Copying	1½d. per folio (72 words).
Carbon Copies	Half-price top copy.
.. .. of Brief and Draft Work	1d. per folio.
Balance Sheets and Tabular Work	2d. per folio.
Authors' MS. in quantities of 5,000 words and over ..	1s. 3d. per 1,000 words.
Authors' MS. in quantities of over 10,000 words	1s. per 1,000 words.
Plays	5s. per Act of 18 Typewritten 4to pages.
.. after 18 pp.	3d. per page.
Actors' Parts	2d. ..
Typing from Foreign Languages .. .. .. from	3d. per folio.
Hire of Machine with Typist	2s. 6d. per hour, 10s. 6d. per day, £2 per week.
Hire of Machine with Shorthand Writer and Typist ..	3s. 6d. per hour, 12s. 6d. per day, £3 per week.

(Hours 10 a.m. to 6 p.m.; overtime by arrangement; cab fare extra).

Typing from Dictation in Private Room on the premises	2s. 6d. per hour.
Shorthand Writer on the premises	2s. 6d. ..
Typed Transcript of Shorthand Notes .. .. from	3d. per folio.
Addressing Envelopes and Wrappers	From 7s. 6d. per 1,000.

MIMEOGRAPHY.

For reproducing Typewritten copies of Letters, Circulars, Specifications, Balance Sheets, etc., etc., 10–1,000 copies from one Stencil.

No. of	Note.			Quarto.			Foolscap.		
Copies.	£	s.	d.	£	s.	d.	£	s.	d.
10 ..	0	1	9	0	2	0	0	2	6
15 ..	0	1	9	0	2	0	0	2	6
20 ..	0	2	0	0	2	3	0	2	9
30 ..	0	2	3	0	2	6	0	3	6
40 ..	0	2	6	0	3	0	0	4	0
50 ..	0	3	0	0	3	6	0	4	9
75 ..	0	3	9	0	4	6	0	5	9
100 ..	0	4	6	0	5	0	0	6	0
200 ..	0	8	0	0	9	0	0	11	0
300 ..	0	12	0	0	13	6	0	16	6
400 ..	0	15	0	0	16	6	0	19	0
500 ..	0	19	0	1	0	0	1	4	0

Typing of Stencil, 6d. per page.

TRANSLATIONS.

From French, German, Spanish, Portuguese, and Italian ..	1s. per folio. (72 words).
Into ditto ditto	1s. 3d. per folio.
From Dutch, Norwegian-Danish, and Swedish	1s. 6d. per folio.
Into ditto ditto	2s. per folio.

From and into Latin and Greek *from* 1s. per folio.
Russian and Oriental Languages .. By arrangement.
Special Terms arranged for large quantities of MS.

It must not be assumed that these charges are general. They are often cut mercilessly by those eager for business. We have seen quotations for copying work at 8d. and even 6d. per 1,000 words. Usually, the quality of the work bears a direct relation to the prices charged, and the office that seeks work at any price develops into a sweating den of the worst type.

Scope for Enterprise. Another class of work has yet barely entered into British practice, although it has a not unimportant vogue across the Atlantic. This is the dictation into the phonograph or graphophone by professional and business men. But it has entered into British practice, and its advantages are bound to carry it into favour. By its agency the need for the presence of a shorthand writer by the side of the dictator is obviated, and this is no small recommendation. We believe that there is a field for enterprise in taking up the typing of matter thus recorded.

The man who dictates into a machine must have either an Edison commercial phonograph, which costs £15, plus 12s. 6d. extra for a recorder, or a Columbia commerical graphophone, which may be bought for £10. With the former machine, an apparatus for shaving the cylinders is provided, but with the latter £5 extra must be paid for a shaving machine, so that the costs of the respective outfits are practically equal. It may be noted, however, that, with the graphophone separate outfit, the recording cylinders may be more effectively cleaned than with the alternate apparatus. Recording cylinders cost 1s. 6d., and take about 700 words each. They may be shaved and re-used some 40 times. For office use two machines are necessary—one for the dictator, and one for the typist, as either machine is too weighty to be transported conveniently. The typewriting bureau, where the necessary machine is kept, is open to overtake the typing of matter recorded upon the wax impressions, and it seems certain that there will be an increase in the demand for such service in the near future.

Business Methods. Little remains to be said about the methods of business. Neat circulars, intimating the opening of an office, and indicating the scope of the work undertaken, ought, of course, to be issued to likely customers. If the office be in a large office building, good may be done by making regular morning calls upon every individual or firm likely to have work. The worst that can happen is a refusal, polite or the reverse, according to the breeding of the individual addressed. Accounts should be rendered whenever any work is done, or, if to regular customers, weekly. Work is often secured by advertising in literary papers. Authors' work is usually desirable, being straightforward and very often in good batches.

GEOLOGICAL MAP OF THE BRITISH ISLES

EARTH'S STORY IN THE ROCKS

Formation of Strata. The Building of the Earth's Crust. The Modelling of Mountains. Features of Strata. Geological Time and the Age of the World

Continued from page 1817

By W. E. GARRETT FISHER

THE history of the earth through uncounted ages is written in the stratified rocks. It is a most fascinating story, and there are few occupations which give the geologist greater pleasure than endeavouring to add a new chapter to it.

Thus, for instance, he finds that seams of coal generally rest upon strata of shale or clay, which are thickly filled with curious branching objects. A happy guess identified these as the roots of fossil trees, while we know that coal itself is the remains of vegetable matter which has lost nearly everything but its carbon. The inference is plain—that the layers of clay or shale represent the soil in which an ancient forest grew. At the same time we know that this clay or shale itself was once laid down at the bottom of a sea or lagoon, since it is arranged in layers such as we know to be due to the deposit of sediment by water, and often contains the fossil remains of marine or lacustrine organisms. But in many places, as we drive our shafts into the ground, we find one coal seam lying upon another with intermediate layers of clay or shale or sandstone, until the whole thickness of the coal measures may amount to many hundreds of feet. We can then reconstruct the history of this part of the earth's crust.

Fallen Forests. Once a sheet of water rested there, far below the present surface. Rivers brought down sediment which they had abraded from the distant hills, and spread it over the bottom of the lagoon or sea until the bed rose above the water, and became land dry enough for the growth of primeval forests. For centuries these forests grew and flourished, and loaded the ground with rich, carbonaceous products of their fallen trees or shrubs, until the ground again began to subside by the slow movement of the crust, and the water overflowed it once more. At the bottom of this new lake the trees fell and decayed, forming a carbonaceous bed ultimately to be converted into coal, which was again covered by the sediment brought down by new rivers. After the lapse of fresh ages the ground again emerged from the water, whether by the accumulation of river-borne sediment or by the actual elevation of the land by internal forces, a new forest grew up, and the wonderful cycle was repeated; and that not once, but perhaps a score of times, until a rich coalfield was stored up against the needs of twentieth-century man.

Almost every part of the earth's crust tells a story as interesting, though not always as clear as this. In the remaining portion of our course it will be our business to show, first, how the sedimentary rocks were moulded into the shape that gives character to the landscape; and, second, how the history of the earth may be read in the innumerable strata which have been deposited by water and other agencies since the beginning of the world.

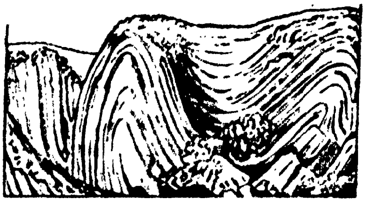
The Making of the Earth's Crust.

The various agencies that have now been described account between them for the slow and painful architecture of the earth's crust. The landscape as we now behold it is the outcome of a balance between numerous and often conflicting causes. It has been moulded partly by the steady shrinking of the earth's crust and consequent production of wrinkles on the face of our aged planet, partly by the chiselling effect of the various agencies of denudation, and partly by the influence of life in all its forms, covering hill and valley with a veil of vegetation, and helping to break down the angular surface of the barren rock into the rounded contours of fertile soil.

By far the greater part of the visible surface of the earth's crust consists nowadays of stratified or sedimentary rocks, which, as we have seen, are derived by the work of various superficial agencies from the igneous rocks. Originally these sedimentary rocks were laid down, mostly on the beds of lakes or seas, by the action of water; a few also, like loess, by atmospheric action; and a few, like tuffs, by volcanic action. But the great majority of sedimentary rocks are of aqueous origin. They were originally laid down, therefore, in layers or strata of various thicknesses, which were roughly horizontal, whereas at the present day we find these strata arranged in the most varied and irregular manner.

Incline of Strata. One may almost say that it is comparatively rare nowadays to find the strata lying parallel to the surface of the earth. A moment's thought will show us that if the strata still lay horizontally, the whole surface of the earth, or, at any rate, of a large area such as a continent, would be covered with a single uniform layer of one kind of rock. But we know that the case is very different. A glance at the geological map of the British Islands [see frontispiece, which is coloured in accordance with the presence of the different kinds of rock] will show that it is far more complicated than any political map of the world. Within the compass of a single day's work the geologist traverses a score of different rock surfaces. What this means, of course, is that, instead of the strata continuing to lie horizontally, they have been tilted, so that the surface of the earth consists in great part not of their flat upper surfaces, but of their *outcropping* ends.

Succession of Strata. The student may familiarise himself with this statement by taking a number of different coloured papers or pieces of cloth, and laying them on the top of one another. If this packet be laid flat, it will represent the mode and position in which the various strata were laid down on the bed of the ancient sea. Each bed or layer of rock is distinct from the one beneath it, although they may all be composed of similar materials. We may, for instance, have a series of layers of sandstone, or an alternation of sandstone with shale, or an intermingling of organic strata such as coal seams, or a still more complicated mixture of strata.



74. CRUMPLING OF STRATA (Lyell)

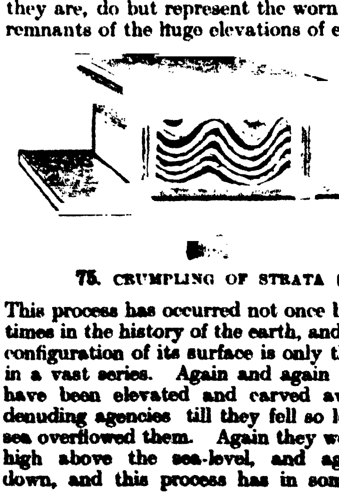
Each bed or stratum corresponds to a definite portion of time in the development of geological history, during which a certain kind of debris or loose material was being laid dawn, afterwards to be consolidated into comparatively hard rock. While the strata remain in their original position, only the one on the top, which, of course, was the last to be laid down, is visible. It is only by boring through the mass, as in sinking a well or coal pit, or in making a railway cutting, or when a natural section is made by a river cutting its gorge, or the sea undermining a cliff, that we learn the nature of the underlying strata. But it is evident that if we take our packet of sheets of paper and turn it on end, an observer looking from above will at once see the whole series of strata exhibited to his view. The same will be the case if, instead of turning the packet on end, we lay it on a sloping desk and, with a sharp knife, cut a horizontal section through it. On the flat surface thus produced the various sheets of paper, representing our typical strata of sedimentary rock, are exposed in the same order as that in which a vertical shaft would pass through them. This is what has actually happened in nature, and simplifies the task of the geologist.

The Strata Tilted. If it were not for the fact that the strata had thus been tilted in most parts of the earth, we should be confined for our knowledge of the earth's crust to such shallow scratches and borings as man is able to make. At the utmost we should know the nature of the crust to the depth of about a mile. But the fact that the strata have been tilted provides us with a far greater range of knowledge. For the denuding agencies which are ever at work on the earth's surface have done for the actual strata precisely what we have done with a sharp knife to our imaginary model. The contours or wrinkles on the earth's crust, which we saw to be a necessary consequence of the earth's cooling and contraction, have tilted the strata to very considerable angles [74]. We can see how this happens if we take a thickish paper-bound volume—a Christmas number of a magazine will do nicely—and, laying it flat on a table, press its edges towards one another. The result is that the middle of the book is elevated, whilst the separate leaves, which represent the strata of the crust, are thrown into a curved form [75], which, of course, means that they are tilted out of the horizontal into an arch.

Mountain Modelling. In this way the vast mountain range or tableland is formed—a wrinkle or swelling on the earth due to the contraction of the interior. The denuding agencies promptly get to work on this elevated region and gradually wear it down. If they were allowed to go on for an indefinite term, they would wear the whole surface down to the sea-level. But as even geological time is not infinite, these forces have succeeded only in wearing so much of the elevated part away as to leave what we now call a mountain range—such as the Alps—which is chiselled into the most wild and picturesque irregularities of shape simply because its materials were not homogeneous but of varying degrees of hardness, and consequently one part has been worn away faster than another.

The details of mountain carving are outside the necessarily limited scope of this course, but they may be studied with the greatest interest in more elaborate textbooks, such as Sir Archibald Geikie's "Scenery of Scotland." We need simply point out that the history of all mountainous districts is one of general elevation of the surface followed by the long secular process of modelling due to the various denuding agencies. It may be compared to the work of children making a snowman, who first heap up a roughly spherical accumulation of snow, and then shape it by scraping away the unnecessary parts.

Remnants of Ancient Mountains. Thus, our present mountain-chains, imposing as they are, do but represent the worn and wasted remnants of the huge elevations of earlier times.



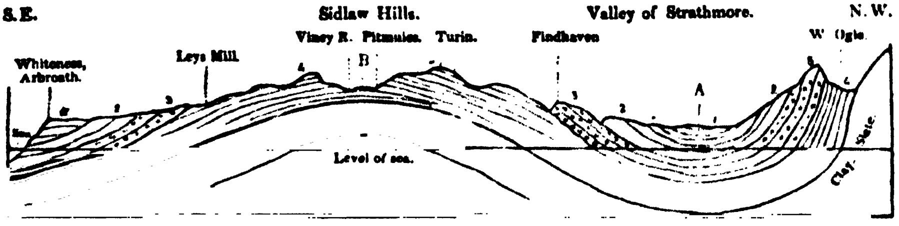
75. CRUMPLING OF STRATA (Lyell)

This process has occurred not once but scores of times in the history of the earth, and the present configuration of its surface is only the last term in a vast series. Again and again vast regions have been elevated and carved away by the denuding agencies till they fell so low that the sea overflowed them. Again they were elevated high above the sea-level, and again carved down, and this process has in some instances been repeated to our actual knowledge five or six times at least.

The "Everlasting" Hills. We may infer that this movement has taken place far oftener. If we think of the slow changes which now occur among the "everlasting hills," which are practically the same to-day as they were when Homer sang and Rome was represented by only a few poor huts, we shall get some notion of the vast and almost unimaginable ages which have elapsed since the earth cooled down sufficiently to develop the seas and watercourses which have been the chief agents in this work. Yet it is probable that even this incalculable space of time is but the smaller part of the æons which have passed away since the whole solar system existed in the condition of a fiery nebula. That nebula itself may, according to a very probable hypothesis, have been the product of an earlier collision between two stars, each of which may have had its attendant planets as far advanced in the order of evolution as the earth is now. Science is impotent to do more than adumbrate such a possibility as this, the serious contemplation of which overwhelms the mind with the sense of its own insignificance.

expect to be the case, since we know that they were originally laid down on a roughly horizontal sea-bed. Sometimes, however, instead of being regularly tilted they have been crumpled into all kinds of bewildering curves, in which case they are spoken of as being *contorted* [74].

Arches and Troughs. The most common way in which strata have been tilted is that illustrated by the experiment with a magazine described above, where pressure from either end of the strata has raised them into a wide arch. In that case the strata at the two ends of the arch will be found to slope in opposite directions [76], while as we travel from one end of the arch or dome to the centre, we find that the dip of the strata is steadily diminishing, until at the centre it is reduced to zero and the strata there are horizontal. If we go further on the dip is reversed in direction and steadily increases. The surface of the ground in many places has been changed by the pressure consequent on the earth's internal contraction into a series of *arches*, which must clearly be divided by corresponding *troughs*, very much like the surface of the sea. In a trough it is clear that the changes in the dip of the strata will be just the opposite to those in an arch. When the strata dip away from a central axis so as to form an arch, the structure is called an *anticline*; when they dip towards the central line so as to form a trough it is called a *syncline*.



76. TROUGHS AND ARCHES OF STRATIFICATION

Dip of Strata. The past history of the earth, so far as geology can read it, is written in the strata of the sedimentary rocks. We can study these at our convenience, owing to the already explained fact that in most cases they have been tilted so that their ends, chiselled off by the sub-aerial denuding agencies, reach the surface, where we can study them at our leisure. These outcrops form, as it were, pages in the great book of the geological record. They are numbered consecutively, so that we know the order in which to study them, the upper ones being the later.

When we find a stratum or bed cropping out on the surface, the first thing that we have to do after finding out of what kind of rock it is composed is to see what angle it makes with the horizontal. This angle is called the *dip* of the strata, and it is measured by a simple instrument known as the *clinometer* [see page 803], which consists of a graduated semicircle with a pendulum pivoted on its centre. Whenever we are able, as in a railway cutting or a quarry, to see the strata in section, we can measure their dip by holding the diameter of our semicircle parallel to a bedding plane, and noting at what division on the scale the pendulum then hangs. As a rule the angle which the beds thus form with the horizontal is fairly constant, as we should

Broken Arches. We seldom find this complete structure now in existence, since the arch has usually been worn away and the trough has been filled up by the processes of denudation and reconstruction which are always going forward. But we can reconstruct it in imagination by studying the dip of the strata. Where at two points some distance apart we find beds of a similar rock cropping out on the surface of the ground, pointing upwards and towards one another, we see without hesitation that they once met each other in a vast dome or saddle; if the dip of the strata be downward and each side towards the other, we infer that they actually meet at a point far below the surface. This curved arrangement of the strata characterises the greater part of superficial sedimentary rocks. In many places the curvature is more complicated and irregular; the strata have been so contorted, as in many parts of the Alps, that they are actually *inverted*, or bent round so that one part of the same stratum lies vertically upon another. But all these more complicated forms of curvature are due to the same cause, the bending of the originally horizontal strata under lateral pressure.

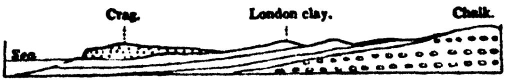
Outcrop and Strike. The part of a tilted stratum which emerges at the present surface of the ground is called its *outcrop*. Where the stratum is of considerable width, this outcrop forms a long streak, the direction of which is known as the *strike*. The strike is obviously at right angles to the direction of dip. The width of the outcrop depends upon the thickness of the stratum and its inclination to the horizontal, since the outcrop is a section cut through the stratum by a horizontal plane. It may be only a few inches in width, or it may be many hundreds of feet. In the latter case it is usually found that the stratum, though composed of the same rock throughout, is divided by a number of fissure planes into a series of thinner strata, or *laminæ*, each of which corresponds to a definite period of the time when the materials of the rocks were being deposited.

The Order of the Strata. One of the most important things to study in connection with the sedimentary strata is the order in which they were deposited. In the rare cases where the strata still preserve their original horizontal attitude, the lowest stratum must clearly be the oldest, and the uppermost one the most recently deposited. If the strata have been tilted or crumpled [77] they still preserve the same relative chronological order. In order to find out from a series of strata cropping out on the surface of the earth which was originally the lowest, we have simply to measure the direction of their dip. Obviously, the stratum which has its outcrop farthest in that direction was originally the uppermost and is, therefore, the youngest. As we walk in the opposite direction we are tracing the strata backwards in time.

In this way we are enabled to say with entire certainty what was the order in which certain sedimentary rocks found in juxtaposition to one another were laid down; and geologists have been able to establish a definite and coherent history of the earth, which it will be our business to describe in the concluding section of this course. We have already seen that the great majority of the sedimentary rocks contain fossils. These remains of prehistoric creatures differ widely in character and species, according to the rocks in which they are found. This fact has been of the greatest service to the study of the evolution of life, since the geologist is able to tell the biologist that certain rocks have invariably been laid down after certain others, and, consequently, that the fossils found in the latter were the ancestors, or at least the forerunners, of those associated with the former.

Geological Time. There is, unfortunately, no absolutely certain method of translating the geological scheme of time into the terms of human chronology. We can say with entire certainty that one stratum or set of rocks has been laid down before another, but we can only make rough guesses at the actual lapse of time which separates these events. Some inference may be drawn from the rate at which we see certain kinds of rock, such as shale or sandstone, being laid down at the present day. But it is very dangerous to argue that the same rate existed in the remote past. What we can be sure of is that the lapse of time represented by the formation of the sedimentary rocks was very great. To take a single instance, the carboniferous limestones of Western Europe are composed entirely of the shells and skeletons of minute organisms which lived in a long vanished sea, and strewed their calcareous remains on its bed when they died and sank down through the water. This process went on long enough to accumulate thousands of feet of limestone; and at the very lowest estimate, that must have taken many thousands of years; yet this is but one layer out of the immense thickness of sedimentary rocks which have been gradually accumulated in the upper part of the earth's crust. The geologist is probably well within the mark when he demands anything from one hundred to five hundred millions of years for the slow unfolding of the earth's physical history.

Joints. The sedimentary rocks are not only characterised by the roughly horizontal divisions into strata, but by vertical fissures or planes of division, which are known as *joints*. These are probably due to the strain which has been brought to bear upon these rocks in the course of the shrinkage of the earth's crust. Experiment has shown that the folding or twisting of the rocks gives rise to joints, just as the strain put on the ice of a glacier by its movement makes it crack into numerous crevasses. Igneous rocks present a jointed structure as well as stratified rocks, in consequence of the same cause. The existence of these joints has a two-fold importance to man. In the first place, they provide channels for the circulation of underground water, which travels along these cracks in an otherwise impermeable rock, and thus is enabled to contribute to those widespread subterranean effects which have already been described, and also to return to the surface in the form of springs where the configuration of the ground permits of this. It is also by taking advantage of these joints that the miner and the quarryman are enabled to perform their work with a minimum of exertion.



77. TILTED STRATA

Division Planes. Stratified rocks, like flagstone and sandstone, are divided into more or less rectangular blocks by the double set of division planes which intersect them—the bedding planes which divide strata horizontally, and the joints which are usually vertical. In this way large cubical blocks can be quarried without much difficulty by taking advantage of these natural divisions. An ordinary block of household coal illustrates both sets of planes very well. It is divided in one direction into comparatively fine laminæ, which have usually soft surfaces and soil the fingers; these are bedding planes, or planes of stratification, which were originally horizontal or parallel to the dip of the coal seam. At right angles to them will be found joints, along which the coal splits when struck with a poker; the face thus exposed is rough and bright, and does not soil the fingers. Good coal will usually split along these two faces into roughly cubical fragments. The picturesque cracks and castellated structure so often seen in sandstone and limestone districts are due to the splitting of the rocks by meteorological action along the lines of joints. Igneous rocks are traversed by one set of divisional planes only, the joints. Thus, the quarrying of a rock like granite is attended with greater difficulties than that of the stratified rock, as it naturally tends to split only in one direction. The remarkable columnar structure of basalt as seen by tourists in the Giant's Causeway [see page 1008] and the Caves of Staffa are due to jointing.

Cleavage Planes. *Cleavage planes*, which we have already described as occurring in minerals, are a third set of divisional planes which have been induced by severe and long-continued pressure in certain rocks. It is most perfectly seen in slates [see page 1355], which can be readily split into thin plates along the cleavage planes. Some igneous rocks like the felsites show well-marked cleavage planes, which enable them to be readily split up into flags for paving.

There is another kind of division in rocks which has been caused by movements of the crust. This is known as a *dislocation*, which is simply a fracture extending for some distance through a mass of rock. Where the dislocation consists of a simple crack in the rock it is known as a *fissure*. But in the majority of cases the fracture has been accompanied by a vertical displacement of the rocks on one side of it, and it is then known as a *fault* [see page 1352]. Where the fault occurs in stratified rocks, the strata on one side of it no longer conform to those on the other. They have been moved bodily up or down, and the result is that they no longer join on to one another.

"Faults" and Earthquakes. Faults of this kind usually lead to weakening of the crust where they occur, and often play an important part in the occurrence of earthquakes or volcanic action. The reason why the district of Comrie is peculiarly subjected to earthquakes is that it lies upon the great fault of Perthshire. Faults are very important to miners, because where one occurs the coal seam or vein of metallic ore seems to come to a sudden end. As a matter of fact, it has been shifted bodily up or down, and some geological knowledge is necessary in order that the miner may know where to look for its continuance. A fault may be a vertical dislocation, but it is usually inclined. Its inclination from the vertical is known as the *hade*, and the amount of vertical displacement of the strata on either side is known as the *throw*. In the case of the vertical fault there is no lateral displacement of the strata, but if the fault be inclined, it will be seen that the lateral displacement may be very considerable, and its extent depends both on the throw and the hade. The strata on each side of the fault preserve their relative positions, and when the hade and the throw are both known, it is an easy matter to calculate where the continuance of the lost seam or vein may be looked for. For further details the student may be referred to the course on Mining.

POOR LAW APPOINTMENTS

Positions on the Non-resident and Resident Staffs. Clerks, Relieving, and Medical Officers, Masters, Matrons, Nurses, Attendants, Storekeepers

By ERNEST A. CARR

Clerk to the Guardians. This, the foremost office on the Poor Law staff, may fairly be compared in more than one respect with that of town clerk. Like the latter official, the clerk to the guardians is at once head of the executive and adviser to his authority. In both capacities his duties are very important. It must be remembered that the board of guardians is an association of amateur administrators; and that while its members are for the most part properly equipped for their tasks, instances of prejudice, misconceived powers, and mistaken zeal are not unknown among them. Naturally, the difficulties arising in the administration of poor relief are, in the main, legal. This work is governed by a complexity of statutes, Local Government Board orders and circulars, official precedents, and decided cases; and with the risk of surcharges always present, it is a responsible and difficult task to pilot the board in safety through its many functions. To take but a single instance, the question of "settlements"—which consists in determining the parish or union to which a pauper is properly chargeable—presents some of the knottiest problems that ever gladdened the heart of a lawyer.

The Need for a Legal Training. Hence it is that some sort of specialised legal training, whether professional or not, is almost as indispensable for the position of clerk to the guardians as a wide experience of Poor Law methods and practice. We may rank as next in importance a thorough knowledge of rating and assessment work. During recent years there has been a growing tendency on the part of the authorities to select for their leading official a solicitor or barrister who is well versed in each of the above requirements, but the proportion of professional men in the service of the guardians is still small. The appointment lately made by the York Board serves to illustrate the class of training that is likely to stand a candidate in good stead. The record of the officer selected as clerk included 11 years spent in a solicitor's office and 15 years' valuable experience in the assessment of property and the details of rating, acquired in the double capacity of assessor of income and assistant overseer.

The Best Training School. A census of guardians' clerks throughout the country would demonstrate that the majority of them qualified for their positions by years of service under the guardians in the capacity of assistant clerk. The best school for candidates is to be found in the office of a clerk to the guardians of a busy area who is himself a solicitor. A stern critic of our Poor Law service has complained that "the system of hereditary succession often prevails in it, as in the case of French executioners under the old régime." Local influence certainly counts for a good deal sometimes in the contest for a chief, although exerted in the direction of official rather than hereditary succession. But the Poor Law service is not the only one in which the reversion of the leading rôle oftenest falls to the understudy.

Salaries and Emoluments. As is inevitable among authorities of such widely differing importance, the remuneration of clerks to the guardians varies greatly. In a small rural union the salary is usually fixed at a figure between £180 and £300 a year. On the other hand, in a busy city or a metropolitan union it may be anywhere within the limits of £400 and £1,000. The clerk to a northern London board, for instance, has received first £500, then £650, and afterwards £850 a year. Those amounts, however, covered the salaries of any assistants employed by him. In this respect there is a good deal of diversity of practice, some guardians paying an inclusive salary, out of which the expenses of an office and staff have to be defrayed, others providing office accommodation or clerical assistance only, and yet others fixing a strictly personal remuneration.

The actual salary attached to a clerkship as such seldom represents the full fruits of the position. The clerk of the guardians very frequently holds several minor appointments in addition, the rewards from which add considerably to his income as clerk, and may even double it. Thus, in the London union already referred to, the total emoluments enjoyed by the clerk as an officer of the guardians are as follow:

	£
Clerk to guardians	850
Clerk to assessment committee (average)	400
Superintendent registrar..	350
Returning officer at elections (average)	25
	£1,625

The first two items include the salaries of assistants.

Similarly, the clerk to a small provincial union at £200 a year receives approximately an equal amount as superintendent registrar of births, etc., £35 a year for his services under the assessment committee, and, in addition (being under no restrictions as to other work), is clerk to the local district council at a salary of £255—a total income of nearly £700 a year. It will be evident, therefore, that the office of guardians' clerk is often a very lucrative one.

Assistant Clerks. The staff of subordinate clerks is small. It ranges from a junior at £40 or £50 a year up to the first assistant clerk, whose pay may reach £350, but is more often between £150 and £275. The number of intermediate posts is naturally determined by the importance of the union. Concerning the prospects of senior assistants there is nothing to add to what has been said in discussing principal appointments. Their practical training should have special reference to Poor Law accounts and the law of settlement and removal, and can be gained only in a guardians' office.

The Relieving Officer. "The pivot of a well-administered Poor Law," says a distinguished authority, "is an intelligent, sympathetic, and high-minded relieving officer." Without undervaluing the services of the indoor staff, most persons who are in touch with the difficult problems of poor relief will be inclined to echo this dictum.

The peculiar importance of this public servant's duties is explained by the fact that he has to investigate the cases of all applicants for relief and to lay before the board or committee a report of their health, circumstances, character, and ability to work. The guardians personally know nothing, as a rule, of the facts concerning these applicants. They rely on their expert to ascertain those facts; and upon his report and advice their action in dealing with each request for aid mainly and necessarily depends. Now, the essence of effective relief is a wise discrimination between the various classes of applicants. The indolent and vicious must be sternly dealt with, the unfortunate aided, the infirm provided with a shelter—always avoiding the extinction of self-reliance and the fostering of a pauper spirit. If, therefore, the relief administered is to prove helpful and not harmful, the relieving officer must be a shrewd, kindly man, neither credulous nor routine-bound, and his reports must be full, impartial and suggestive.

An Official Man-of-all-work. The relieving officer, with or without assistants, is generally placed in charge of a Poor Law district, within which he must reside. His duties, which are regulated by orders of the central authority, are of a very varied character. In addition to the work already mentioned they include the granting of temporary relief in urgent cases, and of provisional orders for the workhouse; placing lunatics under restraint, and transferring to their place of settlement paupers belonging to other unions. He has also to call in the district medical officer and nurse when occasion arises, and to take out-relief to the poor who are too ill or feeble to call at his office for it.

Qualifications. No officially recognised school of instruction for these posts at present exists, and the majority of candidates enter the service without any real knowledge of their work, picking up such information casually and piecemeal after appointment. There are many objections to this method, and it is fortunate that the School of Sociology and Social Economics affords special facilities enabling a would-be officer to learn something of his duties beforehand. It is hoped that the School will soon be authorised to issue certificates of proficiency. In the absence of any such instruction the best training is afforded by a subordinate or assistant position under an able and zealous officer.

Candidates are usually required to be over 25 and under 40 years of age, the upper limit being sometimes reduced to 35. A medical examination is generally compulsory; and as relieving officers hold money of the guardians in trust, a common condition of appointment is that security shall be found in £100.

Rates of Pay. Superintendent positions command from £220 to £250 a year and occasionally £50 more. Apart from these, the range of a relieving officer's earnings lies within the limits of £100 and £200. A post of average value would commence with about £120 a year and advance to £150 or a little more. London salaries, however, are on a slightly higher general level. In the City, for instance, district relieving officers begin at £160 and rise to £200. On the other hand, a good many rural boards are unable to pay more than £80 or £90 a year for relief work; but in such cases the officer's income is usually raised to about £125 at least by other emoluments. These include the appointments of registrar of births and deaths, vaccination officer, and collector to the guardians—all of them being Poor Law posts, and a small stipend being attached to each. Candidates without previous knowledge of relief work must generally be content to enter as assistant relieving officers at £80 or £100 a year, until qualified by experience for a better position.

Other Posts. In busy districts, separate appointments are generally made to the posts of collector and vaccination officer. The collector in such cases usually receives either 10 per cent. of the sums he recovers for the guardians, or a fixed salary of £100 or £120 a year and a commission of five per cent. in addition. Vaccination officers are paid for each case of successful vaccination according to a scale of fees prescribed by the Local Government Board. Under a London board of guardians, such fees may amount to £130 a year or more. Officials of these two grades are frequently allowed to undertake other work during their spare time.

District Medical Officer. In order to make complete our survey of the Poor Law service, it is necessary to refer to the district medical officer, better known among his patients as the "parish doctor." This is a non-resident post, the local practitioner who holds it being required, in return for a fixed salary paid him by the guardians, to furnish the poor of his district with medical treatment and drugs. Extra fees are prescribed by the Local Government Board for certain operations, and there may be special charges made for child-birth cases, and for cod liver oil and other costly medicines supplied. The remuneration paid is never very considerable, varying from a purely nominal sum to £150 or so yearly. But many a struggling young medical man finds his sheet-anchor in the £80 or £100 a year he receives as parish doctor; and even more flourishing practitioners do not disdain such an addition to their incomes.

Indoor Appointments. Certain emoluments or allowances accompany the salaries paid to all resident officers of the guardians and of similar authorities. As a rule the indoor staff are provided with free rations, furnished or unfurnished apartments, lights and washing. Matrons, nurses, porters, and attendants are also entitled to their uniforms; and in many instances the subordinate officers have the option of an annual allowance of £3 or £4 in lieu of intoxicants. The lodging accommodation provided varies in value with the status of the official. The scale of rations is fixed in each parish or union by the guardians. As an instance (though hardly a favourable one) of this allowance, the following weekly dietary list for the officers of a rural workhouse is of interest:

Bread, 7 lb.
Meat (or fish, if desired), 7 lb.
Butter, loaf sugar and bacon, each 1 lb.
Tea, ½ lb.; or coffee, 1 lb.
Milk, 7 pints.
Cheese, 12 oz.
Jam or marmalade and moist sugar, ½ lb.
Eggs, 4.
Vegetables, rice, flour, currants, raisins, pickles and condiments as required.

The Workhouse Staff. The recognised heads of the workhouse, on their respective sides, are the master and matron. They exercise general supervision and control over officers and paupers alike, and are answerable for the safety of the guardians' property, the due performance by every inmate of his or her daily task, and the proper conduct of the whole institution. Their duties are elaborately laid down by the General Consolidated Order of 1847. In the words of a Poor Law expert, "The management of the workhouse is in the hands of the master and matron, whose duties are set forth in the regulations in the minutest detail, from the daily reading of prayers and saying grace before and after meals to the cooking and distribution of the food, the general inspection of the wards, and the maintenance of order amongst the inmates. The temperature of the water for the baths is even laid down in the rules."

Salaries of Chief Officers. Without further instances of their multifarious duties, it will be readily understood that the master and matron of a workhouse are busy, responsible and often much-harassed officials. Their work requires good organising powers, energy, and discretion, and a sound knowledge of all the complexities of Poor Law administration and accounts. The incomes with which these qualities are rewarded cannot be said to err on the side of extravagance. For the larger unions, the joint earnings of master and matron usually amount to £200 or £250 a year, with emoluments computed at from £70 to £120 extra in all. In smaller institutions the total income, excluding allowances, varies between £175 and £80, or even less. "Low-water mark" is probably represented by two recent advertisements, both offering, in return for the responsible services of a master and matron, a joint income of £50 a year! The following are more typical examples, the salary of each officer being given separately in every case:

	Master.	Matron.
Liverpool ..	£150	£50
Woolwich ..	£100 (rising to £130)	£60 (rising to £70)
Ipswich ..	£115	£55
Ormskirk ..	£100	£60
Halifax ..	£85	£50
Sevenoaks ..	£75	£50
Slough ..	£70	£40
Salisbury ..	£70	£35
Stockdale ..	£70	£30
Hertford ..	£73	£20
Smallburgh ..	£50	£30

Previous experience of Poor Law work in some capacity is practically essential for these positions. Hence, they are generally filled by the selection of an assistant master and matron, a relieving officer and his wife, or the superintendent and matron of a casual ward. In more than one recent instance a married couple beginning their Poor Law service as porter and portress have ultimately attained control of an important workhouse. As a rule, the master and matron are chosen from among applicants between 30 and 45 or 50 years of age, and either childless or with only a small family.

Subordinate Officers. Assistant masters and masters' clerks are employed only in the larger institutions. A knowledge of the system of bookkeeping and accounts approved by the Local Government Board is a useful qualification for these offices, which command from £30 to £65 a year, with the usual extras, and are attractive chiefly as stepping-stones to a higher appointment. The positions of labour master and labour mistress, involving supervision of the able-bodied paupers during the performance of their daily tasks are open to candidates who have no previous experience but who can furnish proof of being good disciplinarians. For male officers, ex-sergeants and corporals of the Army are in request; while a knowledge of steam laundry work is frequently a strong recommendation for the post of labour mistress. The limits of age are usually 25 to 40 for men and 25 to 35 in the case of women. Masters are paid £30 to £36 a year, and mistresses about £5 less. The average rate of pay for yardsmen, wardmen, and porters is £27 to £32 yearly. Apart from the ordinary domestic servants, these officials complete the executive staff. Every workhouse also has a small number of skilled operatives, including generally a fireman or engineer at £80 or £90 a year; a baker, receiving £60 or £65; a tailor, shoemaker, and male cook, each earning about £1 a week; and laundresses, at £25 to £35 a year.

The Casual Wards. These institutions are sometimes part of the workhouse itself, but often are at some distance from it. They are designed for the reception of tramps and other "casual paupers" of both sexes, and are in charge of a superintendent and matron, whose duty it is to give their squalid guests the lodging and scanty fare prescribed by the regulations, and to insist on the performance of a proper task of work in return. The qualifications required of these officers, and their earnings, are practically those of the labour master and mistress, which have already been discussed.

Hospitals and Asylums. The Poor Law infirmary or hospital is on practically the same footing, in respect of its medical and nursing staff, as the asylum for pauper lunatics and imbeciles. These two classes of institution may therefore be considered together. In discussing them we may adopt the convenient method (already followed more than once in this course) of selecting a leading and typical authority and commenting on such differences in the conditions of employment as distinguish it from less important bodies.

The "M.A.B." In its Poor Law administration, as in so much else, London affords us the most striking instance of this class. The Metropolitan Asylums Board, popularly known as the "M.A.B.," was created by the Metropolitan Poor Act of 1867, to furnish proper provision for the imbecile poor, and for others who were stricken with fever or smallpox. It now owns 12 great fever hospitals, three others for smallpox, five imbecile asylums, and a training ship and medical homes and schools for workhouse boys. These are controlled by 73 managers, 55 of whom are elected by the London boards of guardians, the remainder being nominated by the Local Government Board.

Through the courtesy of the clerk, Mr. T. Duncombe Mann, we are furnished with authoritative particulars as to the staff of this great Poor Law association. In respect of medical appointments, the following details are given.

Infectious Hospitals. There are 12 medical superintendents at £400 a year, rising £25 annually to £700, all with unfurnished houses, coal, light, and washing, and some receiving extra remuneration for acting as clinical instructors to medical students. These officers are in supreme control, and their duties are, therefore, very wide-reaching. About 50 assistant medical officers are employed, in two grades. Those in class 1 receive £280 the first year, and afterwards £300 per annum; while for class 2 the scale of pay is £180, rising £20 annually to £240—all with board, lodging, and washing. Among the assistant officers about 14 vacancies occur yearly.

Imbecile Asylums. Medical superintendents receive £600, rising £50 yearly to £800, with the same allowance as in the hospitals. Their staff of 14 medical assistants comprises three classes of appointment. The scale of pay in the first class is £250 to £300; in the second, £180 to £200; and in the third, £150 to £170, in each case advancing by £10 yearly. All assistants receive also board, lodging, and washing.

The medical officers of workhouse infirmaries are less liberally remunerated. Where several resident doctors are required—as in the larger London unions—the senior officer may receive between £350 and £450 a year, and his assistants from £190 to £250 or £300, according to their grade. But there is no uniformity in the rates of pay offered by the guardians, and in country areas the scale is often lower.

Matrons and Nurses. The responsible officer in charge of the nursing and household establishment in Poor Law hospitals and asylums is the matron. Her post is generally admitted to be an arduous and anxious one. With or without the aid of an assistant, she is required to superintend the work of her staff of nurses, to train the probationers, and, while thus attending to the professional side of her duties, to secure the smooth working of the whole institution by careful regard for a thousand domestic details. These duties need a qualified nurse who is also a capable, energetic organiser; and well paid as she is, the matron fully earns her salary. In nursing institutions generally, her normal rate of pay as a resident officer is from £80 to £100 a year, and her assistant receives about half as much.

Respecting the Metropolitan Asylums Board service, Mr. Mann writes: "The matrons of the Board's institutions must all be trained nurses; the pay varies from £100 to £150 a year, according to importance of position. In each case full resident allowances are granted. In the case of the medical schools the matron is head of the institution; but in the case of the asylums and hospitals is not, the medical superintendent being in charge. The whole number of matrons employed is about 27."

Nurses under the M.A.B. The staff of nurses employed by the M.A.B. is a very large one; it varies considerably from time to time, but generally numbers about 1,200, the great majority being employed at the Board's hospitals, and a few in the asylums and institutions for children. The appointments made are of three grades—namely, as charge nurses at £36 a year, rising to £40; first-class assistant nurses, £24–£28; and second-class assistants, £20–£24; the increment in each case being an annual one of £1. Full resident allowances are provided in each grade. The annual leave for charge nurses is four weeks, and for the rest three weeks.

Candidates for Appointment as Nurses. Applicants for the position of charge nurse must be at least 25 years of age, and are required to provide certificates of three years' training in either a general hospital with a recognised school for nurses, or "a Poor Law infirmary in which systematic instruction is given and tested by subsequent examination by an independent authority." These officers are eligible for promotion to the position of superintendent nurse and matron. Assistants of the first class must be 23 or older, and must have undergone a year's training at one of the institutions already mentioned. Two years' service in this grade is essential for advancement to the next. For second-class assistant nurses no proof of training is required. Candidates must be at least 22 years of age, and must serve for two years before becoming eligible for promotion to the first class.

unless they have had a year's previous experience in a hospital or infirmary. Promotion and increments are in all cases dependent on the recommendation of the chief medical officer and the matron.

Confusion in the Nursing Service. The Poor Law nursing service, as a whole, exhibits no such uniformity of system in respect of either salaries or qualifications.

Some boards of guardians require merely that applicants shall have had a year's experience in a public institution, while others insist on two or three years' systematic training in a recognised hospital school; and those boards with a large hospital or infirmary under their control generally prefer to train their own staff as far as possible. For general infirmary duty, the L.O.S. certificate in midwifery is a valuable qualification.

For head or charge posts, the usual age limits are 25 and 35 or 40 years, and for assistants or probationers, 21 and 30. Fully trained and certificated nurses are paid from £32 to £45 as resident officers—or £65 to £85 if non-resident—according to the liberality or otherwise of the guardians and the importance and responsibility of the appointment. The initial salaries of those who are less highly qualified, or hold assistant rank, vary in the same way between £30 and £21, or occasionally as low a limit as £18 a year. The following are average figures for probationers: Two years' training, £12 and £16; three years, £10, £16, and £20. It is commonly stipulated that applicants for nursing posts must be either widows without dependent children, or single women.

Position of Poor Law Nurses. The position accorded to Poor Law nurses varies no less than their stipends. The Metropolitan Asylums Board is careful to provide each officer, as far as possible, with a room of her own, and expressly declares that "The nurses rank as a class superior to and separate from the other members of the female staff, and are boarded and lodged apart from the remainder of the hospital staff." But in small infirmaries these officials are sometimes far less punctiliously treated. In this respect, as in others, the service needs to be established on a uniform basis.

A brief reference may be made here to the attendants of either sex employed at Poor Law asylums and hospitals. The rates of pay and conditions of entrance very closely resemble those already given relative to the posts of labour master and mistress. For an attendant's position the qualifications most in request are good character and bearing, sound health, and physical strength.

Stewards and Storekeepers. The terms on which these officers are employed in the larger institutions of the guardians are well exemplified by the following particulars respecting the Metropolitan Asylums Board, which are communicated by the Clerk of that authority.

"Clerks and storekeepers and stewards may be properly classed together. Their pay ranges from 40s. a week, with no resident allowances, to £300 a year, with full allowances, according to the size of institution to which they are attached and the extent of their duties. These institutions vary from a convalescent home for 100 children to an imbecile asylum for 2,000 patients. No technical qualifications are required, but, other things being equal, a man with some experience of the Poor Law system of keeping accounts (which is special and rather complicated) would probably have some preference. The duties consist of keeping the books of account with regard to the institution, receiving and distributing all supplies and stores, acting as clerk to the institution, and of supervising to some extent certain of the male staff; and, in institutions to which land is attached, their duties embrace the control of the farming and other operations."

This section of the Metropolitan Asylums Board staff includes twenty-seven principal posts and a considerable number of subordinate ones. An excellent way of entering is as steward's junior clerk. These officers, who must be not less than eighteen years of age on appointment, receive £40 a year, rising to £50, with board only. Their duties afford the best of training for an assistant stewardship, which is remunerated with £80 a year, advancing by £5 annually to £100, as well as full indoor allowances. Thence, for a capable official, promotion to principal rank should be assured.

Schools and Cottage Homes. These special centres for pauper children form an invaluable means of rescuing young lives from the dismal associations of the workhouse. For our purposes, however, the union school may be dismissed in a few words. It is generally controlled by an experienced superintendent and matron—the latter in many instances a trained nurse—at a joint salary of £120 to £200, with apartments and other advantages. It has its own small staff of teachers, who are often ill-equipped and indifferently paid. Properly qualified instructors of either sex will usually find the County Council a more satisfactory employer than the Board of Guardians.

Cottage homes are practically Poor Law colonies, in wholesome surroundings far from the taint of cities. Each house has its quota of youngsters under the care of a foster-mother—often a kindly-natured widow—who in return for wages of £20 or £25 a year and emoluments cooks and washes for her adoptive family and trains its girls in domestic ways. Sometimes a young or middle-aged married couple is in charge instead—in which case the husband's share is the care of the boys out of school hours, and a salary of some £30 or £35. For these posts, experience of children and the absence of "encumbrances" are generally essential. Humble as the work is, it is at least more pleasant than much that falls to the lot of Poor Law officials.

Our survey of the Municipal Service is concluded, and we now turn to a new branch of our subject—the National Service.

Municipal Service concluded

ELECTRIC TRAMWAYS

Properties of Series Motors. Motor Construction. Control of Tramway Motors. Tramcar Brakes. Overhead Construction. Bonding the Rails

Group 10
ELECTRICITY
14

Continued from page [illegible]

By Professor SILVANUS P. THOMPSON

ONE of the earliest industrial applications of electricity was to the driving of tramways. The first electric tramway was installed by Siemens, of Berlin, in 1882; and the system was quickly taken up and brought to a high state of development by American engineers, owing to the bad roads rendering this form of suburban and intra-urban locomotion practically the only possible one. It is remarkable that the system of traction early adopted is the one which commands practically universal acceptance until the present date. It consists essentially of (*a*) a supply of *continuous current* at 500 to 550 volts, generated in (*b*) a *central power-house*, and transmitted to the cars by means (*c*) of *overhead conductors*, whence by contact with a trolley wheel on a pole on the car it is led down to (*d*) *two series-excited motors*, which are placed electrically first *in series* with one another *at starting*, and then *in parallel* with one another when a sufficient speed has been attained.

Tramway Systems. The only recent modifications (and these have been adopted only in certain exceptional cases) are the substitution of a supply of current from sub-stations where a high voltage alternating current is converted to continuous [see SYSTEMS OF SUPPLY]; the adoption of underground conduits or of methods of surface-contact in place of overhead wires; and the use in hilly districts of shunt-excited motors. A few lines are indeed operated by alternating currents, but they are exceptional. The chief technical interest, therefore, turns on the application of continuous currents by the use of two series-excited motors on the car, since it is this particular combination which has shown itself best adapted to the needs of tramcar propulsion. These needs are, in the first place, a great starting effort when the car begins to move, and, secondly, means of changing the propelling effort as required by the changes of speed and the exigencies of ascending or descending gradients. Attention must therefore be first directed to the properties of the motor, and then to the methods of electrically controlling its speed, its effort, and the amount of current which it draws from the lines.

The Series-excited Motor. On page 1325 we discussed the different methods of exciting the field-magnets of generators. The same arrangements can be used for exciting motors, though, of course, the motors will have different characteristics of working when used under the different conditions.

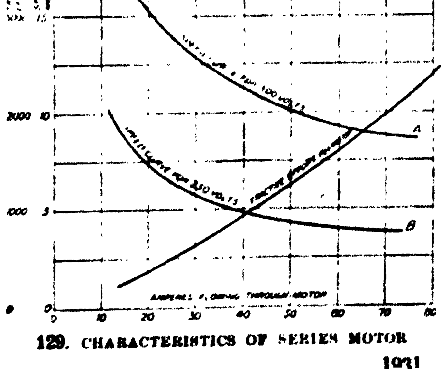
Just as the shunt dynamo is the one principally used at the present day, so the shunt motor, with the notable exception of traction work, is almost exclusively used for power purposes. The article beginning on page 1590 was taken up wholly with a discussion of the shunt motor; we have now to study the series motor in connection with its only present-day application.

The characteristic properties of a series motor are generally considered with reference to the current which it takes, and are expressed in the form of curves, such as are shown in 129.

To help in the study of these we may classify in parallel columns the properties of the series and the shunt motor as follows:

SHUNT MOTOR	SERIES MOTOR
The *speed* is practically constant at all loads, and therefore independent of the current flowing through the armature.	The *speed* varies, and is high with a small current and vice versâ, because the magnetism is created by the same current which eventually flows through the armature, and therefore alters with it, and a high speed is necessary to generate the same voltage with a smaller amount of magnetism.
The *torque* [page 1592] or *tractive effort* is directly proportional to the current, again because the magnetism is constant.	Because the magnetism increases with the current, the *tractive effort*, which depends upon both the magnetism and the armature current [see page 1592], is relatively greater with large currents.

It is the combination of these two qualities which makes the series motor so valuable for



129. CHARACTERISTICS OF SERIES MOTOR

traction purposes, for at starting, when the greatest tractive effort is required, this effort is greater per unit of current than it would be with a shunt motor, and the natural speed of the motor is low when a large pull is required. The advantage of the latter is seen when the car is climbing a hill, for if a shunt motor were used it would require to run at practically the same speed as on the level, and an excessive demand of power would be required from the line.

Construction of Tramway Motors. The manufacture of tramway motors is an art which has been acquired only after years of experience. A minimum amount of space is available underneath the car, and the motor has to be totally enclosed to protect it from the weather. The construction of the various parts must be without fault, for they have to withstand the heavy strains ranging from an expeditious starting up under the maximum load to those due to an emergency braking.

The motor itself is invariably of a four-pole design, and a typical example is illustrated in **130**, **131**, **132**, and **133**. Fig. **130** gives a view of the complete motor ready for mounting on its truck. The box-like casing, which also serves as the yoke of the magnetic circuit, is of the best cast steel, and is made in two parts, which are hinged so that it can be conveniently opened for examination, as in **133**. With one half of the box are cast the brackets which form the bearings of the car-axle and other details necessary in mounting the motor [see **131**]. In tramway work the motor is never placed directly on the wheel axles, but drives through a reduction spur-wheel gear, the ratio of the speed of the motor to that of the wheel axle being from 3·5 to 1 to about 5 to 1. By adopting this arrangement the motor may be mounted on springs [**132**], which take up all the jolts and jars from the road, and thus protect the motor to a considerable extent.

To minimise the energy-losses in the iron of the magnet core, it is generally built up of laminations riveted together. In the motor shown there are four magnet-poles. Two of these, marked MM in **133**, are in the lid, the other two are in the lower part underneath the armature A. The pole-cores are as short as possible, and the exciting coils EE are wound on formers to such a shape as to make best use of the space available between the poles and the case. The armature A [**133**] is always wave-wound [see page 1321], so that only two sets of brushes are needed [**68**, page 1322], and in this way the whole of the brush gear becomes easily accessible for inspection and repair, as in **132**. The brushes BB themselves are of carbon, covering two or three commutator segments, and are fixed once and for all in the neutral position [page 1323], because the motor is required to run in both directions.

131. MOTOR, SHOWING SPRING SUSPENSION

When the motor is closed, they press on the commutator C at parts distant from one another by a quarter of the periphery. P is the pinion of the speed-reducing gear.

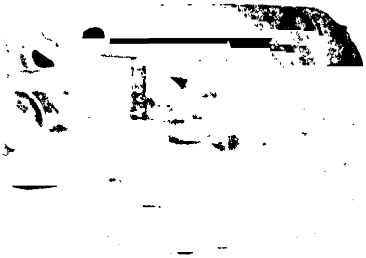
The laminations of the armature are extra thin, and are carefully selected for their magnetic qualities. The slots in the tramway motor armature are relatively larger and fewer than in other types, for by this means the total space taken up by insulation is somewhat reduced.

130. TRAM-CAR MOTOR (Witting, Eborall & Co.)

The Control of Tramway Motors. We have already said that tramway motors are connected in series at starting and afterwards in parallel. The reason is one of economy, for at the start the value of the current is controlled solely by the insertion of resistance in series with the motor, just as in the case of the shunt motor [page 1594], and we may just as well let the same current pass in succession through both motors as take double the current from the line and send it in two branches through the two motors. The various stages in the control which follow are diagrammatically shown in **134**. After the car has once started moving, the next operation is to cut out the resistance, generally in three stages, for the current value becomes more and more determined by the speed of the motor than by the resistance in series with it. When all the resistance is short-circuited [**134c**] the car gradually attains a steady speed, and the current consumed will be that necessary to provide a tractive effort in the two motors, just sufficient to overcome the running friction of the car.

Suppose in our motors [**129**] that this tractive effort were 1,000 lb., this being divided equally between the two motors, we see from the curve that for a tractive effort of 500 lb. each motor is requiring 25 amperes, and that according to the curve B, which represents the relations for series connections, the speed will be 6·2 miles per hour.

Parallel Connections for Top Speed. Under certain conditions—for example, on a long hill—it is advisable to continue to run with the motors in series, but often a higher speed is required. We put the motors in series to economise current at starting; we now put them in parallel to attain a high speed when the car is well under way, for the speed is dependent on the voltage, and when they are running steadily in series, the voltage on each motor is about 250, while if we could get them running steadily in parallel—*i.e.*, each straight across the mains—the voltage across the terminals of each would be 500, and a high speed would result, as shown in curve C [129].



132. MOTOR: END COVER OPENED, SHOWING COMMUTATOR AND BRUSHES

The transference of the motors from series to parallel must be done in stages, for resistance must first be introduced to limit the rush of current which takes place when the motor connections are altered from **134c** to **134*d***. This resistance is then cut out in stages, as shown in **134**, *d*, *e*, and *f*. With conditions **134*f*** a steady speed is again attained, and to continue our example, we will take it that at this increased speed a larger tractive effort of 1,500 lb. is required. With 750 lb. effort per motor we see [**129**] that about 34 amperes are required per motor, and this time twice this amount—namely, 68 amperes—will be required from the line. Referring to curve A, we also see that the speed (corresponding to these 34 amperes per motor) will now be about 12 miles per hour.

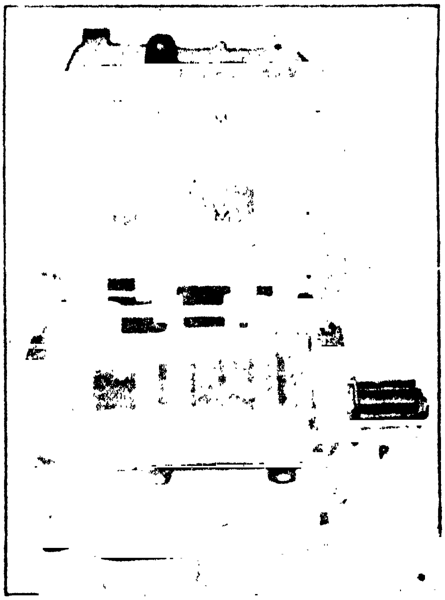
The Tramcar Controller. The controller is really a series of switches by which the driver, by moving a handle, performs, in successive stages, the operation of cutting out resistance and of placing the motors in series and in parallel with one another as required. The principle of the apparatus is shown in **135**. By this it will be easily understood that as the handle is moved round in the direction indicated, and more of the wipers come in contact with the serrated copper-plate upon the controller drum, more of the resistance is cut out. The reader should follow out the path of the current in the position sketched, and the diagram **135** should be compared with the upper part of the actual apparatus shown in **136**, in which the serrated plate takes the form of strips which are connected electrically by being fastened to the same brass spindle.

Series-parallel Contacts. Fig. **137** is a developed diagram to show the operation of switching the motors in series and parallel. When the controller is in the *series positions* the current flows through GI, *a*, H, and J, and the motors are thus in series; and when in the *parallel positions* the current divides at G and flows thus:

$$G < \begin{matrix} b\,H \\ I\,c \end{matrix} > J.$$

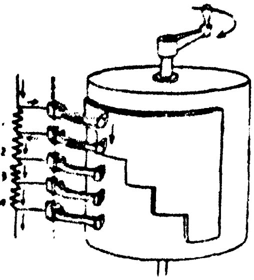
Reversing the Motors. This is generally performed by a separate drum, one type of which is shown diagrammatically in **138**. To reverse the direction of rotation of a motor, the field current has to be reversed with respect to the armature, and this is done by moving the drum to the left or to the right so that the metal plates A and B come into contact with the left-hand or right-hand set of wipers. In the former case the path of the current is + M′*d*N′XYO′*e*P′Z −, and in the latter +M*d*NYXO*e*PZ −, so that, while the direction Z to − remains the same, the direction between X and Y is changed.

Tramway Trucks. Small cars are mounted upon single trucks with a motor mounted upon each axle of the truck. As, however, it is not practical, from the point of view of rounding curves, to have the wheel base—*i.e.*, the distance between centres of the wheels of a truck, much more than six feet, it becomes necessary to mount the larger cars upon two trucks. In the inter-urban cars much used in America, each axle is again used for driving and four motors in all are installed, but the usual practice in England is to have only two motors, one on each truck. By this arrangement a certain percentage of the weight



133. MOTOR, OPENED, SHOWING ARMATURE AND UPPER PAIR OF MAGNET POLES

of the car is lost for tractive purposes, and the driving wheels will slip sooner. To get over this the car is mounted on the trucks as indicated in 139, so that the weight is taken nearer the driving wheel than the pony wheel, and in this way from 75 to 80 per cent. of the weight of the car is used for giving adhesion to the rail when driving.

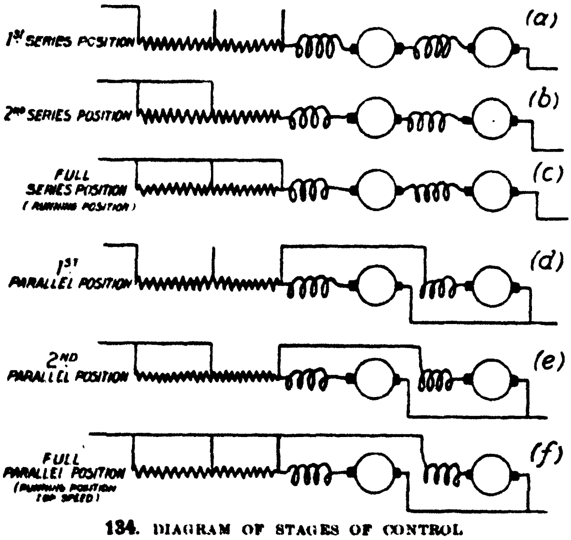


135. PRINCIPLE OF CONTROLLER DRUM

Brakes. The safety of a car depends upon the reliability of its brakes, and these should, therefore, receive the best attention. All the different forms of brakes may be divided broadly into three classes—namely, wheel brakes, track brakes, and electric brakes.

Rim Brakes. Of the first the best known form is where cast iron or hard wood brake shoes press against the rim of the wheels. The limit to the power of this form of brake is the adhesion of the wheels to the rail. When the brake shoes are pressed so hard against the wheel that the grip between the wheel and the rail is overcome the wheel slips, and it has been found by experiment that when the wheels start slipping they continue to slip even after the brake pressure has been considerably relieved, and that at the moment of slipping the braking action *becomes reduced to a third of the former value when the friction was all at the brake shoe.*

The question of the distribution of the weight of the car on the wheels comes up again in connection with this question of wheel brakes. If most of the weight rests on the driving wheel, it is obvious that if all wheels are provided with brakes, the pony wheels will tend to start slipping first, so that, in order to prevent this, the lengths of the rods which transmit the pressure to the several wheels are so proportioned that the leverage on the driving wheels is relatively greater than that on the pony wheels, and all wheels tend to slip at the same time.

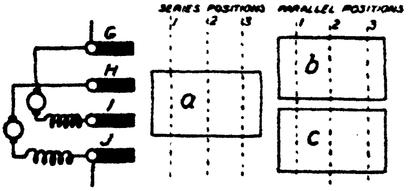


134. DIAGRAM OF STAGES OF CONTROL

Track Brakes. In the second type of brake—namely, the track brake—a shoe is pressed down on the track, and the limit to this form is, of course, the weight of the car; for any downward pressure on the rails is counteracted by an upward force which tends to lift the car off the rails, or, if not altogether lift it, to relieve the wheels of a portion of the weight of the car and so make their running less certain. This objection is, however, got over by making an electromagnet of the brake shoe and producing the necessary pressure by the magnetic attraction between the iron shoe and the steel rail.

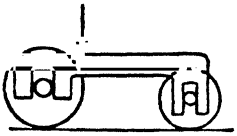
Motor-generated Brakes. The third form of brake is that in which the motors are made to act as generators, and the energy they produce as such is of course taken from the moving car, with the result that it is retarded. The generated current is often passed through resistances, but it may be used to excite the magnets in the previous type of brake. The Westinghouse Co. have on the market an emergency brake in which the motors are made to act as generators and the current so derived being sent round the coils of the slipper brake. The attraction of this to the rails also actuates the wheel brakes, so that all three types of brake are instantly applied by a movement of the controller handle.

The Return Circuit. To provide an efficient return path for the current after it leaves the trams is always an important matter. In telegraphy the currents are allowed to return for hundreds of miles through the earth; for here the currents are small. With electric cars, it was found that, with the large currents used, neighbouring gas and water pipes became damaged. With a view to protecting these pipes the Board of Trade have made rules, the



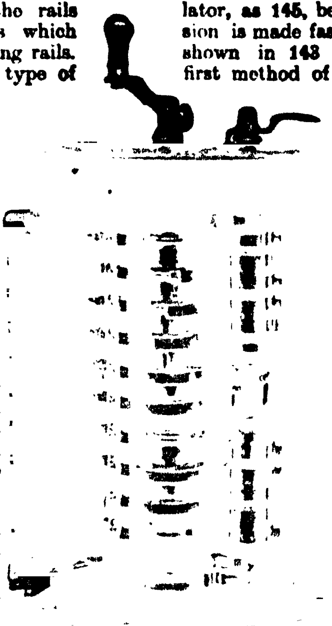
137. ARRANGEMENTS FOR SERIES AND PARALLEL

most important of which is that on no part of the return circuit shall there be at any time more than seven volts above the negative terminal of the generator. To ensure that this is so, among other things, the separate lengths of rail which form the track must be connected together electrically. The means used for mechanical fastening are not sufficient for the electrical purpose, so that special arrangements have to be adopted. In some systems, the lengths of rail are welded to one another, but the usual way is to bond the rails with thick copper connectors which are firmly riveted into adjoining rails. Fig. 140 shows a well-known type of bond. Holes are drilled into the web of the rail and they must be thoroughly cleaned before they receive the shank of the bond. When this has been fixed firmly in place, a hard steel stud is then forced into the hole down the centre of the shank, with the result that the bond and the rail are forced into very intimate contact. It is found that by far the greater part of the resistance of the bond is in the contact between it and the rail, so that the greatest care must be taken to see that the rivet is right home. As a further precaution the various track rails are cross-bonded at intervals.

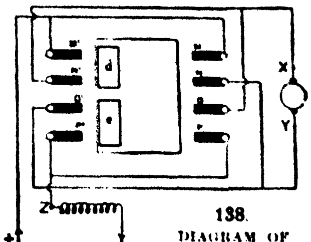


139. DISTRIBUTION OF LOAD ON TRUCK

Overhead Construction. The problem in overhead construction may be stated thus: *Suspend a copper wire, of diameter about ⅜ of an inch in such a way that great mechanical strength is obtained, and with an insulation sufficient to withstand 500 volts.* As regards the poles, three methods of construction are used in England—namely, (1) a side-pole on one side of the road with a long bracket which supports both the up and the down wire; (2) a centre-pole along the middle of the road, with short brackets on each side; and (3) poles on both sides of the road, the conducting wire of copper being slung from a steel suspending wire stretched right across the road. Of these three the second makes the best mechanical job, although in busy thoroughfares it is out of the question. The first is cheaper than the third in other cases where the width of the road would not necessitate an extra long bracket. The wires themselves are supported by soldering their ends into what are known as *ears* [141*b*], which are screwed into *insulators*, such as 141*c* and 142. The whole arrangement is then slung as shown in 143 and 144; a second insulator, as 145, being inserted before the suspension is made fast to the pole. The constructions shown in 143 and 144 are adopted for the first method of suspension mentioned above, 143 showing the arrangements on straight runs of line, while 144 is the arrangement which is used on curves, where the wire must be on the same level as the tackle which takes the side thrust from the trolley-pole.



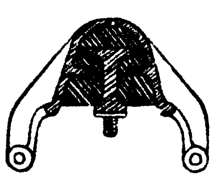
136. CONTROLLER
(Witting, Eborall & Co.)



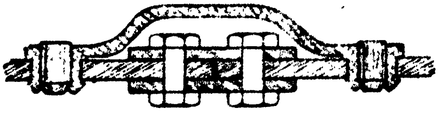
138. DIAGRAM OF REVERSING DRUM

Construction of Insulators. The material used for tramway insulators is brittle, and, in consequence, cannot withstand any great tensile stress, although it is strong against compression. In consequence of this the insulators have to be so constructed that the pull between the ends is taken up in the insulator by a compression. How this is done may be easily seen by tracing out the path of the stress in the section shown in 145, and also in 141*c* and 142. The insulation resistance of an exposed insulator depends upon two things—namely, the material of which it is made, and the state of its surface to prevent creeping of the current along any film of moisture that may form. The section in 145 has been specially chosen to meet this last point, for the rain falling on it will not drain off on to the metal eye-pieces at the end, but will flow to the projecting rib which passes around the centre.

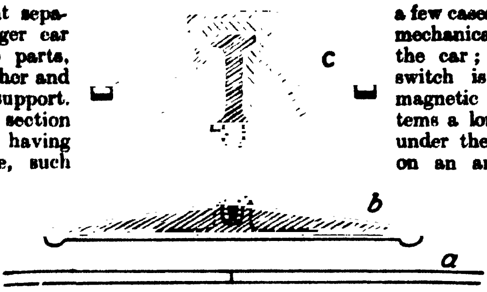
Special Details. For crossings, special ears, known as *frogs*, have to be provided to guide the trolley on to the required line. Other special requirements are when the line runs from one section to the next, each section being



142. INSULATOR FOR CURVES



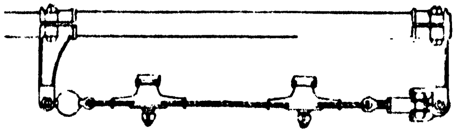
140. BOND BETWEEN RAILS OF TRACK



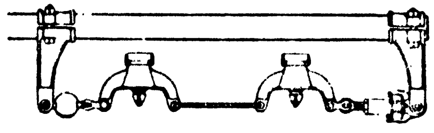
141. DETAILS OF OVERHEAD SUSPENSION

supplied with its current separately. For this a larger car is used, made in two parts, insulated from one another and from the common support. Many types of frogs and section insulators are used, and, having described their purpose, such and other details may be readily studied by anyone living in the neighbourhood of an electric tramway.

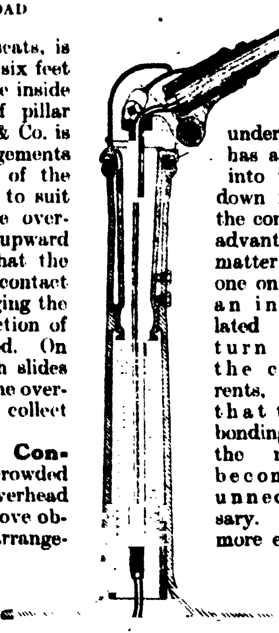
Collecting Trolley. The means almost universally adopted in England and America for collecting the current from the line is by a trolley. A trolley is a grooved wheel mounted on the end of a more or less flexible steel pole, which, in the case of cars with roof seats, is supported on a pillar about six feet high. A section showing the inside mechanism of the type of pillar used by Messrs. Blackwell & Co. is shown in 146. The arrangements provide for the movement of the trolley-pole up and down to suit the varying heights of the overhead wire, for supplying an upward pressure to the pole, so that the trolley-wheel makes a sure contact with the wire, and for swinging the pole round when the direction of motion of the car is changed. On the Continent a bow, which slides along the under surface of the overhead wire, is often used to collect the current.



143. OVERHEAD CONSTRUCTION FOR STRAIGHT PART OF ROAD



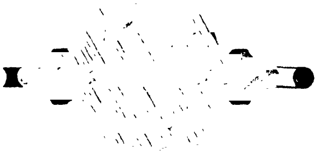
144. OVERHEAD CONSTRUCTION USED IN CURVES



146. STANDARD FOR TROLLEY-POLE

Surface-contact and Conduit Systems. In crowded city streets, where any overhead construction is likely to prove obstructive, other collecting arrangements are sometimes adopted which collect the current from the road below the car. In *surface-contact* systems, the current is collected from studs set in insulating blocks of cement or asphalt in the surface of the road. At times, when no car is passing over them, these studs are "dead," being automatically disconnected from the feeding mains. The car itself when it comes over the stud must make it *alive*—that is, put it into communication with the mains by some sort of switch. In a few cases this switch is actuated mechanically by the weight of the car; but more often the switch is actuated by electromagnetic means. In some systems a long electromagnet fixed under the car acts magnetically on an armature in a sunken box under the stud. In others, the electromagnet that moves the switch is placed in the stud-box, and is brought into operation by the car making electric contact with the stud. In all cases the car is provided with a long metal skate or runner under the car, which glides from stud to stud and so continually picks up the current from the mains through the studs.

In the conduit system the live conductors are placed on insulated supports in a tunnel or conduit which runs along under the middle of the track. The conduit has a slot about 1 in. wide opening all along into the road, and through this slot is let down from the car a *plough*, which glides along the conductor and so collects the current. An advantage with this system is that it is an easy matter to mount two conductors in the conduit, one on each side of the slot, and so provide an insulated return for the currents, so that the bonding of the rails becomes unnecessary. But in any case a conduit is much more expensive than either the overhead or the surface contact system.



145. INSULATOR TO TAKE STRAINS

Regenerative Control. One disadvantage of the ordinary use of series motors is that the energy spent in pushing the car up a hill cannot be recovered when the car is running down the other side, for the energy given out by the car when running down must be absorbed in resistances, motors of this kind not being adapted to return it to the line. If, however, shunt motors are used instead, the case is altered, for then when the car is running quickly down hill the motion makes the motors act as generators, which feed the current back into the line.

IMPERIAL ROME

Claudius Proclaimed Emperor. Messalina and Agrippina. Rome under Nero. His Death. Vitellius and Vespasian

By JUSTIN McCARTHY

AFTER the death of Caligula there came a short interregnum. Chaerea, by whom Caligula had been put to death, was a Republican in politics, and many of the Senate had grown into revolt against the Imperial system because of the atrocities which had been perpetrated during the recent reigns, and they were also anxious to obtain once again the real control of the State.

An attempt was made to bring the Imperial succession to an end, and to set up a Republic. Chaerea and the Senate, however, were counting without the army. The soldiers were devoted to Imperialism, and their leaders found an heir to the throne. Their choice lighted upon Claudius, the brother of Germanicus; they found him in the Imperial palace, made him their captive in a friendly fashion, carried him to the camp, and proclaimed him Emperor. Claudius, who had himself no inclination for an Imperial position or public life, yielded to their demands, and the Senate saw no chance of resisting them. Claudius, who became the fourth of the Roman Emperors, was born at Lyons in the year 10 B.C. As he grew to manhood he lived in seclusion, devoting himself to study. His way of life had made Caligula regard him as a harmless, contemptible personage, and he was thus probably saved from hostile feeling on the part of the Emperor and his favourites. But the man who was thought too insignificant to be a dangerous rival became Caligula's successor to the throne.

A Weak Character. Claudius, while in seclusion, had written a history of the Etruscans and the Carthaginians—books which are wholly lost; and he wrote works in Greek as well as in Latin. He was fifty years old when he was almost literally lifted to the throne. He began his reign with good intentions, and gave promise of success; but he was weak and timid, and was always under some influence not that of his own inclination. At first he came under the influence of the army, and allowed Rome to become once again a military despotism. His armies were victorious in many wars, converted Mauratania into a Roman province, and began a new conquest of Britain. But in the meantime a conspiracy against him was plotted on behalf of new aspirants to the throne, and the discovery of this scheme made him a victim to panic, and brought him under the absolute influence of his wife, Messalina, who had a short way of getting rid of personal or political enemies. History and literature have consigned the name of Messalina to eternal infamy, and made it the synonym of profligacy and cruelty in woman. Messalina prevailed upon her timid and yielding husband to sanction all manner of cruelties and death warrants against those whom she made him regard as his most dangerous enemies, and 35 senators and 300 men belonging to the order of knighthood were put to death. Messalina carried her outrages upon law and humanity so far that even Claudius was prevailed upon to stand up against her. In defiance of all public law and public decency, she entered openly on a second marriage, although she had not been divorced by her Imperial husband. This was too much even for Claudius, and he gave his consent to the passing of a sentence of death on her, and to its execution. Claudius afterwards married his own niece, Agrippina, a widow who had, by her former husband, a son named Nero.

Agrippina. Agrippina soon showed herself an appropriate successor to the infamous Messalina. Nero was then about 11 years old, and Agrippina, who exercised for a time full control over her husband, soon made it apparent that she was determined to secure the succession to her son, and to exclude from it Claudius's son, the young Britannicus. She appointed Seneca, the philosopher, tutor to Nero. When Claudius succeeded to the throne he gave an enormous sum of money to the army, to be distributed proportionately amongst the officers and the men. This was done to secure the support of that military strength without which he did not believe that he could hold his position. This display of premeditated extravagance had an important effect on some succeeding chapters of the Imperial history. It made it the interest of the army to have as many vacancies as possible in the succession, and also left it open to those who believed they had claims on the throne to become rivals in the market for the purchase of the military support.

Claudius still continued to reign, and, although he had yielded so far to the influence of Agrippina as to adopt Nero for his successor, the Empress feared that he was not satisfied with this concession on his part, and that he might pluck up spirit and restore the natural order of succession.

There was one ready way for such a woman in such a Court to secure the fulfilment of her great scheme. She arranged for the poisoning of Claudius, and thus made the way open for the accession of Nero in 54 A.D.

Accession of Nero. Nero was but a youth when he came to the throne, and for the first few years gave good promise. He professed a love for peace, justice, and order, and the teachings of Seneca seemed to have some influence over him. One story illustrating Nero's disposition at this time has been preserved for us by his biographers. When he was called upon for the first time to sign a death warrant he declared pathetically his sincere wish that he had never learned to write, that he might thus have escaped from so painful a duty. This condition of the Imperial mind did not last long, and Seneca soon saw that his pupil was endowed with a fierce and passionate nature which philosophy could do little to restrain. There was in Nero's temperament a singular blending of the furious tyrant and the artistic amateur. He loved music, and tried to make himself an accomplished performer, and he had a taste for the stringing together of verses—they could hardly be called poems. He had a passion for the stage and even for the arena. It was one of his delights to drive chariots and display his skill in the management of horses before the assembled multitudes in the great Roman Amphitheatre. The citizens of Rome had thus the opportunity of seeing their Emperor, who belonged to the family of Julius Cæsar, make exhibitions of himself in this unseemly fashion. Often, too, he indulged his humour for the recitation of some of his own verses on the public stage, accompanying himself with what he believed to be appropriate music on a harp.

The Burning of Rome. These were only harmless absurdities, but Nero indulged in other tastes in the fashioning of public exhibitions which were abominable even for the worst days of the Roman Empire. His reign was marked by its persecution of the Christians, which he endeavoured to justify by accusing them of having carried out a plot for the burning of Rome. A great conflagration did break out in Rome during the year 64 A.D. which caused the utter destruction of nearly two-thirds of the city. Many historians have stated that the great fire in Rome was the work of Nero himself, or those whom he employed for the purpose, but there did not seem any substantial ground for such a charge. It is said, and the story may be true, that he admired the sight of the burning city from one of the surrounding hills, while he declaimed some lines about the burning of Troy and accompanied them with his lute. Literature and poetry have many allusions to Nero fiddling while Rome was burning, and there would have been nothing out of keeping with his character if he had made the occasion an opportunity for such a display. He asserted that the fire was the work of the Christians, of whom there were many in Rome at the time, and he made this belief an excuse for the infliction of cruelties on them which were strange even to his days.

Cruelty to the Christians. Many of the Christians were by his orders wrapped up in the skins of beasts and sent through the public arena pursued by fierce dogs, who tore them to pieces for the amusement of the assembled crowds. On the occasion of a public festival in his public gardens, Nero had a number of Christians smeared all over with pitch, and at his command the pitch was set aflame and the unfortunate Christians were made to burn as living torches until they fell upon the ground, died, and then gradually burned to ashes.

Nero rebuilt the city of Rome with great magnificence, and had a new and superb palace raised for himself on the Palatine Hill. When his extravagances became too costly even for his means, he plundered the provinces without any form of law in order to make good his expenditure. If a wealthy citizen refused to contribute towards the Imperial expenses, Nero ordered the confiscation of his property, and condemned the offending owner to perpetual exile, or, in some instances, to death.

Conspiracies Against the Tyrant. These insufferable excesses at last drove some of the Senators and the Equestrian order into a conspiracy against the tyrant, but it was discovered before it could be put into execution. Among those who were accused of having taken part in it were the poet Lucan, whose famous "Pharsalia" has still a place on the shelves of our libraries. Another of the accused and condemned conspirators was Seneca, Nero's early teacher. Lucan had been at one time Nero's friend, and they had many tastes in common; but Lucan's poetry was genuine, while Nero's was only sham, and the Emperor became jealous of the poet, and would have nothing more to do with him.

Seneca, Lucan and the rest were declared guilty and sentenced to death, and were ordered to bring about that death by opening their own veins. Seneca's wife, Paulina, was so devoted to him that she implored his consent that she should die with him. Seneca, after endeavouring to persuade her to endure life without him, consented at last to her prayers.

Boadicea's Rising. During the reign of Nero took place the famous rising in Britain under Boadicea, "the British Warrior Queen." Boadicea was the wife of a British king who ruled over the Iceni, a people occupying that part of England now known as Norfolk and Suffolk. When her husband died, one of the Roman commanders in the island seized the territory, made the queen a prisoner, brutally scourged her, and ill-treated her daughters. Cowper tells us how Boadicea, "bleeding from the Roman rods," called for "vengeance from her country's gods." Boadicea escaped from her captors and raised a large army to defend the British soil. Her army defeated the Romans at Colchester, occupied London, and destroyed in their battles, so Tacitus tells us, some 70,000 Romans. Boadicea's victory seems to have been only a sudden surprise which disarranged the preparations of the Roman garrison. The Roman Governor of the island was absent in Anglesey when Boadicea's movement broke out, but returning, advanced against her and inflicted an overwhelming defeat on her army. The historians state that the Roman army had only 10,000 men, while the British forces numbered 200,000, and that the British loss amounted to 80,000 killed, while that of the Romans did not exceed 400. We must bear in mind that we have to depend on Roman historians for the details of these events, and it is not unreasonable to assume that they made the most of the Roman victory. What is certain is that Boadicea was completely defeated, and in her despair, took poison and died.

Rome Weary of Nero. The Roman world was growing weary of Nero, and Nero appears to have been growing weary of the Roman world. He made an expedition to Greece not with the object of effecting any great conquests there, but for the purpose of displaying his own skill in dramatic performances and in games of strength and athleticism. Either Nero's good opinion of himself was fairly justified, or the Greek spectators were disposed to be very generous with their plaudits to the Roman sovereign, for Nero seems to have made quite a triumphal progress, and even at Olympia—the historic ground of the famous Olympian games, where stood the colossal statue of Zeus, by Phidias—Nero's feats were actually rewarded with a prize. He expressed his gratitude for the honours paid him by proclaiming the liberty of Greece, but it does not seem that Greece benefited much by his cheap generosity. He returned to Rome, where the people in general were thoroughly tired of his tyranny, his cruelty, his utter indifference to the welfare of the State, and his absurd eccentricities. A conspiracy was formed against him, led by some influential public men, and Nero soon found that he had no powerful friends left in the capital or in the State. He fled from Rome and hid himself in the farm of one of his freed men, one of the very few friends he had left to him on earth. He realised that there could be no safe refuge for him on Roman soil, and that there was no time for him to make his escape into any foreign land.

Nero Commits Suicide. When he heard the trample of the horses of his pursuers from Rome who were riding to his capture, he resolved to put an end to his life with his own hand. His latest words were characteristic of his extraordinary self-conceit. "What an artist," he exclaimed, "perishes with me!" Then he plunged a dagger into his throat and died. The line of the Cæsars came to an end with the death of Nero. That line, however, had not been continued even thus far by actual family descent. The succession, as we have seen, was brought about in some instances by the arrangement of legal adoption. But the line of the Cæsars brought to a close a most memorable historic chapter of history, and it is not easy to imagine any stranger anti-climax than is represented by that Imperial line which began with Julius Cæsar and came to an end with Nero.

Then began a struggle for the creation of a new Imperial line. The movement against Nero, which had ended in his death, was mainly promoted by Sulpicious Galba, a member of a powerful family. Galba had been a Consul, had charge of the government of Gaul and afterwards of some of the Spanish provinces. He had made himself popular with the army and when the plot against Nero was organised, the Prætorian guards had been promised in his name, though it does not seem by his authority, a huge money gift if they would adopt his cause in the contest for the throne.

Galba Proclaimed Emperor. Galba came to Rome at the time of Nero's fall, offered himself as a candidate for the succession, and was proclaimed Emperor. His reign was very short—lasting only about seven months. The lavish gifts which the soldiery expected did not come and historians credit Galba with the honourable declaration that he chose his soldiers, but did not and would not buy them. Galba, during the short opportunity given him, did not display much capacity for dealing with a great crisis, and made himself conspicuous only by his extreme parsimony and reckless severity when he met with opposition. There was a rising of the soldiers against him chiefly inspired by Otho, a former friend of Nero, and an ambitious man. Otho had during Nero's reign governed some of Rome's foreign provinces, but when the uprising against Nero became serious, Otho, putting aside all his past associations, became filled with the idea that as his old friend and sovereign was now out of the way there was no reason why he should not himself be chosen Emperor. Otho became one of the adherents of Galba, but when he found that he had other views as to the best candidate for the throne, Otho turned against him, sought and obtained the support of the military and was proclaimed Emperor by the soldiery who put Galba to death.

Vitellius. In the meanwhile a new claimant had arisen, with a powerful force behind him. This was Vitellius, the commander of the Roman legions on the Rhine. Vitellius, although he had never displayed great military qualities, had succeeded in making himself popular with his soldiers, and when the rising against Galba took place, the legions of the Rhine proclaimed Vitellius Emperor at Cologne.

His troops marched through Italy and defeated the troops of Otho in a decisive battle. This defeat so disheartened Otho that he killed himself and thus left Vitellius master of the political and the military field. Vitellius was proclaimed Emperor at Rome. He was not, however, statesmanlike enough to see that his fabric of Imperial greatness stood on a foundation of sand. The manner in which he had been raised to the throne might have afforded him obvious reasons for distrusting the solidity of such a success. He had been proclaimed and, practically, created Emperor by the legions of Rome in one of her foreign provinces, and this might have served to remind him that there were other Roman forces, equally great, in other foreign provinces, which had not sustained his candidature, and which might at any crisis raise up a rival.

But Vitellius persisted in acting as if nothing could threaten his position. He did all he could to retain the devotion of his legions, allowing them the fullest license in their dealings with civil affairs while all he asked for himself was the indulgence of his own pleasures, among which a love of eating and drinking was the most dear to him.

The period was one of great anxiety for Rome. There was a great rising in the Jewish provinces, and the commander of the army sent to subdue that rising was destined soon to make an historic name. This was Vespasian, who was born of humble family, but who showed much capacity for political and military life, who had risen in the army and served in Germany and in Britain. He was conducting the military operations for the suppression of the Jewish rising when the struggle began between Otho and Vitellius. The Roman troops in eastern regions took example from the conduct of the legions of the west. They had proclaimed their commander Emperor of Rome, and now the army of the east thought the time had come for them to assert their right of election, and in the city of Alexandria they proclaimed Vespasian Emperor.

Vespasian. The same ceremony was performed in other eastern cities, and Vespasian was called upon by his supporters to go to Rome and claim the throne. Vespasian saw that the situation was not only serious but critical, and we may suppose that he considered the condition of Rome, then and for some time past, absolutely intolerable, that he had patriotism enough to wish to help towards the setting right of the Empire, and sufficient faith in himself to believe that he could accomplish his purpose. He left his son Titus to conduct military operations in the east, and as he had to superintend affairs in Egypt he sent one of his commanders to march upon Rome. Before he could arrive, however, the legions who were engaged in the dethronement of Vitellius had captured Rome, and Vitellius had been put to death. Vespasian, therefore, found no difficulty in his way when he arrived in Rome and accepted the position of Emperor.

The reign of Vespasian opened amid severe struggles in Judea and also in some of the German and the Gallic provinces of Rome. The uprising among the Jews proved to be serious. The Jews resisted the Roman soldiers with all the hereditary courage and perseverance of the Maccabees. Josephus, the Jewish historian, took a leading part in the defence of his country.

The Capture of Jerusalem. The arms of Rome prevailed and the city of Jerusalem was captured by the soldiers of Titus. Josephus had been made a prisoner by the Romans, and was a captive in the Roman army at the time when this event occurred. Jerusalem had borne with heroic and desperate resistance the siege of the legions of Titus, but the result was inevitable, and the Romans entered the city. The conquerors behaved as conquerors were in the habit of doing in those days. They burned the great Temple of the city, and dispersed its very ashes by passing the ploughshare over its site. They caused an immense flight of the inhabitants from the land of their birth, which was the beginning of the dispersion of the Jews which went on for so many generations.

During the wars in Judea and in the European provinces of Rome Vespasian was doing his best to restore order to his capital and his country. He removed many unfit and corrupt office holders who had been put into power by Nero and other Emperors. He reorganised the financial system, which was in utter confusion; he restored the Capitol, which had been reduced to ruins by the great fire; he built the Coliseum; established a great public library, and appointed a number of State-paid teachers to give instruction in literature and rhetoric.

The exponents of the Stoic doctrines in Rome were loudly proclaiming republican principles, and Vespasian thought it his duty to expel them from the country. He had so little inclination for war and conquest that, owing to his influence, the Temple of Janus remained closed, showing that peace prevailed throughout the land. Janus was one of the ancient Latin divinities, and the opening or closing of his temple gates denoted a state of war or peace. Vespasian lived after the simplest fashion, and the habits of his court life were in striking contrast with the luxury and extravagance of some of his predecessors. He so steadily avoided all unnecessary expense that he was accused of avarice by some of his contemporaries; but it does not appear that love of laying up money formed any motive for his simple and modest life. Wherever and whenever money was wanted for any purposes of value to the State and the public he always had an open hand.

A New Atmosphere in Rome. His influence and example accomplished much for the reform of morals and manners in Roman society, and an atmosphere of purity and patriotism breathed once again throughout the State. Vespasian was entirely without affectation, and not only was he totally unashamed of his humble origin, but he treated with scorn the attempts of some of his adherents to trace out for him a lineage which might bring his family into the sphere of aristocracy. The later years of his reign were marked by few events of great historical interest. One of these was the rise into reputation and fame of Julius Agricola, who held for seven years the government of Britain. He subdued completely the whole of that island, with the exception of the Highlands of Scotland, and ruled with such moderation and justice that he all but reconciled the British people to the domination of Rome, and succeeded in making the study of Roman literature and art a favourite occupation among the intelligent classes. His daughter was married to the illustrious historian Tacitus, who has written that life of his father-in-law which is a classic in our days as it was when Rome was still mistress of the world.

Vespasian's health broke down in 79 A.D., and he went to recruit his strength to his country home in the Sabine mountains. But the removal came too late to effect any change in his condition, and in the middle of that year he died. When he felt his last moment approaching, he said to those around him, some of whom had wished to gratify him by proclaiming him a divinity, "Just now I begin to believe that I am becoming a god." This was evidently a closing touch of his characteristic humour, and he added, "An Emperor ought to die upstanding," made a sudden effort to rise to his feet, and then died.

THE NERVOUS SYSTEM

The Conscious Mind and the Unconscious Mind. Their Separate Systems and Work. Their Structure. Work and Nourishment of the Nerves

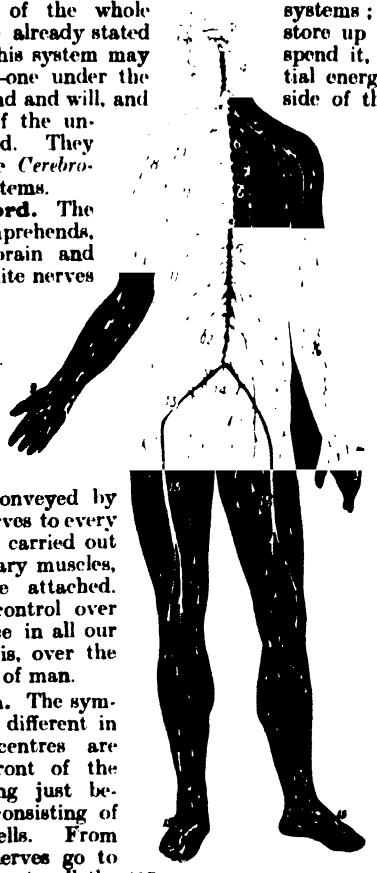
By Dr. A. T. SCHOFIELD

THE nerves are not mere expressions or ideas; they are actual threads or fibres, stretching all over the body just as the mass of telegraph and telephone wires run everywhere over London. They connect the "brain-centres" with every part of the organism, and along them impulses are incessantly travelling to and from the brain. In order to understand the machinery by which the mind controls the body, it is necessary first of all to get an idea of the arrangement of the whole nervous system. We have already stated in an earlier section that this system may be subdivided into two—one under the control of the conscious mind and will, and the other under the sway of the unconscious part of the mind. They are called, respectively, the *Cerebro-Spinal* and *Sympathetic* systems.

Brain and Spinal Cord. The cerebro-spinal system comprehends, as its name implies, the brain and spinal cord and all the white nerves connected with them. This complicated machine forms the executive of the government, which consists of the supreme controlling power of the conscious mind, and transmits its will to the whole body. All com- onveyed by the white cerebro-spinal nerves to every part of the body, and are carried out by the striped and voluntary muscles, to which the nerves are attached. This system has special control over the expenditure of life-force in all our actions and words—that is, over the animal life or *kinetic energy* of man.

Sympathetic System. The sympathetic system is entirely different in every particular. Its centres are situated all along the front of the spine, the chief one being just behind the stomach and consisting of a large mass of nerve-cells. From these centres small *pink* nerves go to all the organs of the body, to all the blood-vessels, and to many other parts. It is also closely connected with the lower part of the brain and the spinal cord.

This system acts and carries on its ceaseless and most complicated operations without the conscious mind having any power to interfere or even to discover what is going on. Its actions appear at first sight to be mainly mechanical, but a longer study shows they are all controlled and set in motion by a central purposive power for the good of the body; this power is the unconscious mind. Although the sympathetic system appears to carry on all the complicated processes of life on self-acting principles, they are really under the control of the mind, which thus directs the actions of the *digestive*, *circulatory*, and *respiratory* systems; in short, those that produce and store up life-force rather than those that spend it, or over the vegetative or potential energy rather than over the animal side of the life of man. The sympathetic nerves are connected with the smooth, unstriped muscles.



105. NERVES OF THE BODY

1. Cerebrum 2. Cerebellum 3. Medulla 4. Cervical nerves 5. Spinal cord 6. Dorsal nerves 7. Phrenic nerve 8. Brachial plexus 9. Nerves to the palmar surface of the hand 10. Nerves to the dorsal surface of the hand 11. Intercostal nerves 12. Lumbar plexus 13. Great sciatic nerve 14. Cauda Equina. 15. Nerves to the lower extremities

Cerebro-spinal Nerves. The cerebro-spinal nerves themselves [105] are, as I have said, the cords or electric wires that stretch from the brain and spinal cord to every part of the body. They are *white threads* of microscopic size collected into bundles or bands called nerve trunks, the largest being three-quarters of an inch broad in the thigh [106], and the smallest, almost invisible, like the fin thread If we examine one we find surrounded by a sheath of connective tissue, and consisting of bundles of smaller nerve bundles and blood-vessels and lymphatic fibres. In the nerve trunk these bundles are not twisted, but lie straight side by side. The bundles can be subdivided still further, until we get to the single *nerve fibre* [107].

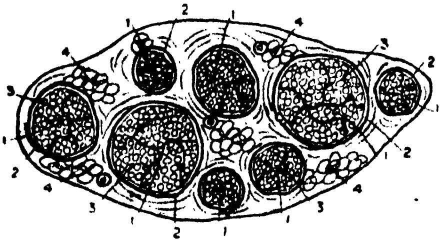
Every nerve fibre runs (just like a telephone wire) straight from its starting point to its end, and without branching or uniting with others. The trunks branch and divide and join, but the undivided fibres never do so during their course. One thirty-sixth part of the whole weight of the body is nerve substance.

Structure of a Cerebro-spinal Nerve. The medullated or cerebro-spinal nerves of which we speak vary in size from $\frac{1}{12000}$ to $\frac{1}{1500}$ of an inch, and consist of three parts.

First there is a protective sheath like the *hemp covering* of an underground electric wire; then a fine white substance sheathing the nerve all round, like the *sheath of guttapercha* which insulates (or prevents any of the electricity escaping from) the electric wire in the centre; and lastly not a *wire*, but a tube full of fluid, along which, it is believed, the impulse travels from the brain.

The outer covering [107] is called the primitive sheath or the *neurilemma*, and is a delicate membrane with constrictions every one-fifth of an inch and occasional corpuscles between. The sheathing or insulating substance is called the medullary sheath, medulla, or *white substance of Schwann;* it gives these nerves their white appearance, and it also affords rich food for the nerve within, on account of the large amount of fat it contains in an emulsion, the globules of which refract the light, and thus account for its colour. It is semi-fluid and like chyle.

The electric wire in the centre is called the *axis cylinder* [108], and is the essential part along which all impulses travel. It occupies a quarter of the diameter of the nerve, and in a cut specimen often projects like the wick of a candle. It is a tube of fluid enclosed in a delicate membrane, and is really an enormously long living protoplasmic process from a central nerve cell.



106. TRANSVERSE SECTION OF SCIATIC NERVE

1. Bundles of nerves 2. Epineurium round them
3. Medullated nerve fibres (axis cylinder in middle)
4. Fat

As the nerve fibre approaches its termination at either end, it first loses its central coat, the medullary sheath, and then the outer one, the primitive sheath, the naked axis cylinder breaking up into fibres at its attachment.

Structure of a Sympathetic Nerve. In sympathetic nerves the non-medullated nerve fibres are also gathered up into trunks and bundles, and consist of axis cylinder and primitive sheath only; they vary in size from $\frac{1}{5000}$ to $\frac{1}{3000}$ of an inch. The absence of the medulla coat, the white substance of Schwann, gives these a greyish or pinkish colour.

These nerves differ further from the medullated in branching frequently and forming networks.

In the brain and spinal cord we get innumerable naked axis cylinders without any sheath at all. The cells from which these fibres spring occur generally in clusters called ganglia, and may be of any shape. They always have a nucleus, and have one or more branching processes or poles; hence they are called unipolar, bipolar, multipolar, or, if without bundles, apolar. One of these processes, which is probably prolonged into a nerve, is always unbranched, and is called the axis cylinder process.

These cells have no distinct limiting membrane, and consist of granular protoplasm with a large nucleus. They are often angular and triangular in shape, and able to move when living.

Four Kinds of Nerve Cells. We may recognise four varieties of these cells:

1. Those with no white substance of Schwann or covering of neurilemma, as in the brain, and connected with the naked axis cylinder nerves.

2. Those with no white substance of Schwann, but with neurilemma, as in the sympathetic ganglia, and connected with the non-medullated sympathetic nerves.

3. Those with the white substance of Schwann and no neurilemma, as in the brain, and connected with nerves of similar construction, which form the white substance of the brain.

4. Those with both the white substance and neurilemma, as in the ganglia of the spinal cord, connected with ordinary medullated nerves.

Where the Cells are Found. Nerve cells are found in the brain and spinal cord, in ganglia, and at nerve endings in the tissues. The spinal cells are generally unipolar, and are embedded in a finely granular ground substance (neuroglia), and have no neurilemma. In the ganglia of the posterior root of the spinal nerves the nerve cells have a sheath of neurilemma and a short process which branches like a T.

The function of these cells appears principally to consist in the nutrition they afford to the nerve. They may also increase the area of nerve action, and here also non-medullated nerves are often changed into medullated. There is very little evidence that these spinal root ganglion cells possess any automatic or reflex power. All such action appears to exist in the brain and spinal cord only.

Nerve matter has a specific gravity of 1,031. It is 70 to 80 parts water and 20 to 30 parts solids. The solids are composed as follows:

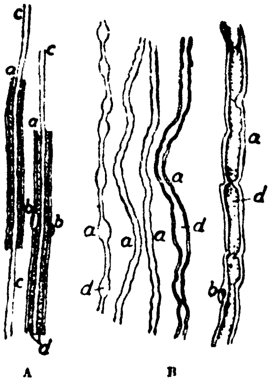
Phosphoric acid	9·0
Phosphate potash	55·0
Phosphate sodium	23·0
Phosphate iron	1·0
Phosphate calcium	2·0
Phosphate magnesium	3·0
Chloride sodium	5·0
Sulphate potash	1·5
Sulphate silica	·5
	100·0

These elements are combined to form characteristic compounds, of which the chief are cerebrin, lecithin, and other substances. The very large proportion of phosphorus will be noted.

Nerves are not elastic and do not retract when cut, but they can be stretched without rupture.

We know little of the active life of nerves. It has not been proved that they absorb O and give out CO_2. They are very excitable, as can be shown in various ways.

Stimulation of Nerves. *Mechanical stimuli* produce at first either sensation or movement. If continued a long time the sensation gets lost and the movement ceases. When a leg sleeps the temporary paralysis is believed to be due to the continued pressure of the under-knee into the hollow of the upper one, when the legs are crossed, so that the axis cylinder gets squeezed. Heat and cold stimulate a nerve, unless they are excessive, when they paralyse it. Chemicals also, such as acids, alkalies, alcohol, ether, chloroform, at first stimulate and then paralyse. Electrical stimuli act most on a nerve at the moment of application (making) or cessation (breaking). Single shocks rapidly applied so excite the motor nerves that tetanus is produced in the muscle. It is frequently found that the further a motor nerve is from the central system, and the nearer a sensory nerve is to it, the greater the effect produced by electrical stimulus.



107. ISOLATED NERVE FIBRES

A. Two fresh nerve fibres
B. Nerve fibres, showing medullary sheath broken up

a. Neurilemma b. Nuclei c. Axis cylinder d. Medullary sheath, or white substance of Schwann

The nature of the *normal stimulus* is entirely unknown. It travels from or to the brain, giving rise to motion, or sensation, and moves more slowly than stimulus induced by electricity.

Nutrition of Nerves. The nutrition of nerves depends to a great extent on the nerve cells, and their excitability depends on their nutrition. Nerve fibre gets exhausted more slowly than muscular fibre, and recovers more slowly. Continued inaction of a nerve diminishes its excitability. If any nerve be severed, degeneration sets in, and the irritation decreases from the cut end upwards. Repair takes place when the severed ends are brought together from the sound parts in the reverse direction. The effects of cutting a spinal nerve are very instructive. (1) If the *whole nerve* be divided after the junction of the anterior and posterior roots, complete peripheral degeneration of both sensory and motor fibres sets in, the central part remaining unaltered. (2) If the *anterior root* alone be divided, only the motor peripheral fibres connected with it degenerate, the rest of the nerve remaining sound. (3) If the *posterior root* be divided before the ganglion, the nerve only perishes between the cut and the spinal cord. (4) If it be divided both before and after the ganglion, the degeneration spreads both ways. These experiments show that the centre of nutrition of anterior nerves lies in the spinal cord; of the posterior in the ganglion.

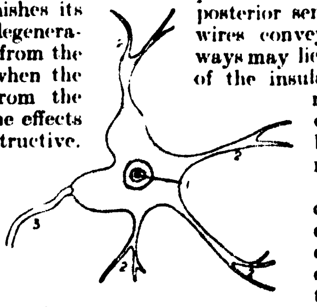
Electric Nerve Currents. There are small currents of natural electricity in healthy nerve tissue as in muscle. Natural nerve currents in sensory nerves travel about 140 ft., and in motor 111 ft., per second. Electricity and light travel about 200,000 miles per second. Sensory and motor nerves will conduct impulses indifferently either way. The direction of the current is determined by the source of the impulse, which in sensory nerves is peripheral; in motor, central.

As we have seen, the effect of stimulation of a nerve depends on the manner of its ending. Theoretically, a nerve can carry a current either way, but practically it can only be used in the body to convey a current in one direction, because of the nerve ending. The passing of a nerve current is therefore shown in an afferent or sensory nerve by pain or other sensation; in an efferent or motor nerve by muscular twitching or movement. Sensation is the result of organic change in a central nerve cell, just as movement is the result of organic change in a muscle cell. The terms sensory and motor are not, however, quite accurate.

Another Classification of Nerve Fibres. Nerve fibres are better divided into (1) afferent or centripetal; (2) efferent or centrifugal; and (3) intercentral—*i.e.*, between the two nerve cells.

Motor, or *efferent nerves* carry orders from the brain and spinal cord to all the muscles of the body. When it is remembered that each muscular fibre has a nerve attached to it, the great number of them is apparent. The longest nerve fibre is, of course, that which reaches from the brain to the big toe.

These nerves end in the muscular fibre in a sort of flat plate, which is fastened on to it; it has the power, by means of its current, of suddenly causing the fibre—and hence the whole muscle—to *shorten and thicken*. The nerves leave the brain and spinal cord from the front part, and run in bundles with the posterior sensory nerves. Thus, two wires conveying currents in opposite ways may lie side by side; but because of the insulating sheath the currents never mix. The nerves all commence or end in some brain cell in the grey matter.



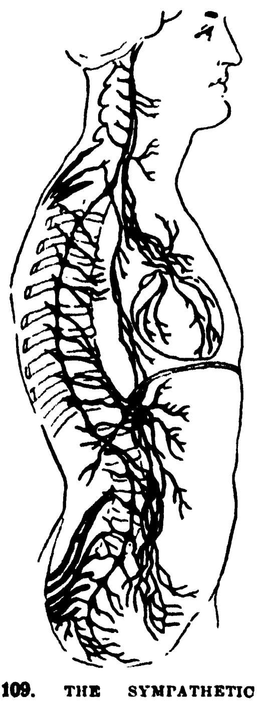
108. NERVE CELL, SHOWING AXIS CYLINDER

1. Nucleus 2. Branched processes 3. Unbranched process, forming axis cylinder of nerve

Sensory, or *afferent nerves* convey impressions from every part of the surface of the body, and from every part of its interior to the brain, making it acquainted exactly with all that is going on. Every single fibre of the countless millions starts from beneath the skin, or from some part or organ, and runs, joined with others in bundles, to the back of the brain or spinal cord, which it enters, and then terminates in one of the central nerve cells. These nerves convey all the intelligence to the brain of what goes on inside and outside the body. They convey sensations of heat and cold, of pain and pleasure, of hardness and softness, smoothness and roughness, as well as sensations of taste and smell. In the ear and eye they are connected with elaborate instruments to convey light and sound.

Sympathetic Nervous System. We will now leave the cerebro-spinal system, and turn to that with which the conscious mind and will have nothing whatever to do—the *sympathetic nervous system* [**109**]. We have already seen that it lies all along the front of the backbone. It is also connected in very many parts with the spinal system, so that some of our actions are partly voluntary and partly sympathetic. Our mind can recall actions which make us blush for shame, but the blush itself is due to the enlargement of the capillaries by the sympathetic nerves.

The sympathetic nerves have, speaking generally, the same functions as the cerebro-spinal nerves, being both afferent and efferent. That they conduct afferent impressions, not generally felt as sensations, is clear in disease when we experience sensation in parts that are ordinarily without any feeling whatever, and are supplied by sympathetic nerves. Only intense impressions or sensations in disease are thus conducted on to the conscious brain. The sympathetic nerves are pink or grey, because they consist only of two parts, the outer fibrous coat and the inner tube of nerve matter. Many of the internal organs have sympathetic systems of their own. The heart has no less than three sympathetic nerve centres in it, in virtue of which it beats, and can go on beating, even when removed from the body, for many hours if fed with blood and kept warm. The beating is, however, controlled in two ways—from the medulla, by means of the pneumogastric nerve that slows it; and from the main sympathetic system, by a nerve that accelerates it. Hence, in indigestion, etc., when the sympathetic nerve is irritated, the heart's beat is quickened, and it palpitates or beats very fast; whereas, if the nerve in the neck be compressed or irritated, the heart is slowed, and might be stopped altogether. Although it has been broadly stated that the cerebro-spinal system controls the *actions of life*, and the sympathetic system the *processes of life*, yet it must be understood that the fibres of both often intermingle, and it is frequently impossible absolutely to distinguish the one from the other. As a general rule, however, the above distinction holds good, and it is most valuable.



109. THE SYMPATHETIC SYSTEM, SHOWING SPINAL AND SOLAR PLEXUSES

Nerves Given Off by the Brain. Nerves are arranged in pairs, right and left, all over the body—that is, there are always two alike. The brain itself gives off twelve pairs of nerves, as follows:

One pair of sensory nerves from the nose, conveying smell.

One pair of sensory nerves from the eye, conveying light.

One pair of sensory nerves from the ears, conveying hearing.

One pair of sensory nerves from the tongue, conveying taste.

One pair of sensory nerves from the face and teeth, principally conveying feeling.

Three pairs of motor nerves, giving movement to the eye-balls.

One pair of motor nerves, giving movement to the face.

One pair of motor nerves, giving movement to the tongue.

One pair of motor nerves, giving movement to the neck; and

One pair of motor and sensory nerves running to the larynx, lungs, heart, stomach, and liver, and hence called the *pneumogastric* or the lung and stomach nerves.

Large nerves supply the arms with motion and sensation. They leave the spinal cord in the neck, and, passing out between the vertebræ, unite in a large cord that runs under the collar-bone, and there divides into five large nerves. One of these five can be felt at the inside and back of the elbow, where it is called the funny-bone, and can be rolled about under the finger. It gives sensation to the little and ring fingers, and when it is rolled about a pricking sensation is felt in these.

All down the back a pair of nerves is given off from the spinal cord about every inch, and runs along inside each pair of ribs. Lower down in the abdomen they run in the muscular wall. At the base of the spine two great cords are given off; these soon divide again, one on each side, one for the back and the other for the front of each leg. The posterior nerve is called the sciatic, and when it is inflamed we are said to have sciatica, which is very painful.

The nerves, like the blood-vessels, are well protected from violence by running along the inside or least exposed parts of the limbs.

JUDGMENT IN ALL THINGS

The Necessity for Criticism and Selection. The Intellectual Conscience. Value of Reason in Daily Life. Testing Opinions by the Highest Standards

By HAROLD BEGBIE

TO have a right judgment in all things is one of humanity's oldest aspirations. No man, in whatsoever field of activity he exercises his energies, can dispense with this faculty of judgment. The horsedealer as well as the picture-dealer, the tradesman as well as the artist, must know how to criticise before he can hope to succeed in his enterprises. Criticism is not, as too many people suppose, a petulant finding fault, but rather is it that practical and utilitarian "art of judging of and defining the qualities or merits of a thing."

And yet, important as is this faculty in the practical affairs of life, the art of criticism remains untaught in our schools. No one is instructed how to discriminate between good and bad literature, between true and false art, between wisdom and folly. The schoolboy is supposed to emerge at the end of his studies a wise and prudent man, able to choose the good and discard the evil. And yet the most casual reflection must show us that only the closest and most watchful studies can produce a discriminating mind.

The Intellectual Conscience. It is the object of this article to indicate the easiest manner for acquiring that sensitiveness of intelligence which ends in the creation of the intellectual conscience. We may perceive from the fact that it is not the profound theologian whose faith is shattered by a sixpenny reprint of one of Haeckel's ventures into philosophy, nor the consummate painter who breaks into rhapsodies at the latest picture-poster blazing from street hoardings, that a wide culture is the best means for acquiring sensitiveness of intelligence. The more extended a man's reading, the deeper is his reflection, and the more thorough and profound his experiences, the less likely is his mind to be the sport of every changing fashion and every sudden enthusiasm in the sphere of the intellect. It is, therefore, before all things, necessary for a man to study and to reflect before he can trust his judgment. The intellectual conscience, indeed, may be said to hang as one of the first fruits on the tree of knowledge.

But since it is a platitude that no man can complete in a single life his search after wisdom, it is apparent that there must be some method of acquiring sensitiveness of intelligence as the student pursues his journey. Indeed, it is essential that this should be the case, for without such running acquisition of sensitiveness the student would be for ever selecting wrong models and following false masters. Let us, then, endeavour to discover in what fashion the student may possess himself of an intellectual conscience before he has graduated in knowledge and become a scholar.

The A B C of Criticism. In the smallest and most common acts of life a man may set himself to learn the art of criticism. He will find it possible to begin this education at every step and turn of his everyday life—nay, he will find it impossible to avoid it. For directly a man has seen that it is good to ask himself why he admires or condemns a thing before deciding about it, he has learned the alphabet of criticism, and for ever after, in some fashion, is a critic. This is the beginning of the gospel of criticism: *not* "do I like such a book or do I detest such a picture?" but "*why* do I like, and *why* do I detest?"

It is a common experience to find people expressing opinions and passing judgments who confess, on being questioned, that they have no reason for their faith. They accept without question the dictates of some instinct in their mind, and are not in the least perturbed to be told that this opinion of theirs is in sharpest opposition to the uttered judgment of many centuries. Never once have they asked themselves what are the qualities they admire or dislike in the work about which they are ready to express so fluent and decided an opinion.

Now, a man without scholarship cannot ever pass a satisfactory judgment upon a work of art—to do that necessitates acquaintance with the best that has been said and written on the whole subject; but he can at least give to himself reasons for his own sensations concerning the particular thing, and this he must accustom himself to do if he would create an intellectual conscience. He must learn to suspect his first impressions, to be chary of listening to his dumb predilections; he must examine and cross-examine himself till he has good and substantial reasons for his judgment. Even in buying a newspaper, let a man ask himself why it is that he prefers this particular paper to the others lying on the bookstall. In selecting cloth for a suit of clothes, or carpets for his house, let him question himself as to why he chooses such a pattern or rejects such a fabric. Let him always be intelligent, logically intelligent, in exercising his power of will.

Creating a Free Will. That great artist G. F. Watts once lamented to the present writer that men and women more and more asked themselves if a thing were fashionable, and not if it were true or beautiful—blindly following a prejudice, and never educating in themselves their own faculty of selection. Criticism, be it particularly remembered, does not concern art and literature alone—it concerns nature, it concerns life, it concerns the destiny of the soul. To pass through existence without having consciously used the faculty of selection is to miss one of the first educative forces of human experience. We are largely what our opinions make us, and not to have opinions is not to exist as an intelligible being. On the other hand, to concentrate the mind upon the exercise of the critical faculty is to find oneself treading that shining path of life made luminous by the brightness of the greatest human souls. By such exercise we call into being the highest and the most helpful faculties of intelligence, and establish in ourselves that oft-debated but rare possession of humanity—a free will. Instead of being dumb and driven cattle, we become separate and distinctive personalities. For a man who cannot give himself reasons for the creeds that he holds, the opinions he advances, and the course of action he pursues, is not a distinct and individual personality—he is merely the pallid shadow of a million inarticulate lives.

Test Opinions by Noble Standards. This is the great value of learning the art of criticism—it intensifies personality. The man who accepts blindly the machinery of his period is never likely to be a great inventor. The man who unquestioningly accepts the commercial methods of his fathers is never likely to make a future. But he who studies the existing order of things with the conviction that there is no finality in human progress, with a certain dissatisfaction of mind in the progress of the present time, is he who will find himself presently discovering new avenues of advance, and perceiving in the mists of the future new and more delectable goals for human seeking.

But the highest form of criticism lies in testing opinions by the noblest standards. If we are asked to exalt a sailor to the heavens, we must first compare him with Nelson. If we are asked to salute a poet as the brightest of stars, we must first compare him with Shakespeare. Or, if we are asked to praise the ethics of a moral teacher, we must compare him with Plato, Aristotle, or Marcus Aurelius. We must never be carried away by the heady excitement of a moment, or by the generous enthusiasm of a sudden fashion. Always we must have in our possession some definite and articulate opinions concerning what is the noblest poetry, the greatest seamanship, the sublimest philosophy. We must know *why* we prefer Wordsworth to Martin Tupper, Cervantes to Hawley Smart, and Leonardo da Vinci to Phil May.

A Persuasive Reason. Once reflected upon, the serious student of life will perceive that loyalty to the intellectual conscience is one of the first duties of the soul. The intellectual conscience will appear to him as greatly sacrosanct as the moral conscience. He will be honest with it. He will permit of no shuffling with it. He will accept no dictation from priest or journalist, will not be swayed by the intolerance of parents nor by the prejudice of schoolmasters. At the bar of his own reason he will arraign every question calling for judgment, and only by the arguments of his intellectual conscience will his decision be influenced. He will perceive more and more that by the exercise of his judgment his character is formed, his individuality is developed; and he will gradually come to see that an increasing nicety of discrimination is the main progress of life. Every man who has learned to withhold admiration from meretricious art or false literature is stronger to conquer in himself faults of disposition and evils of character. By having always a persuasive reason for what we do and think, we grow further from our animal ancestry and approach nearer to our divine destiny.

Education and Personality. The full value of cultivating the art of criticism side by side with study may be seen in the sameness of effect produced upon boys' minds by public schools and universities. Education is here witnessed producing a pattern, manufacturing and perpetuating a type. Instead of developing individuality and increasing the forces of personality, our popular system of education tends rather to suppress individuality and to paralyse personality. It should, obviously, be the function of education to draw out, intensify, and fortify the separate and distinct personality of every student, since flexibility of intellect and originality of ideas are indispensable qualities in a great people. Therefore, it is of high importance that the claims of criticism should be urged by reformers of education. Criticism ought to be taught, if not directly, in any case indirectly, in every class and during every study. Boys ought to learn, as soon as they can use their wits, to be able to say why they give particular answers to the questions of their schoolmasters.

Criticism in Daily Life. But for every man the art is to be cultivated in his everyday life, and all his learning is to be applied to this end. He may neglect it, he may decide to trust his instincts, he may ridicule the idea that he should bother himself in these rushing times with reasons for his every action and opinion; but without some application of criticism to his daily life it is impossible for him to succeed in his undertakings, and certainly without it he cannot rank himself with reasoning creatures, with the innovators, inventors, and discoverers who are the advance-guard of humanity.

Finally, a critical mind is not a pessimistic mind, and must on no account be confused with the spirit of pessimism. The critical mind can admire generously and praise encouragingly; but it refuses to admire without discrimination or to eulogise without reason. Moreover, it refuses to perceive final perfection in any achievement of humanity. The architect criticises buildings in order to build better; the surgeon criticises an operation in order to save life with greater certainty. Always a student, always conscious of the sanctity of his intellectual conscience, the educated man holds a balance, and is always able to express with perfect lucidity the reason for the faith that is in him.

BRICKLAYING MATERIALS

Various Forms and Qualities of Bricks. Cutting and Rubbing Bricks. Varieties of Brickwork. Composition and Mixing of Mortars. Gauged Work

By Professor R. ELSEY SMITH

THE manufacture of bricks has been described, but it must be understood that the qualities of brick produced by burning show very great variations, depending largely not only on the nature of the earth from which the brick is made, but also on the manner of moulding and burning them. As a rule, bricks burnt in a clamp show greater differences between the best and worst brick produced than do those burnt in a kiln.

Bricks moulded in a plastic state are more liable to damage after moulding than those moulded dry. The manufacture of the latter requires very powerful machinery, and such bricks are, as a rule, denser, heavier, stronger, and have truer and more uniform edges than those moulded when plastic ; they also exhibit a much smaller range in quality and colour.

Malm Bricks. *Malm* bricks burnt in a clamp will result in bricks practically perfect in shape and of an even texture and colour. Such are known as *cutters.* They stand at the top of the scale of quality, and are used for *rubbed and gauged work* [20 and 22]. The next quality is known as *seconds ;* they are suitable for the best facing work. *Shippers* are bricks well burnt and hard, but not of perfect shape. They derive their name from having been largely exported in ships as ballast.

Stocks. *Stocks* are also sound and hard, but inferior in form ; the majority of bricks in a clamp are of this quality, and are in common use for all ordinary work. Where the outer face of brickwork is required to present a particularly good appearance, free from any great irregularities in colour, the bricks used to form the surface should be picked out from the general mass for evenness of colour and good form, or seconds may be employed for very good face work. All the above classes of bricks, some of which have further subdivisions, are sound and reliable, and are classed according to the regularity of their form and evenness of colour when burnt. They are available for all classes of ordinary building and for either external or internal walls. The prevailing colour is a bright, rich yellow.

Inferior Bricks. The remaining bricks to be described are of a distinctly inferior quality, and their use is restricted to internal walls in inferior work. *Grizzles* are bricks to which air has had access during burning, and are of a greyish colour. *Place bricks* are bricks which are not thoroughly burnt and the surface of which is not vitrified ; they are porous, weak, and usually of a pinkish colour. *Chuffs* are bricks that have been acted upon by rain during burning, or have not been efficiently dried ; they are soft, and liable to disintegrate, and their employment should be prohibited. *Burrs* are masses of brick which have become fused together during burning ; they are found generally near the live holes, where the heat of the clamp is excessive ; they are unsuited for ordinary building operations, but are employed in rockeries, or they may be broken up for use in concrete.

Machine-moulded Bricks. The majority of machine-moulded bricks are burnt in kilns, and the quality of bricks produced at each burning is much more nearly uniform than in the case of clamps; but there are very many varieties in this class of bricks produced, due in a large measure to the chemical composition of the clays of which they are composed, and to variations in manufacturing processes. The local varieties are very numerous. Some of the bricks in most general use are the following.

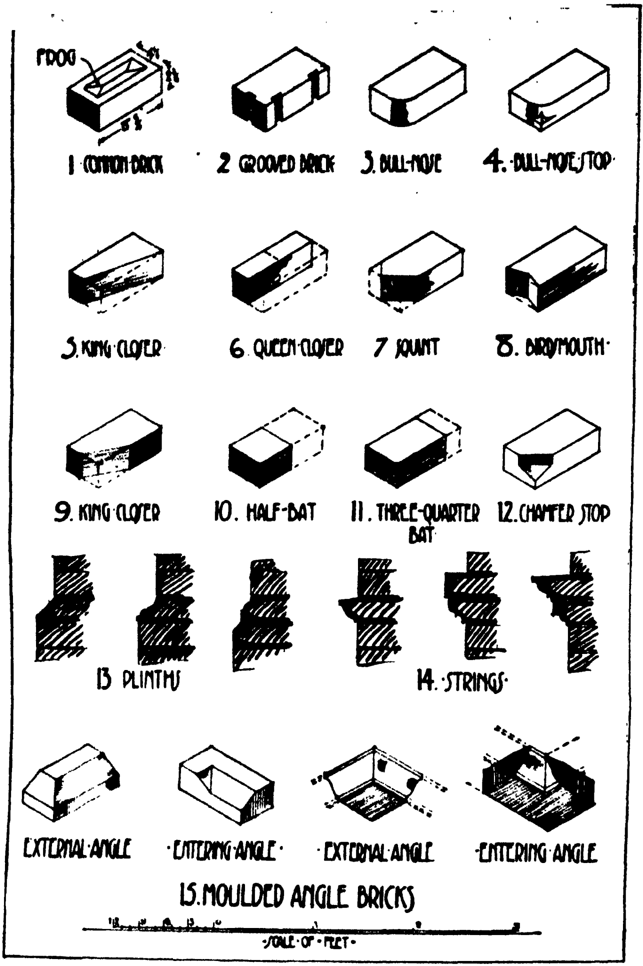
Gault bricks are burnt from the Gault clays in kilns ; the best are hard and white, and are usually perforated with circular holes, running vertically through the brick with a view to reducing their weight.

Suffolk bricks are a variety of Gault brick of a very pale yellow colour, and are known as white bricks ; they are dense and heavy, and expensive, and are often used for facings.

Fareham bricks are of a bright red colour varying in tone, and are much used as a facing brick, and the best qualities of them for rubbers.

Flettons are bricks made in the Midlands. They are very heavy, dense, and true to form, and work constructed with them will carry heavy loads. They are not of a very good colour, and the surface of the brick is smooth. For walls that are to be plastered these bricks are sometimes moulded with dovetailed grooves [2] to give a better key for the plaster than the smooth brick surface affords. For internal walls left unplastered they offer a very true and even surface for the application of distemper or whitewash ; they are sometimes marked with bands nearly black in colour, due to variation in burning.

Staffordshire Bricks. *Staffordshire* bricks are made from a very dense clay ; they are extremely hard, dense, almost non-porous, and of a very dark blue colour, verging sometimes on black. They will carry very great loads, and are used for brick piers carrying concentrated weights, and for railway and other engineering work ; the surface will also stand much wear, and they are often employed, where their colour is not an objection, in the walls of passages and gateways subject to much traffic. Being non-porous, they are also much used for copings to walls, and in the form of paving bricks for yards and stables, and for such purposes are moulded in a great variety of forms.



Clinkers. *Clinkers* are small, hard bricks burnt at a high temperature, with a smooth, vitrified surface. For paving, the edges are generally chamfered, forming a V-shaped joint when laid; they are also employed in forming kerbs and channelling.

Fire-bricks. *Fire-bricks* offer great resistance to heat, and are used for setting stoves and boilers, and in any position where such qualities are required. The Dinas fire-brick, which is extremely refractory, may be used for lining regenerative furnaces, and in other situations where exposed to intense heat.

Glazed Bricks. *Salt glazed* bricks have the surface covered with a thin transparent glaze, caused by introducing salt into the kiln during burning, the sodium combining with silica in the clay to produce the glazed surface.

Glazed or enamelled bricks have the surface covered with an opaque glaze or enamel, either white or of various colours; such bricks cannot be easily cut or rubbed and are made in a variety of forms for special positions. The glaze is produced by dipping the brick into a *slip* formed of finely-worked superior clay, with which the colouring material is incorporated, and then burning in a kiln. It is more liable to chip than salt glazing, and is more costly.

Qualities of Good Bricks. It is not possible to supply an exhaustive list of the various bricks manufactured, but after a little experience of well-known types of brick it should not be difficult to determine, in most cases, if any given class of brick is likely to be reliable. The following characteristics should be sought for in any class of bricks to be used in building.

SIZE. This should be uniform. If bricks vary much in size, very uneven work results. The bricks used in London average about 8·75 in. by 4·25 in. by 2·75 in. [1], but many classes of bricks are considerably larger, and some are made smaller.

SHAPE. The faces should be square, and the arrises fairly true and not twisted.

ABSORPTION. This should not be excessive, and should not exceed 20 per cent. A brick should not absorb water very readily, but should give it off freely. An ordinary brick will often absorb about one-sixth of its weight of water, but a highly vitrified one not more than one-fifteenth, and some even less. Absorption may be tested by weighing a brick when thoroughly dry, completely immersing it in water till saturated, and then re-weighing it after any surface water has been drained off. The difference in the weights represents the amount of water absorbed. The tendency to absorb water readily or reluctantly may be tested by standing a brick half-immersed in water, and noting to what extent the water is absorbed by the upper half.

UNIFORMITY IN BURNING. This can be observed when a brick is broken across; the colour in section will often differ from the colour of the face, but even burning should result in a uniform character and texture, and should show slight vitrification. The brick, when broken, should be free from cracks and other flaws, and from stones.

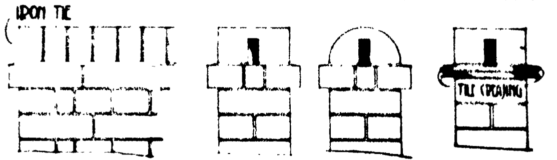
RING. A well-burnt brick struck against another, or with a bricklayer's trowel, should give a sharp metallic ring.

COLOUR. Where bricks are to be used in the face of a wall, the colour is of importance, but is entirely a matter of taste. For any work, the colour having been selected, samples of bricks should be approved and labelled, showing the extreme limit of variation in colour or shade from the standard sample that will be accepted. It may be noted here that the general character of the colour of any piece of brickwork is materially affected by the colour of the mortar used in pointing the joints.

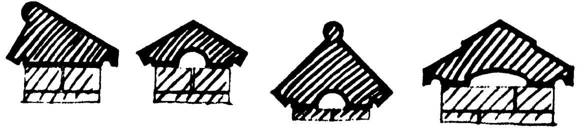
Judging Bricks by Appearance. The appearance of the brick will, as a rule, indicate the process by which it has been moulded. *Hand-moulded* bricks have a *frog* [1] on one side; the edges are, as a rule, not quite uniform or even, and the surfaces are somewhat rough. *Wire-cut* bricks are without frogs, and the top and bottom beds generally exhibit traces of the dragging action of the wires by which they have been cut. *Machine-moulded* bricks have sharp clean arrises, smooth surfaces, sharply-marked frog, with a trade-mark or maker's name, and sometimes a frog on both sides. Some kiln-burnt bricks are marked with dark bars, caused by the method of stacking the bricks in layers or rows at short distances apart, these bars representing the parts that have been in actual contact.

Special Bricks. Special forms of bricks are sometimes required in addition to the bricks of ordinary dimensions which have been described. It is possible to make bricks of any desired pattern and size within certain limits. Many manufacturers keep stocks of various moulds for special bricks, from which bricks can be supplied with due notice. Special shapes of bricks in frequent use are often stocked. It is also possible to have bricks specially moulded to suit any required situation, but their manufacture involves delay and some extra expense; where a large quantity of bricks of any particular form are required, it proves, however, more economical and satisfactory than cutting bricks to the required form. This is especially the case with glazed bricks. For certain work, especially that with delicate mouldings, rubbing gives much more satisfactory results than moulding. Of stock forms of bricks, the varieties that can be readily obtained, as a rule, are *splits*, bricks of ordinary length and breadth, but of less thickness. *Splayed bricks* [13] are those having a chamfer worked on one edge, made with splays of various sizes. *Bullnose* bricks [3 and 4] are those having one angle rounded or circular, on plan, the circle being usually struck with a 2¼ in. radius. Double bullnose bricks are also made, having two rounded angles. *Stops* [4, 12] for bullnoses and splays are made in various shapes when the surface is required to be brought back to a rectangular form. *Angle*, or *mitred bricks* [15] for dealing with such forms at angles, are also made, and are more satisfactory than cutting the bricks to mitre.

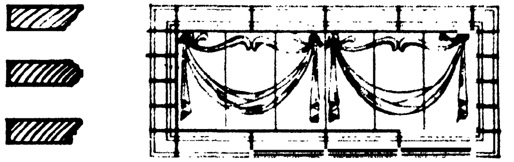
Moulded bricks for *plinths* [13], *strings* [14], *sills* [22], *moulded ribs* [18], *cornices* [19], *copings* [17], mouldings for *window jambs* [22], *sunk panels* [18], and similar purposes, are made in great variety. Different manufacturers make and stock different sections, and some makers include plain and enriched bricks of *voussoir* [21] shape for arches of different radii, including enriched voussoirs. All such bricks are carefully arranged to bond with ordinary brickwork, and include, as a rule, all returns, mitres, stops, etc., that are usually required.



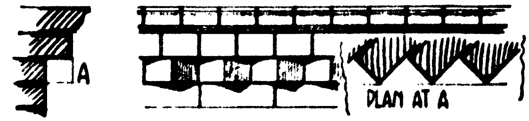
16. BRICK PARAPETS



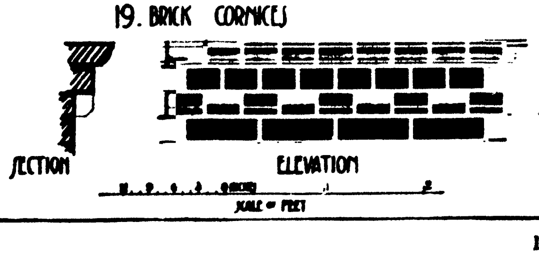
17. MOULDED COPINGS



18. RIB & PANEL MOULDINGS & ENRICHMENTS



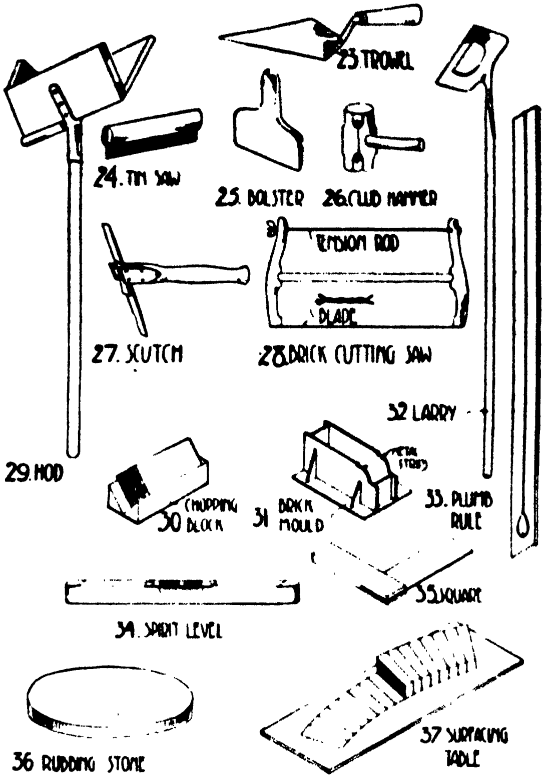
19. BRICK CORNICES



wood, and consist of a base and of two sides cut to the profile of the required brick, but a little full. They are stiffened with brackets, and the upper surfaces covered with strips of zinc, so that they are protected from damage when the saw-blade works over them.

This class of work is used for plain walling, which is the simplest work, and for straight mouldings; also for circular work, either plain or moulded, and for what is known as *circle on circle* work, in which a double curvature occurs.

In working a brick for plain work a beginning is made with one broad surface. This is rubbed on the rubbing stone with a sweeping motion till perfectly true; next one edge is similarly worked, so that it is perfectly true, and is tested with a square to ensure that it is at right angles to the face first finished. It is then placed in a mould of the size required to give it the necessary thickness, tightly wedged, and the upper part is removed with a saw; and by the use of similar moulds the width and length may also be reduced to exact dimensions, and the sawn surfaces are afterwards rubbed or finished with a hand-stone or file. For moulded work, or for circular work, the wood moulds are prepared of the necessary form, and the process is similar though not quite so simple.



Rough Cutting. We have now considered the manufacture of various forms of brick, most of which the bricklayer is able to lay just as they are delivered on the scaffold, and we have also described the careful preparation of bricks for special situations by different processes, which are all covered by the general term *fair-cutting*. Such bricks are not prepared on the scaffold by the bricklayer, but in a shed, and are sent to the scaffold ready for fixing.

For many situations, however, some cutting on the scaffold is necessary, and this is generally termed *rough cutting*. It includes the rough shaping of bricks by the bricklayer's trowel to suit special positions, the cutting off of angles of brickwork with a hammer and chisel before plastering, and the cutting of perforations and chases, and generally such work as does not involve forming a carefully finished face to the cut surface.

Uniting Brick to Brick. All walls or other structures built up of a number of blocks of materials of moderate size compared to the total mass, require that some means be taken to secure the combination of the component parts into a solid structure. In very favourable circumstances, where the individual blocks are comparatively large and finely wrought, friction by itself may suffice, as in some of the old Greek buildings. But, even when such materials were used, ties of bronze were largely utilised for uniting adjacent blocks and courses. Such work involves much labour in preparing the stones with true beds and joints, and in fitting in the ties.

Where the blocks are comparatively small, such a system is not practicable, and the usual practice has been, and still is, to fit them together with the help of some material that will bind them together. There is this further advantage in the use of such material, that it is not necessary to prepare the beds and joints with the same scrupulous care as when they are to come into actual contact, when perfectly true beds are required to secure an even bearing. The materials in general use for this purpose are all of them applied in a soft condition, and allow for slight irregularities in the adjacent surfaces, and the extent to which such irregularities exist will determine the thickness of the material used in the joint. For example, when bricks are used as delivered on a building, if they are placed one upon the other it will be noted that any two surfaces, as a rule, are not in contact all over, and in practice it is usual to form a bed or joint of about ¼ in. thick. If, for any reason, a very fine joint be required, the bricks have to be prepared by rubbing the adjacent surfaces till they are quite true. Much the same is true of stone walling. If small stones be used with rough surfaces, thick joints are necessary, and if a fine joint be required, the surfaces must be carefully prepared.

Mortar for Brickwork. The material used for forming these joints between the hard blocks of material is usually described as *mortar* or *putty*. Bitumen has been employed in countries where it is found, but is not a cementing material in ordinary use. Mortar varies considerably in its nature and properties, according to the ingredients of which it is composed. The word usually implies a material composed of a fine *aggregate* [see page 332], such as sand, and of some form of lime as a *matrix* [see page 332]. *Cement mortar*, often referred to briefly as *cement*, consists of a similar aggregate mixed with Portland cement, or some other cement. It is a material similar to concrete, but requires a very much finer aggregate.

Mortar Aggregate. The aggregate for mortar is usually *sand*, which may be pit sand or river sand, and is required to be clean, sharp, free from all animal and vegetable impurities, and from loam or salt. If necessary, it must be washed, as described for use in CONCRETE [page 334]. If the sand be mixed with gravel or stones, it may be screened. This is done by erecting near the heap an oblong frame of wood, filled in with a series of stout wires running vertically. For ordinary mortar, these are usually ⅛ in. diameter, with three wires and three spaces to 1 in.; stronger horizontal wires occur at short intervals. The frame is fixed in an inclined position; the material to be screened is taken from the heap in a shovel and thrown against the face of the screen; the finer particles, forming sand, pass between the wires and fall behind the screen; the larger particles and stones run down the face of the screen, and are reserved for concrete.

Various substitutes may be employed if sand cannot be obtained, or may be used as a portion of the aggregate, provided the particles are sharp, clean, and durable. The most usual substitutes are crushed sandstone, crushed pottery, or crushed brick, but the bricks for such purposes must be thoroughly burnt, hard, and vitrified, and, if old bricks are used, should be cleansed of any old plaster adhering to them. Fine ashes often make a very satisfactory mortar, but give it a dark colour.

Qualities in Mortar Aggregates. Whatever the aggregate employed, it must be clean; particularly it must be free from salt, which would cause dampness and efflorescence in the mortar, and from loam or clay, which would prevent the matrix adhering to the particles. The presence of loam may be detected by rubbing a small quantity in the fingers when it is damp. If loam be present, the clay will be rubbed off, and remain as a slightly sticky yellowish substance on the fingers. The only means of getting rid of such matter is by washing as already described.

The sharpness, which is also essential, may be detected by employing a magnifying glass, when the grains should appear irregular and angular, not rounded and smooth. Sharp sand, if rubbed between the fingers close to the ear, will give a sharp grating sound.

Quality of Lime for Mortar. The matrix selected depends largely upon the purpose for which the mortar is required, and the strength expected in the walling. A pure or fat lime should never be used in making mortar, except for temporary work, where no strength is required; such lime can set only by the absorption of carbonic acid from the air, which never reaches the inner portions of a bed of mortar, and in consequence this never sets. A feebly hydraulic lime, such as the greystone lime burnt in the neighbourhood of Halling, Dorking, or Maidstone, may be used for ordinary building work in which no great strength is required to be developed, but is not suitable for footings in damp situations. Blue lias lime, which possesses considerably higher hydraulicity, is used for building of a good class, and may be utilised even for foundations in damp situations. The most eminently hydraulic are Aberthaw and Halkin Mountain lime, but where an eminently hydraulic material, or one possessing great strength is required, Portland cement is usually specified. Other cements, such as Roman, are confined, as a rule, to rendering or covering walls externally.

Composition of Mortar. The sand in mortar is employed partly for reasons of economy; it also serves to lengthen the time within which setting takes place, and renders the material easier to use; but it diminishes the strength of the resulting mortar, and the proportion in which it is employed is, therefore, regulated by these considerations. The proportions of aggregate and matrix usually employed are the following:

1 part of feebly hydraulic lime, 2–3 parts aggregate; 1 part eminently hydraulic lime, 3–4 parts aggregate; 1 part Portland cement, 2–3 parts aggregate.

Portland cement is usually mixed with a comparatively small proportion of aggregate. Its strength is greatly reduced if a large proportion of aggregate be employed, and as cement is, as a rule, employed mainly where considerable strength is essential, it is important that it should not be seriously impaired.

Experiments by Grant showed the results given in the following table:

1 part P.C. + 1 part sand = 75 per cent. of neat Portland cement.
1 „ „ + 2 „ „ = 50 „ „ „
1 „ „ + 3 „ „ = 33 „ „ „
1 „ „ + 4 „ „ = 25 „ „ „
1 „ „ + 5 „ „ = 17 „ „ „

They also demonstrated that it takes a much longer time for the cement mortar to attain its ultimate strength when a large proportion of aggregate is employed.

The methods of slaking limes and cements for using in mortar have already been described, and the nature of the setting, but the method of mixing may be briefly referred to.

The Mixing of Mortar. Much will depend on the amount of mortar required daily. If this be small the mixing will be done by hand, but in large works a mortar mill is often used. In the case of a mortar which sets slowly there is no great harm in mixing up more mortar than can be used in a single day; but in the case of mortars made with eminently hydraulic limes and cements this must on no account be allowed. Where a quick-setting cement is mixed with a small amount of sand, it must be made fresh and used up before setting begins. In any case, mortar cement that has once set should not be allowed to be "knocked up again"—that is, mixed with a further supply of water till it is soft and then employed as mortar. This is a practice that is often indulged in and even supported, but should not be allowed, for such mortar or cement may reset, but it will never attain the strength that freshly-made mortar would do.

Working up by Hand. In working up by hand it is usual, if the lime be in lump, to measure out the amount of sand and lime required, to form a roughly circular ring of the sand, or other aggregate, to place the lime within it, to sprinkle it with water, and to leave it till slaking has taken place. When this is complete more water is added, the sand from the ring is gradually worked into the centre with a spade or shovel, and incorporated with the lime by means of a *larry* [32], which resembles a large hoe with a long handle, and with a hole formed in the blade. With the larry the mortar is worked over till all the sand is incorporated and thoroughly mixed. Mortar so made is often kept for a day or two before use to ensure that the lime is thoroughly slaked, but this method only applies, as a rule, to pure and feebly hydraulic limes; the more eminently hydraulic limes and cements are usually ground.

Transporting Mortar. With ground limes and cements the proper proportions of aggregate and matrix are usually mixed dry, the necessary water added, and the whole intimately mixed, and conveyed as soon as possible to the scaffold for the bricklayers' use. This may be done in *hods* [29], which are made of such a size that they can also be used for carrying bricks, and are filled and carried by labourers to the point of use and tipped out on to *mortar boards*, boards about 30 in. square, from which the bricklayer picks the material up with his trowel [23], in building the wall on which he is working. In larger works it may be put into barrows or baskets or pails, and hoisted to the scaffold; in such cases the mortar is usually mixed as close as possible to the bottom of the hoist.

The Mortar Mill. Where a large and regular supply of mortar is required, a mortar mill is best employed; but this requires an engine or motor to drive it in most cases, though smaller mills worked by hand or by a horse have been used.

The mill itself [see 66, page 645] consists of a circular iron pan from five to ten feet in diameter which revolves round a central pillar by means of machinery under two heavy rollers weighing together from one to three tons, and iron plates are used to direct the mortar, during mixing, under the rollers. Lime in lumps must be previously slaked. The ingredients are fed into the pan in their correct proportions, including a proper quantity of water, and are intimately mixed by the rollers. Where the aggregate requires to be crushed before use—as, for example, in the case of old brick, stone, pottery, etc.—the crushing should be performed by the rollers before the other ingredients are added.

Setting Gauged Work. Where rubbed and gauged work is employed it is not usual or possible to set it in ordinary mortar, which would be too coarse for the fine joints that are required in this class of work, but it is customary to set all such work that is completely finished before setting in pure lime putty. This is slaked and run into a bin, and kept moist till required for use, and is then worked up into a consistency resembling cream; the brick to be set has the surface dipped into the putty, and is then placed into position, and gently driven against the next brick. When this brick is set the putty should fill the joint and stand slightly in front of the general face like a small bead, which is afterwards cleaned off, and there should be no gaps, or cavities apparent on the face of the thin mortar-bed, which is usually not more than $\frac{1}{16}$ in. in thickness.

The joint being so fine, the use of lime without sand is permissible; but with thicker joints it would be undesirable, apart from the question of cost. Lime tends to contract somewhat during the process of setting, and it is partly on this ground that it is usual and desirable to add a fairly large proportion of sand or other incompressible aggregate in making lime mortar. Were this not done, in a lofty wall the loss of thickness in a great number of mortar joints would be very marked, and even with the usual proportion of sand there is a quite appreciable reduction in the height of brickwork laid in lime mortar during the process of setting.

Setting Gauged Work for Carving. A bed of lime putty never attains great hardness or strength, and is not suitable for use where the surface of the brick has afterwards to be cut away, as it must be when brickwork has to be carved. For such work it is usual to employ a mixture of white lead and shellac in forming the joints, and this, when set, allows the work to be treated by the carver as though it were a solid mass. Such carving should not be very deeply cut in—certainly not to such an extent as to penetrate the full depth of a brick below the original face, and where carving exceeding about 3 in. in projection is required it is desirable to construct the gauged work exclusively of headers.

It is not necessary to use this material in cases where the work is entirely finished before fixing, as is usually done with all moulded work round openings, and in the case of all plain walling or corbelling executed in gauged work and not intended for carving.

Continued

A SHORT DICTIONARY OF BRICKLAYING AND PAVING

See also Short Dictionaries of Building Construction (page 310) and of Civil Engineering (page 1961)

AIR BRICK—A brick perforated to admit air into a building.

Air Flue—A conduit for the conveyance of air.

Annular Vault—A vault springing from two circular concentric walls.

Arch—An arrangement of blocks of material in the line of some curve supporting one another by mutual pressure, the outermost blocks resting on or against an abutment.

Architrave—The ornamental band of mouldings run round a door or window opening.

Archivolt—The ornamental band of mouldings worked on the voussoirs of an arch.

Arch Stone—See *voussoir*.

Archway—An arched opening in a building.

Axed Arch—A brick arch of which the bricks are roughly cut into the form of voussoirs.

BACK HEARTH—That part of a hearth within the recess for a fireplace.

Backing—The inner portion of a wall behind the facings.

Backs—Large shallow tanks into which malm earth is run to consolidate.

Bat—Either portion of a brick formed by dividing it across its length.

Batter—A term signifying that the face of a wall is not vertical, but is inclined backwards from its base.

Beam Filling—The filling in of walling between joists or rafters.

Bed—The upper and lower surfaces of a brick or similar block of material.

Bed Timber—The laying of timber plates on a mortar bed.

Bevel—The surface formed by cutting off an arris by a plane; *or*, a tool for setting out surfaces at various angles.

Bird's Mouth—A notch cut in the end of a brick used in bonding obtuse entering angles.

Blades—Loosely built walls of unburnt bricks formed in a kiln for burning.

Blue Brick—A strong, dense brick, dark blue in colour, largely made from Staffordshire clays.

Bolster—A tool used in cutting bricks.

Bond—The arrangement of bricks or stones throughout a wall so that successive courses interlock.

Bonding Iron—A small iron tie used to bind the two parts of a hollow wall.

Breaking Joint—The arrangement of materials so that cross joints in adjacent courses do not coincide.

Breeze—Fine ashes used in burning bricks.

Breeze Bricks—Blocks of breeze concrete the size of an ordinary brick.

Brick—A material produced by burning special forms of clay.

Brick nogging—Brickwork filled in between the timbers of a wood partition.

Brick on Edge—Bricks laid not flat but on edge.

Build-in—Fixing work into a wall as it proceeds.

Bullnose Brick—One having a quadrant curve at one corner.

Bull's Eye—A circular window or opening.

Burrs—Lumps of brick vitrified and run together in burning.

CASING—The covering of the outer face of a wall with another thin substance.

Cement Fillet—A band of cement, the upper surface sloped or weathered.

Chamfer—The surface formed by the cutting of an arris diagonally by a plane.

Chase—A shallow channel cut or formed on a wall face.

Chimney—A conduit for smoke or fumes.

Chimney Bar—An iron bar supporting the arch over a fireplace.

Chimney Bond—A special form of bonding used in chimneys.

Chimney Breast—The side of a chimney or group of chimneys next a room.

Chimney Piece—The fitting, usually ornamental, fixed in front of a fireplace.

Chimney Pot—A tube of terra-cotta or earthenware forming the finish to the top of a chimney.

Chimney Shaft—A large single chimney connected with a furnace or boiler.

Chimney Stack—A structure in which several chimneys are contained.

Chuffs—Bricks on which rain has fallen while burning—soft and useless.

Circular Work—A term applied to any work having a cylindrical face.

Clamp—A carefully-built stack of dried raw bricks for burning.

Closer—A brick cut in half lengthwise.

Coping—The course covering the top of a wall.

Copper—A receptacle for heating water by means of a furnace.

Corbel—A projection from the face of a wall to carry some superstructure.

Corbel Table—A continuous projection carried on corbels or projecting arches.

Core—The heart or centre of a wall; applied also to other objects.

Core and Parge—The operation of finishing the interior surface of a chimney flue.

Cornice—An ornamental course projecting from the face of a wall at or near the top.

Course—A layer of materials contained between two horizontal joints.

Creasing—Courses of tiles set in cement projecting beyond each face of a wall below a brick-on-edge coping.

Crown—The top of an arch or vault.

Cut and Pin-in—Cutting out a part of a wall to receive a step or other object and fixing same in securely.

Cutters—The best malm bricks used for gauged work.

Cylindrical Vault—One in the form of a segment of a cylinder.

DAMP COURSE—A layer of material impervious to moisture introduced into a wall.

Damper—A sliding diaphragm introduced into a flue to regulate the draught.

Dinas Firebrick—The most refractory firebrick made from Glamorganshire fireclay.

Discharging Arch—An arch built over a lintel to relieve it of the weight of the superstructure.

Dry Area—A space constructed outside a wall below the ground level to keep it dry.

Dwarf Wall—One that only rises a short distance from the ground.

EFFLORESCENCE—A floury substance, often occurring on new walls, due to crystallisation of salts in the materials used.

Elliptical Arch—One taking the form of an ellipse.

English Bond—The form in which headers and stretchers appear in alternate courses on the face.

Equilateral Arch—A pointed arch in which the chord subtending each curve equals the width at the springing.

Extrados—The upper surface of any arch.

FACINGS—Material of a selected quality for the face of a wall.

Faircutting—The careful preparation of bricks for special positions.

Fair Face—The face of a brick wall in which both headers and stretchers lie in a true plane.

Feeding Holes—Openings in a kiln to admit fuel.

Fender Wall—One built to carry the hearth of a fireplace.

Fillet—See *cement fillet*.

Firebrick—Bricks formed from refractory clays capable of withstanding high temperatures.

Fireclay—A refractory clay used in setting firebricks.

Fireplace—The place in a room provided for the fire.

Flat Arch—An arch formed with voussoir-shaped bricks, but having a flat soffit.

Flaunching—A weathered surface formed in mortar around a chimney pot.

Flemish Bond—The form in which headers and stretchers appear in the face alternately in every course.

Flue—A conduit for conveying air or smoke.

Flush—One surface is flush with another when they are in the same plane.

Flush-up—A term applied to filling up vertical joints with mortar.

Footings—Courses projecting on either side of the base of a wall to increase its bearing area and stability.

Frenchman—A tool used by a bricklayer in pointing.

Frog—A hollow formed in the face of some bricks.

GANISTER—An extremely refractory sandstone used in a powdered state for lining steel converters.

Gathering-over is causing successive courses of brickwork to overhang those below.

Gauged Brickwork—Work in which large bricks are rubbed down to exact dimensions.

Gault Bricks—Those manufactured from gault clay, usually hard and white.

Glazed Brick—One the face of which is covered with a transparent or opaque glaze.

Grizzles—Inferior soft bricks to which air has had access during burning.

Grout—Mortar or cement made liquid with water and poured into brick walls at intervals to fill up interstices.

HACKS—Long, low banks on which bricks are stacked to dry.

Haunch—The curved sides of an arch between the springing and crown.

Head—The horizontal member forming the top of an opening.

Header—A brick laid in a wall with its length perpendicular to the face.

Header Bond—A bond formed entirely of headers.

Hearth—A slab of incombustible material laid under and in front of a fireplace.

Hod—The receptacle in which a bricklayer's labourer carries mortar or bricks on his shoulder.

Hollow Wall—One in which a continuous cavity is provided between the inner and outer faces.

Honeycomb Wall—One built with intervals between the ends of the bricks.

Hood Mould—A moulding projecting beyond the wall above an opening.

Hoop-iron Bond—Strips of thin iron built into walls longitudinally.

Horseshoe Arch—One consisting of a part of a circle greater than a semicircle.

IMPOST—The top of a pier from which an arch springs.

Intrados—The under surface of any arch.

Inverted Arch—One of which the arch is formed below the level from which it springs.

JAMBS—The vertical sides of a door or window opening.

Jump—An abrupt change in the level of a horizontal course.

KERFS—Heaps of brick earth, dug and covered with fine ashes.

Kiln—A brick structure in which bricks are burnt.

King Closer—A brick cut to a bevel to show a face 2¼ in. wide.

LABOURS—A general term denoting work incidentally necessary, but not specifically described.

Lap—In brickwork, the horizontal distance between vertical joints in successive courses.

Larry—An instrument for mixing mortar.

Limewhite—A mixture of quicklime and water used as a wash.

MALM—A brick earth made in imitation of natural marl.

Marl—A brick earth containing much carbonate of lime.

Mat Sinking—A sunk space formed in the paving inside a door for a mat.

Mortar—The adhesive material formed of lime or cement and sand placed between adjacent bricks.

Mortar Board—A square board on which mortar is deposited on the scaffold.

Mortar Mill—A machine in which mortar is mixed.

Moulded Bricks—Those which have some special moulding on them.

Moulding—The process of forming clay into the form of a brick; also an ornamental contour applied to a surface to enrich it.

Mullion—A vertical pier sub-dividing an opening.

Mural—Appertaining to a wall.

NICHE—A recess formed in the thickness of a wall.

Nogging—See *brick-nogging*.

OBLIQUE ARCH—One in which the face is not perpendicular to the axis.

Offset—A ledge formed in a wall by reducing its thickness.

Oversailing Course—A course which overhangs the course below.

PANEL—A surface enclosed by moulding or other surfaces in different planes.

Parapet—A wall carried up above the level of the adjoining roof.

Parge—The process of rendering the inside of a flue.

Paviors—A hard quality of bricks used for paving.

Perpends—The perpendicular alignment of vertical joints.

Pier—A detached or projecting portion of brickwork or masonry carrying a concentrated load.

Pin-in—Fixing any work into a cavity prepared for it in a wall.

Pin-up—Finishing a new piece of wall tight up against superincumbent work.

Place Bricks—Soft under-burnt bricks, suited only for internal walls.

Plinth—A slight external projection at the base of a structure.

Plumb Rule—The tool with which a bricklayer ensures that walls are built truly vertical.

Pointing—The filling-in with mortar of joints in walling which have been previously raked out.

Pressed Brick—Bricks moulded by dry-clay machinery.

Pugging—A layer of material used to deaden sound.

Pug Mill—The receptacle in which brick earth is worked up before moulding.

Purpose-made Bricks—Those specially formed or moulded for a particular piece of work.

QUEEN CLOSER—A brick of the ordinary length and thickness, but only half the usual width.

Quoin—The external angles of a structure.

RACKING BACK—The end of a wall temporarily formed so that each course is set back by the extent of the lap.

Rake Out—The clearing out of mortar joints previous to pointing or rendering.

Ramp—A curved form connecting a higher and lower part of a wall.

Relieving Arch—See *discharging arch*.

Reveal—The vertical return on the outside of a door or window opening.

Rib—A projecting band, usually moulded, separating adjoining surfaces.

Rod—A standard measure of brickwork equivalent to 272¼ superficial feet of wall one and a half bricks thick.

Rough Arch—One formed with parallel sided bricks and irregular joints.

Rough Cutting—The cutting that may be done to brickwork on the scaffold or in position.

Rubbers—A special class of brick used for rubbed and gauged work.

Rubbing Stone—A gritty stone on which bricks are rubbed.

SAND MOULDING—Sprinkling the mould in brickmaking with sand, to prevent the clay adhering to it.

Scintling—Placing half-dried bricks diagonally at short spaces apart.

Scutch—A tool used for brick cutting.

Segmental Arch—An arch, the intrados of which forms less than a semicircle.

Set-off—A small ledge formed by reducing the thickness of a wall.

Shippers—Sound, hard bricks, not perfect in form, largely exported.

Sill—The horizontal member forming the bottom of an opening.

Skewback—The sloping abutment from which an arch springs.

Sleeper-wall—A low wall carrying the plate or sleeper for a floor.

Slop-moulding—When the mould in brickmaking is dipped in water to prevent the clay adhering to it.

Soil—Very fine ashes that are mixed with brick earth.

Splay Bricks—Those having one angle bevelled.

Splits—Bricks of usual length and breadth, but 1 in., 1½ in., or 2 in. thick.

Springer—The block of material from which an arch rises.

Springing—The horizontal line from which an arch rises.

Square—A tool used for setting out surfaces at right angles.

Squint—A brick used in bonding external obtuse angles.

Stilted Arch—One of which the springing is above the level of the impost.

Stock Board—The loose bottom of a brick mould.

Stocks—Hard, well-burnt bricks not perfect in form.

Stop—The term for the finish of a chamfer or moulding not run out.

Straight Arch—A gauged arch having a horizontal intrados.

Straight Joint—A vertical joint that extends through more than one course.

Stretcher—A brick laid in a wall, its length being parallel to the face of such wall.

Strike—A straight-edge used for removing surplus clay from a brick mould.

String Course—A small continuous horizontal projecting band or moulding.

Struck Joint—A joint with a weathered face, formed as the wall is built.

Surfacing Table—A table on which gauged work is set out.

TEMPERING—A process in preparing clay for brick-making.

Terra-cotta—A hard durable material composed of special clays and burnt in a kiln.

Tessellated Pavement—One composed of small cubes of suitable material.

Tessera—Small cubes of material used in forming mosaic work and tessellated pavements.

Tile Creasing—See *creasing*.

Tin Saw—A saw used for cutting lines into a brick.

Toothing—The end of a wall left with alternate courses projecting one quarter brick, with a view to continuous bonding when extended.

Trowel—The tool used for cutting and laying bricks.

Tuck Pointing—A narrow line of white lime putty worked on the face of ordinary pointing to imitate gauged work.

Tumbling—A method of finishing a sharply-inclined brick surface.

VERTICAL DAMP COURSE—One used in a vertical position in walls, the outer face of which is in contact with the soil.

Voussoir—Each of the wedge-shaped blocks of material of which an arch is formed.

WALL—A structure formed of small component substances used to separate adjoining areas or to enclose spaces.

Wall Tie—The ties of brick, terra-cotta, or metal used to construct the two parts of a hollow wall.

Washing—The process of mixing brick earth with mortar.

Weather Fillet—See *cement fillet*.

Weather Moulding—A moulding having its upper surface formed to throw off water.

White Bricks—Bricks of a whitish colour, largely made in Suffolk.

White Glazed Bricks—A brick with a fine white glazed surface.

Whitewash—A material made from whiting, often applied to brick interiors.

Whiting—A pure chalk ground in water and run through a fine sieve.

Wire-cut—A brick formed in a plastic clay machine.

With *or* **Wythe**—The partition separating the flues in a chimney stack.

Wood Brick—A block of wood the size of a brick built into a wall for fixing joinery.

BANK ACCOUNT & CASH BOOK

Documents Connected with a Banking Account. Paying-in Books. The Cash Account. Notes on the Improved Form of Cash Book

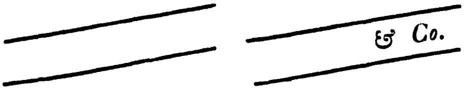
By A. J. WINDUS

AN allusion has already been made to variations in English and Scottish banking practice in relation to pass books. First let us note that in Scotland, as in England, the pass book is generally recognised as the *customer's* book. That being the case, lodgments are entered on the debit, and cheques on the credit side thereof, and the two sides harmonise with the two sides of the customer's cash book. Occasionally, however, the sides of the pass book are reversed so as to correspond with the customer's account in the bank ledger, where lodgments must appear as credits, and cheques paid as debits.

A Rare Pass Book. There is a third form of pass book—but this is more rarely met with—which has the usual columns for debit and credit entries, and a balance column besides. In the latter is shown the effect of each operation upon the banking account. That is to say, the pass book is balanced, item by item, but the balances are relegated to a special column or columns, and are not allowed to interfere with the continuity of the entries in the remaining columns of the pass book.

Next to be considered are the documents used in connection with a banking account. The chief of these are the "paying-in" slip and the cheque. The former is used when a lodgment is made. It shows for whose account money is paid in, the date, and the sum total, and tabulates the items comprising the lodgment, as bank notes, gold, silver and copper, town cheques—country cheques being paid in on a separate slip—postal orders, etc.

Crossed Postal Orders. Postal orders received by a person possessing a bank account are often treated as "crossed" cheques. If not already crossed by the senders, they are crossed by the receiver, who draws or stamps two parallel lines across the face of each order, with or without the addition of the words "& Co.," thus:



The effect of both crossings is exactly the same—namely, that payment can be obtained from the Postmaster-General only through a banker acting on behalf of a customer. The arrangement is a very convenient one for traders who receive a great number of small remittances. The peculiar feature of this system is that, while a cheque to order requires endorsement, and a postal order cashed for a private person must bear the signature of the payee, a postal order presented for payment through a bank needs neither endorsement nor signature of the payee.

When two or more postal orders are lodged at the bank, the total amount is entered on the town pay-in slip, and the details on a supplementary slip for the use of the bank.

"Paying-in" Books. Banks in England supply paper-bound books of pay-in slips to their customers. Each slip has a counterfoil. Particulars of the lodgment are entered on the counterfoil and repeated on the slip. The dividing line between the counterfoil and the slip is perforated, so that when the paying-in book is presented with the lodgment to the bank teller he may, after satisfying himself that all is in order, easily detach the slip from the counterfoil. The latter he initials, and hands back the paying-in book to the person who presented it, retaining the slip to be dealt with by the bank.

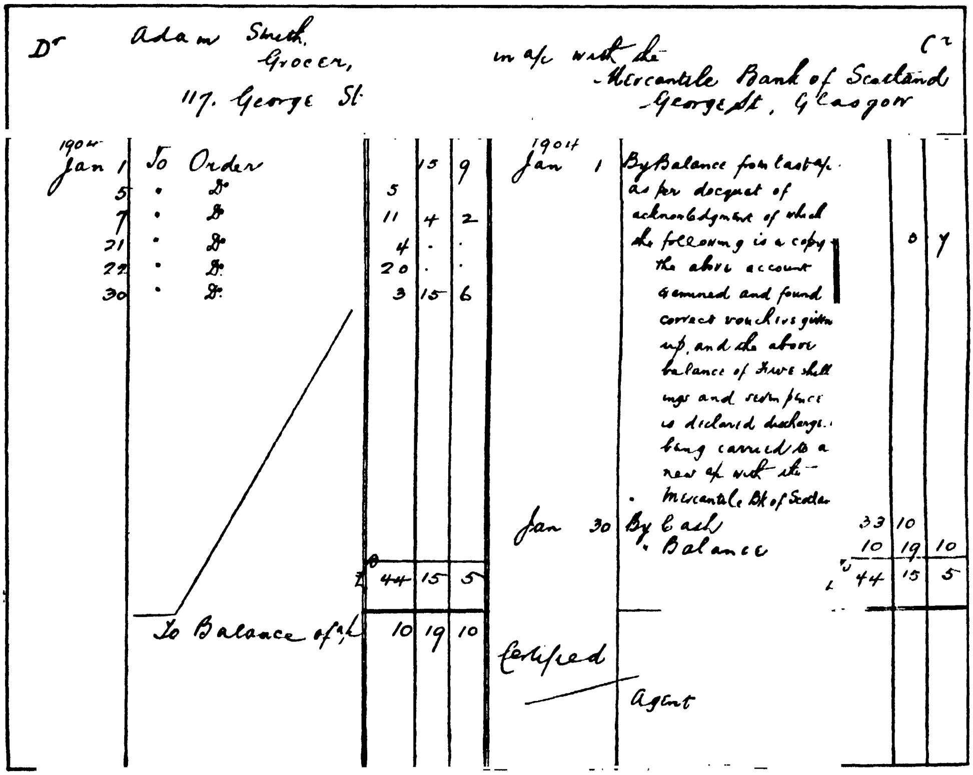
In Scotland the counterfoil paying-in book is dispensed with. The customer merely enters the items of the lodgment on the pay-in slip which he presents with the money and his *pass book.* Instead of initialling the counterfoil of the paying-in book, the teller, after verifying the slip, enters the amount in the pass book, in words as well as in figures, and initials the entry. The book and slip are handed back to the customer, who presents them to the cheque clerk. The latter compares the entry with the slip, initials the entry, and returns the pass book to the customer, retaining the slip to be dealt with by the bank. In some places it is the custom for the entry to be written in the pass book by the person making the lodgment.

Cheques Paid by the Bank. The other side of the pass book is concerned with cheques paid by the bank. In England, these are entered by the pass book clerk. In the metropolis, paid cheques are placed in the pocket of the pass book, and thereby reach the customer the next time he calls for his pass book from the bank. In Scotland, the customer himself enters the cheques in the pass book, and leaves the book with the bank now and again, so that his entries may be verified. In England, the pass book is in the bank's custody the greater part of the time, being withdrawn at intervals; in Scotland, it is seldom at the bank for any length of time, being required by the customer almost daily. By virtue of the system explained above, the Scottish pass book tends to become a copy of the customer's cash book rather than a copy of the customer's account in the bank ledger. Hence it is necessary, before striking the periodic balance in the pass book, to carry forward to next account all entered cheques which have not yet been presented for payment.

Paid cheques are treated with a certain amount of ceremony in Scotland, for there it is customary to send out a notice as follows:

> *Mercantile Bank of Scotland,*
> *Glasgow,*
> *January 6th*, 1904.
>
> *Sir*
>
> *Your Current Account with this Office has been made up to 31st December*, 1903, *at which date the balance due......you was £..........* *..........and I shall thank you to call at the Bank, at your earliest convenience, and docquet the ledger as correct, and receive paid cheques for year.*
>
> *Yours faithfully,*

The meaning of the word "docquet" in the foregoing notice may be best explained to readers by an illustration of its use in connection with a banking account—an extract from which is given below:



Dr	Adam Smith, Grocer, 117. George St				in a/c with the Mercantile Bank of Scotland George St, Glasgow				Cr
1904 Jan 1	To Order		15	9	1904 Jan 1	By Balance from last a/c as per docquet of acknowledgment of which the following is a copy: the above account examined and found correct vouchers given up, and the above balance of Five shillings and seven pence is declared discharged, being carried to a new a/c with the Mercantile Bk of Scotland		5	7

		£44	15	5			£44	15	5
	To Balance of a/c	10	19	10	Certified	Agent			

The epitome of ledger accounts at page 1750 is a continuation of the synopsis or birdseye view beginning at page 1751 and, hence, does not embrace accounts other than those affected by the (*a*) to (*u*) transactions, or items other than those dependent for their validity upon the journal entries located in another part of the synopsis. The ledger accounts as seen in the epitome are incomplete and, therefore, we need not be surprised at the accident of a *credit* balance, where we were entitled to expect a *debit* balance, as in the accounts headed "Cash" and "Bank" respectively. In business, a credit balance on the latter is regarded as a bad sign, because it signifies an *Overdraft*, but a credit balance on cash account is ludicrous, since it implies that more money has been spent than has been received!

There are other reasons, however, why the cash account in the epitome cannot be held up as a model. One of them is that we are left in doubt as to the fate of cheque £10 16s. 3d. received from J. Bruce on September 28th. We know that Bevan and Kirk pass all receipts of cash through the bank, and yet we cannot find in the cash account any credit for the above amount; neither can we trace in the neighbouring bank account any debit for same.

The fact is, the journal entry recording the lodgment of Bruce's cheque at the bank is lacking. The omission must be repaired before the balance shown in cash account can be agreed with the actual amount of cash in hand. If the cash is balanced daily, as it should be, any such discrepancy as that indicated would be speedily brought to light; but sometimes cash is balanced weekly or even at less frequent intervals, and then an error may go undiscovered for an indefinite period. The use of the form of cash book shown on page 779 minimises the risk of omitted bank entries, for when an amount received is entered in the bank cash book, by that very fact the bank is duly charged.

But the main objection to Account No. I in the epitome is that it confounds, under a common designation, transactions which are dissimilar. The first item on the debit side represents a withdrawal from the bank and an addition to the stock of ready money. The four remaining items represent receipts from outside sources which are lodged at the bank, and are not an addition to the stock of ready money. Yet all five items are entered in one column under the heading of receipts. Again, in this cash account there is but one column for the reception of amounts representing payments into bank (lodgments) and also for amounts representing actual expenditure. How easy it is under these circumstances for errors to creep in unawares may be judged from the fact that the credit item of £8 should not be in cash account at all, but should appear on the credit side of bank account—journal entry (*p*) being revised so as to read:

Wm. Bevan, Drawings a/c Dr. 5 0 0
J. J. Kirk Do. Dr. 3 0 0
To Bank 8 0 0

The Cash Account. The cash account, the source of whose entries was the journal, is now no more, its place having been taken by the cash book—an original register of receipts and payments. But the primitive *form* of the cash account is frequently perpetuated in the cash book. Two money columns, one on each side of the cash book, doubtless suffice for the entry of receipts and payments by traders and others who do not avail themselves of banking facilities.

Not only ordinary receipts and payments but also receipts and payments by the bank of moneys lodged and cheques drawn require registration in the cash book, and at this point the single debit cash column and the single credit cash column will be found inadequate to modern requirements. The most scientific method yet devised for recording cash and bank transactions has been explained on pages 977 and 779. But that method cannot succeed unless the rule as to lodging intact all moneys received from outside sources is rigorously enforced.

On various grounds some business men maintain they cannot adopt this system in its entirety. They are willing to pay into the bank all cheques received, and so much of the cash as may not be required for the till (petty cash), but they object to lodge all moneys without deduction as and when received. The question is, What is the proper method for recording cash and bank transactions in circumstances like these ?

We have seen that a cash book modelled on the lines of its forerunner, the cash account in the ledger, would be found insufficient for present-day needs. Assertion is not proof, however, and therefore a demonstration of the futility of the old form of cash book may be welcomed, and will now be given. The improved style of cash book in general use, where some, but not all, receipts are lodged at the bank will then be shown.

The table below comprises the cash and bank transactions of Harris, Green & Co., furniture dealers, for the week ended August 6th, 1904. The transactions are arranged in datal order, the petty cash expenditure for the week being summarised for the sake of convenience, and entered in one sum under the head of Trade Expenses. The cash book is balanced off weekly to guard against errors and omissions.

The adoption of single-column rulings on each side of the cash book will necessitate passing all discounts through the journal, cash and bank transactions being entered in the cash book as shown on the following page.

The student may find the following notes on the improved form of cash book useful.

1. In the earlier form of cash book, as shown, the bank balance has no place, and must be ascertained from the bank account in the ledger.

2. The rule is here to bank daily round sums of cash and all cheques received, but if a received cheque instead of being banked were to be paid away again or cashed it would be treated as coin, and entered in the "cash" column.

	Cash sales	44	3	0

3. Rightly viewed, the cash in hand and the balance at bank constitute one fund divided into two parts, styled "cash" and "bank" respectively. The fund may be increased by cheques and cash received from outside sources, and it may be depleted by cash and cheques paid away. But the total fund can neither be augmented nor diminished by the improvement of one part of it at the expense of the other. If, then, the bank portion of the fund be added to by subtracting a like amount from the cash portion, a transfer has taken place, and should be recorded in the cash book. This has occurred four times in the case before us. Ticks have been

placed in the folio columns of the cash journal (or cash book) opposite the several transfer entries signifying that such entries need not be posted. The very fact of their duly appearing in the cash book is sufficient to adjust the cash and bank accounts as between themselves, in proof whereof we observe that the difference between the two "cash" columns is £48 10s. 6d. (£214 13s. 2d. – £165 13s. 8d.), which agrees with the balance previously obtained by a different method.

4. **Cash Sales.** In many retail businesses these form so large a proportion of the total takings that it is found expedient to insert an extra column on the Dr. side of the cash book for their reception. The daily totals of cash sales besides being entered in the cash column (or in the bank column if *all* moneys are paid into bank) are also recorded in the cash sales column. By this means, a separate total of the cash sales for a given period can be obtained. If the cash book is closed off monthly, the cash sales column would be ruled off every month, and the monthly totals posted to the credit of sales (or cash sales) account.

ENSILAGE

Preservation of Green Fodder in Silos. How to Build and Fill a Silo. Sour and Sweet Silage. Crops Suited for Silage

By Professor JAMES LONG

ENSILAGE, a word which is derived from the French *ensiler*—to seal up—is the process of preserving green fodder either in a stack or a properly constructed silo. The "silo" is a receptacle or apartment so built that the air cannot pass through its walls or floor, while the word "silage" is the material which has been preserved. Whether silage is stacked in the open or pressed in a silo, it is necessary to weight it heavily to exclude the air and thus to prevent excessive fermentation. Some twenty years ago the writer acted as one of the judges in the great silo contest conducted by the Royal Agricultural Society of England, and this experience, together with that obtained on the farms of M. Goffart, Baron Cottu, and Professor Lecouteux, three of the pioneers of the system in France, was sufficient to satisfy him as to the value of the system and of its simplicity when the principles which govern it are once understood.

Value of the Silo. The ensilage system was initiated in this country at a time when frequent bad seasons were accompanied by the destruction of large quantities of partially made hay, but since that date it has been comparatively little practised owing to better seasons, to the more extensive use of rapid haymaking machinery, and to the general preference of the farmer for hay. We do not, however, in England value the process as we should, inasmuch as it is adapted for the preservation of certain forage crops which are of extreme value in winter, and which cannot be systematically preserved in any other way. In the United States and Canada maize, which can be equally well grown throughout a large part of England, is preserved in the silo on a large scale for winter use. With us vetches, peas, lucerne, and trifolium incarnatum are well adapted to preservation in the silo, and if grown for the purpose, together with maize, they would materially add to the winter food supply. In some cases mixed grasses and clovers, cereals and pulse, have been preserved with great success, and the remark equally applies to the top of the Jerusalem artichoke, to sunflower stalks and heads, and maize chopped and mixed at the time of pitting.

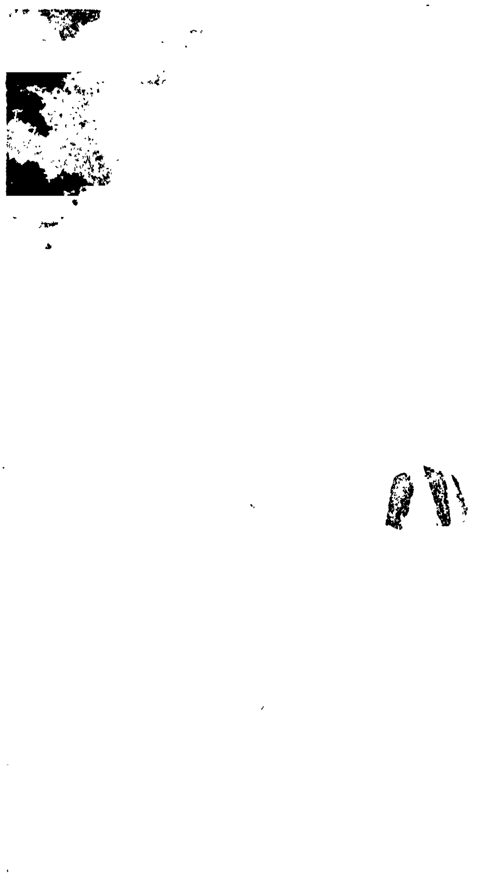
Building and Filling a Silo. When the silo is properly filled and pressed, the fodder is practically kept in a sealed condition. Its walls must be smooth, and the bricks, where these are used, faced with cement, and finished with a steel float, while the corners should be rounded off so as to minimise the quantity of air retained. In filling, the process should be gradual, one layer being allowed to settle before another is brought in. The fodder should be well trodden, especially around the sides, with the object of compressing it as much as possible. It was at first supposed that grass and other green crops intended for silage could be cut and carted during any weather with equal success, but this is not the case. To fill the silo with fodder heavily wetted by rain is to court partial or entire failure.

Sour and Sweet Silage. The success of silage manufacture depends upon control of the temperature; but here it is necessary to explain that there are two classes of silage, the sweet and the sour, with their various gradations. If a silo, having been gradually filled and trodden from day to day, is finally pressed, whether by the aid of a mechanical appliance or by a dead weight, and pressure is applied too early, the result may be the production of sour silage. On the other hand, pressure being applied at a later period, the silage will probably be sweet, owing to the fact that heating or oxidation has intervened. In a word, if the temperature does not exceed 125° to 130° F., the silage will be more or less sour; whereas, if it reaches from 140° to 160° F., it will be more or less sweet. With the application of high pressure at an early period oxidation is checked, and the temperature fails to rise; whereas, if pressure is deferred, heating is encouraged, and the temperature rises to the degree already suggested. It must not, however, be allowed to go too far, or the result will be, as in the case of an overheated haystack, spoiled fodder, and consequent loss. Although there are many producers who make and even prefer sour silage, the production of which is almost unavoidable with the most succulent fodder crops, it is not to be regarded as a food for dairy cows, especially owing to its pungent odour, and to the fact that it is almost impossible to prevent it conveying a taint to milk.

Sweet Silage Most Nutritious. Sweet silage, which is more agreeable both in odour and flavour, is regarded as the most nutritious. Its sweetness is owing to the destruction of the organism to which acid fermentation is due. Grass silage contains from 71 to 72 per cent. of water, or slightly less than grass; while the soluble feeding materials, the albuminoids and carbohydrates, are slightly increased, the insoluble albuminoids and digestible fibre are decreased in quantity. Silage, and especially that which is sour, contains acetic and other acids, although the percentage varies with the temperature at which the fodder has been made.

As compared with hay, which loses considerable weight in the process of drying, the loss of weight as between grass and silage is much less considerable. In round numbers, while grass loses 20 per cent. of its weight during its conversion into silage, it loses 70 to 75 per cent. during its conversion into hay.

Crops Most Suitable for Silage. The colour of silage should be bright, and the flowers of the plants well preserved. Where, however, it is made at a high temperature, the colour deepens materially, until having passed 160° F. by several degrees, it becomes a deep brown, and thus resembles burnt hay. A good crop should never be preserved in a silo if it can be converted into hay. Silage has no market value whatever it may be worth on the farm, and although there is no ostensible reason why it should not be used for stock of various kinds as systematically as hay, there is greater risk in its production owing to general want of knowledge on the part of both farmers and workmen, while the loss which may follow the opening of a stack or silo, and consequent exposure to the air, is much greater than that involved in the opening of a hayrick. We cannot refrain, however, from emphasising the value of the system to those who are able to grow such foods as maize and vetches. In the preservation of maize, which may be grown at the rate of from 20 to 35 tons per acre, a silo is essential; while the fodder must be cut by a special machine, practically a large chaff-cutter, and packed as tightly as possible in an airtight silo.



GREEN MAIZE

Best Form of the Silo. A silo may be built in the form of a pit on the side of a hill for convenience in unloading and removing; it may be circular—a common plan in the United States—or it may be formed by running a wall across one end of any suitable and substantial building. A roof is essential, together with means of elevating the weighting material. Where a silo, having been gradually filled for more perfect treading and settlement, is ready for pressure, the fodder may be covered either with chaff or dried earth, which, if preferred, may be spread upon boards made to fit as closely as convenient, the object being to provide an even surface, and thus to ensure even pressure on the forage. In the absence of a mechanical press, bricks, bags of earth, or stones, blocks of concrete, or any similarly suitable material, may be placed on the top at the rate of 120 lb. to 200 lb. per square foot, the weight being increased with the depth of the silo and the quantity of forage it contains. It is a mistake to suppose that the ensilage process does more than preserve the material submitted to it. There are many who believe that the feeding value of silage is greater than that of the crop from which it has been produced. On the contrary, the value is slightly diminished, owing to the loss which follows heating, or oxidation. The successful preservation of such succulent crops as rape, mustard, mangel, or turnip-tops has, we believe, never been accomplished, and care should be taken never, unless as an experiment, to attempt to ensile foods which are practically foreign to the system.

Grass and other crops intended for silage should be cut when in bloom, and allowed to lie in the field sufficiently long to part with a small proportion of their moisture. In all cases the worst material, that cut around the hedgerows and roadsides, should be packed around the sides in the silo and covered over the top, for in both places there is usually a proportion spoiled.

87. MODERN GERMANY

THE GERMAN EMPIRE

Grouping of Mountains and Rivers around the Fichtel Gebirge. The Rhine Highlands. The German States. Climate. Products. North Germany. River Basins

Group 13
GEOGRAPHY
14

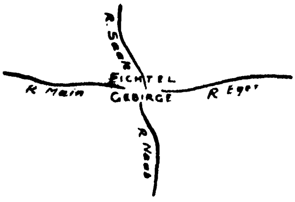
Continued from page 1839

By Dr. A. J. HERBERTSON, M.A. and F. D. HERBERTSON, B.A.

IN our view from the summit of the Alps, and again in tracing the course of the Rhine, we have seen something of the second great geographical feature of Europe—the Central Highlands. These are a broken system of forested mountains, nowhere rising above a few thousand feet, which stretch across Europe at the northern base of the Alps.

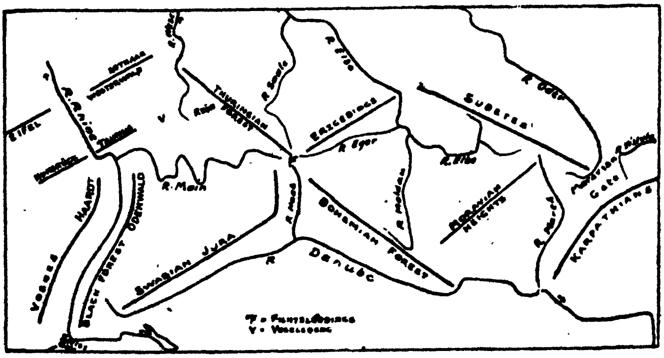
The Hub of the Central Highlands. We grouped the complicated topography of the Alps round the St. Gotthard mass and the mountains and rivers flowing from it. There is a similar point in the Central Highlands, a sort of hub from which mountains and rivers radiate like the spokes of a wheel. This is the Fichtel Gebirge, or Pine Mountains, clothed, as the name shows, with forests of pine. Look now at the rivers flowing from it, north, south, east, and west, to all four points of the compass [88]. They are: (1) To the north the Saale, the most important tributary of the Elbe, corresponding with the Reuss in the St. Gotthard series; (2) to the south the Naab, flowing to the Danube, corresponding with the Ticino; (3) to the east the Eger, flowing to the Elbe, corresponding with the Rhine; (4) to the west the Main, flowing to the Rhine, corresponding with the Rhone. The diagram 88 shows this remarkable resemblance between the rivers rising in the St. Gotthard [83, page 1839] and the rivers rising in the Fichtel Gebirge.

Mountains and Rivers East of the Fichtel Gebirge. Alternating with these rivers are the mountain ranges separating their basins. Look these out carefully first in the diagram [89] and then in an ordinary map. From the Fichtel Gebirge spring to the north-east the Erz Gebirge, or Ore Mountains, and to the south-east the Böhmer Wald, or Bohemian Forest, enclosing two sides of the diamond-shaped province of Bohemia, politically part of Austria. Between them and the Riesen Gebirge and Moravian Highlands, which enclose the two remaining sides, is the Elbe, flowing to the North Sea. Between the Sudetes and Moravian Mountains to the west and the Carpathian Mountains to the East is the important gap known as the Moravian Gate, with the Oder flowing north to the Baltic, and the March flowing south to the Danube. Compare these with the Saale and Naab farther west. The Vistula rises a little east of the Oder in the northern slope of the Carpathians, and flows across Russian Poland before it crosses the North German Plain to the Baltic.



88. RIVERS FLOWING FROM THE FICHTEL GEBIRGE

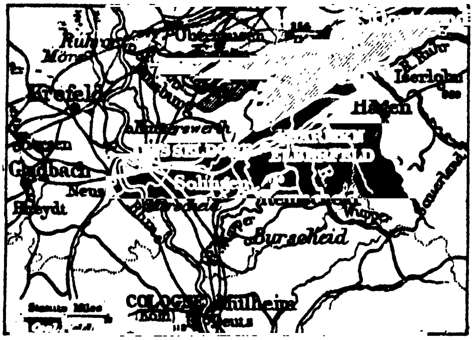
Build of the Country West of the Fichtel Gebirge. The arrangement of mountains and rivers west of the Fichtel Gebirge is more complicated. We can make out three sides of a western diamond, but not so clearly as in the case of Bohemia. From the Fichtel Gebirge to the north-west springs the Thüringer Wald, or Thuringian Forest, connected by lower heights with the Harz to the north, and the Vogelsberg and Rhön to the west. This forms one side of a diamond. The second is formed by the Franconian Jura, springing south-west from the Fichtel Gebirge, and continued by the Swabian Jura. At the western end of the Swabian Jura we have another important meeting-point of mountains and rivers, from which radiate, in addition to the Swabian Jura, the Rhine Highlands, running north, and the French Jura, running west. The last-named separate the Rhine from the Rhone, and connect the Central Highlands with the Alps. The rivers are the Rhine, breaking through the mountains and turning north at what we might call the Swiss Gate, and the Danube, flowing east, between the southern slopes of the



89. THE RELATION OF MOUNTAINS AND RIVERS IN CENTRAL EUROPE TO (*a*) THE FICHTEL GEBIRGE, (*b*) THE MORAVIAN GATE, AND (*c*) THE SWISS GATE

Central Highlands and the northern slopes of the Alps.

The Rhine Highlands. These have already been described, but here their connection with the rest of the Central Highlands is what we must be quite clear about. The Rhine has cut a wide valley across this broad eastern part of the Central Highlands, dividing them into the Eastern and Western Rhine Highlands. These are again broken up by the tributaries coming in from east and west. This gives us on the east the Schwarzwald, or Black Forest, the Odenwald, the Taunus, and the Westerwald. On the west are the Vosges, opposite the Black Forest, the Haardt, opposite the Odenwald ; the Hunsrück, opposite the Taunus ; and the Eifel, opposite the Westerwald. The Eifel and Westerwald represent the third side of the western diamond.



90. THE RUHR COALFIELD

On the east, the Neckar comes in between the Black Forest and Odenwald, the Main between the Odenwald and Taunus, and the Lahn between the Taunus and Westerwald. On the west the rivers coming down between the Vosges, Haardt, and Hunsrück are unimportant, the only considerable western tributary being the Moselle, between the Hunsrück and Eifel. The relation of all these highlands to each other is shown in the map or in the diagram [89], which is a sort of skeleton key to the ordinary map.

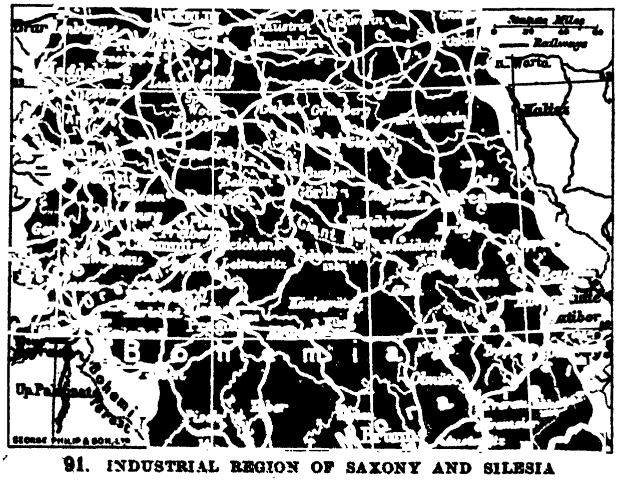
THE GERMAN EMPIRE

What Germany is Politically. The German Empire (209,000 sq. miles) dates only from 1871. The German Emperor, who is not Emperor of Germany, is the King of Prussia, the largest of the many independent States which make up the German Empire. With Prussia are united for political, military, and fiscal purposes the three kingdoms of Saxony, Bavaria, and Würtemburg, six grand duchies, many duchies and principalities, and the free cities of Lübeck, Hamburg, and Bremen. All these are independent in their internal relations, and all but the cities have hereditary rulers who rank among the royal houses of Europe.

What Germany is Physically. In a geographical sense South Germany consists of the Alpine foreland from the Swiss Gate to the valley of the Inn, a tributary of the Danube. In the west the frontier follows the crest of the Vosges, the valley of the Moselle for a short distance, and then runs roughly north. In the east it is more definitely physical, and is determined by the Böhmer Wald, Erz Gebirge, Sudetes, and the mountains beyond the Oder. Then it crosses the featureless plain in an irregular line trending considerably to the north-east. South Germany thus consists of the Central Highlands, and North Germany of the plain to which they slope.

Climate. We can deduce the general character of the German climate from our knowledge of the climate of Europe. In summer the isotherms will approximately follow the parallels of latitude, in winter they will cross them almost at right angles—that is to say, the south will be warmer than the north in the valleys in summer, but there will be very little difference in winter. Then the difference will be between the east with a severe winter, and the west with a mild one.

All this is true, but we want a little more detail. Take the January isotherm of 32° F., indicating frost. The Rhine basin lies outside it, and has mild winters and early springs. The isotherm enters Germany at the mouth of the Weser, and runs nearly due south through Munich. East of it the winters are long and severe, and spring late. The isotherms of 30°, 28°, 26°, indicate increasing severity of frost, so that we can readily understand how much more intense the winter cold becomes as we go east. "In the Rhine district, when the swallows return and the almond and apricot blossoms are opening, snow is still lying in east Prussia, where the frost does not break up till



91. INDUSTRIAL REGION OF SAXONY AND SILESIA

the middle of March." Another consequence of the severe winters in the east is that the Baltic ports are closed by ice in winter, while those of the North Sea are open.

The summer climate of North Germany is very much that of the Thames basin, both having an average July temperature just over 62° F. South Germany is warmer. The July isotherm of 64° passes near Mainz, curves a little south, and oscillates round the parallel of 53°, south of which the summers are warm in the valleys, especially in those of the Rhine and its tributaries.

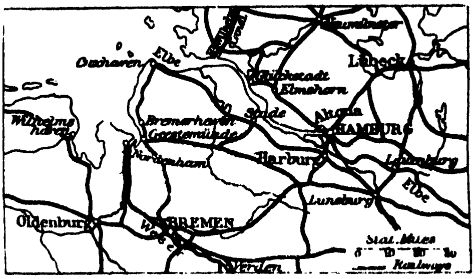
Products. Magnificent forests cover the mountains of South Germany and parts of the northern plain, in all about one-quarter of the surface of the country. About one-half is under cultivation, the most fertile part being the Upper Rhine plain, the Garden of Germany. Here the vine comes to perfection, yielding famous wines. Its northern limit is about that of the warm summers, lat. 53°. In the east the winters are too severe for it. Much wheat is grown in the Rhine plain, but in most other parts rye is the chief cereal. The potato is grown in enormous quantities in North and Central Germany, and a coarse spirit, sold as brandy, is made from it. The sugar-beet is important in the same districts. Hops are grown chiefly in Bavaria, the beers of which are famous.

Mineral Wealth. We have seen that Germany has an important coalfield, the Westphalian field, mainly in the Ruhr valley, at the northern margin of the Central Highlands [90]. Other coalfields occur in similar positions—(1) the Saar field, on the Saar ; (2) the Saxon field, north of the Erz Gebirge, drained by tributaries of the Elbe ; and (3) the Silesian coalfield, between the Oder and the Vistula [91]. Iron is found near most of them. Other minerals are abundant in the Central Highlands, one part of which is called the Erz Gebirge, or Ore Mountains.

The Rhine Provinces. From Basle to Karlsruhe the Rhine flows between the Grand Duchy of Baden on the west and the Imperial provinces of Alsace and Lorraine, annexed from France in 1871, on the west. From Karlsruhe to Mannheim the western bank belongs to the Palatinate, politically part of Bavaria. From Mannheim to Mainz the river flows through the Grand Duchy of Hesse, and from Mainz to the Dutch frontier it is in Prussia. The kingdoms of Würtemberg and Bavaria, east of Baden, are partly in the Rhine basin and partly in that of the Danube.

The Other River Basins of Germany. The rest of Germany consists of the whole or part of the basins of the Ems, Weser, and Elbe, flowing to the North Sea, most of the basin of the Oder, and parts of those of the Vistula and Memel or Niemen, flowing to the Baltic. Before describing them a word must be said about the plain of North Germany, so different from the forested highlands of South Germany.

The North German Landscape. North Germany consists of two belts. The south is a low plain, sloping from the Central Highlands ; while the north is broken by wooded hills, forming the Baltic Heights. Much of both is moorland or *heide* (heath), poorly watered, and covered with heather or coarse grass. Only the sheep and the bee thrive, and villages are consequently few and population scanty. Along the coast in the west is a belt of marshy but fertile alluvial land, consisting of deep soil, without a stone, formed of the sediment brought down by the rivers. When drained it makes rich pastures. Population centres round any little height, on which are built churches and farmhouses, the latter with moats, and approached by bridges. They look out over a wide expanse of grass lands and cornfields, drained by innumerable canals. Seawards, the view is bounded by the dam, " beyond which extends a tract browsed only by sheep, and traversed by a network of salt sea runs."



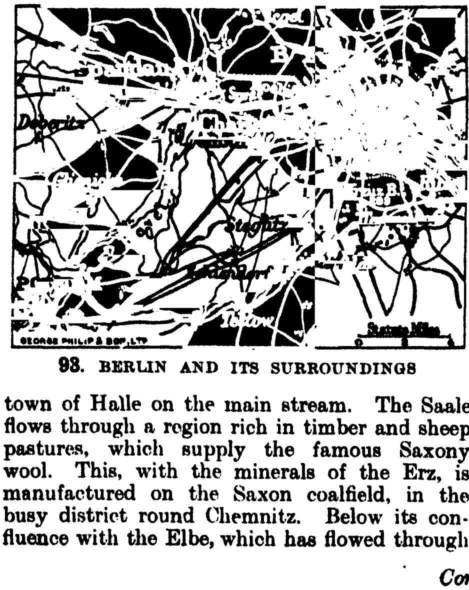
92. ESTUARY OF WESER AND ELBE

The Baltic Lakeland. The map of Germany east of the Elbe shows the character of the region. It is dotted with thousands of lakes, set among pine-woods, with irregular wooded heights—the Baltic Heights—rising above them.

The North German Coast. This has been aptly compared to a tattered lace fringe, especially east of the Jutland peninsula. Here the rivers flow to fresh-water *haffen*, or lagoons, almost landlocked by broad sand bars. In the North Sea, where the strong tides carry the sediment out to sea, the rivers form estuaries.

The Ems and Weser Basins. The Ems rises in the Teutoburger Wald, an outlier of the Thuringian Highlands. It flows north through a marshy country to the North Sea, with Emden as its estuary port. Separated from it by the Teutoburger Wald is the Weser, formed by the union of the Fulda from the Rhön, and the Werra from Thuringia. It leaves the highlands by the gap known as the Westphalian Gate, affording a railway route. It flows across marshy country to the North Sea with the great port of Bremen at the head and Bremerhaven at the mouth of its estuary. The naval station of Wilhelmshaven is on the Jahde Bay just west of the Weser estuary [92]. South of the Ems are the industrial towns of the Ruhr coalfield [90]. Between the Ems and Weser is Bielefeld, the centre of the German linen manufacture. To the Weser flows the Aller, on tributaries of which are the fine old towns of Hanover, Hildesheim, and Brunswick. These tributaries drain the wooded Harz, rich in minerals, the highest point of which is the Brocken, famous in legend. Picturesque old towns, with fine timber houses, are built at the mouth of the Harz valleys, many engaged in mining. The free city and port of Bremen owes its prosperity to the deepening of the Weser. It has a large import and export trade, and manufactures many raw materials brought to its docks.

The Elbe Basin. The Elbe rises in the wild Riesen Gebirge, part of the Sudetes, and receives many tributaries in Bohemia. On the largest of these, the Moldau, is Prague, the capital of Bohemia. The Elbe enters Germany between the Sudetes and Erz Mountains, flowing through the district of Saxon Switzerland, with bottomless ravines and isolated flat-topped hills. At the north end of its gorge is Dresden, the capital of Saxony, with famous art treasures. The tributaries of the Elbe drain the Erz, Thuringian, and Harz Mountains. The largest is the Saale, from the Fichtel Gebirge, with Leipzig, the great printing and publishing city, on a tributary, and the salt town of Halle on the main stream. The Saale flows through a region rich in timber and sheep pastures, which supply the famous Saxony wool. This, with the minerals of the Erz, is manufactured on the Saxon coalfield, in the busy district round Chemnitz. Below its confluence with the Elbe, which has flowed through the potato and sugar-beet district, is Magdeburg, a great fortress, and the centre of the Elbe sugar manufacture. To the east the country is marshy and studded with lakes round Berlin, the capital of Prussia, on the Spree, which flows to a tributary of the Elbe. Berlin is a magnificent modern city, in the centre of the North German plain, with excellent canal and railway communication and numerous industries [93].



93. BERLIN AND ITS SURROUNDINGS

Hamburg. At the head of the Elbe estuary is the port and free city of Hamburg, the greatest commercial town in Germany, doing an immense trade with all parts of the world. Its imports are very varied. Its exports show the character of the Elbe basin. They include iron and machinery, textiles, woollens and worsteds, glass, cattle, cereals and timber. Altona, in Prussia, is now practically part of Hamburg. Cuxhaven is a port at the mouth of the estuary, belonging to Hamburg, opposite to which is the island of Heligoland, once British [92 and 87].

The Kiel Canal. Below Hamburg the Elbe estuary is connected by a ship canal with Kiel, giving a direct route from the North Sea to the Baltic Sea, without going round Denmark. Both Kiel, therefore, and Lübeck, a free city and port south of Kiel, are, in a sense, ports of the Elbe, to which indeed Lübeck is joined by the Trave Canal.

The Oder Basin. The Oder also rises beyond the frontier of Germany, which it enters at the Moravian Gate. It flows north-west across the plains of Silesia and the Baltic Lakeland, through a region producing rye, sugar-beet and timber. Round its upper course are the Silesian coalfields, where Breslau manufactures wool from the sheep pastures of the Central Highlands, linen from local flax, and cotton. Sugar-making is important in and around Frankfurt-on-the-Oder, which must not be confused with the town of the same name in the Rhine basin. The Oder enters the Stettin Haff. Its port, Stettin, is connected by canal with Berlin.

The Vistula and Memel Basins. Only the lower courses of these rivers are German. Danzig is the port of the Vistula, and manufactures much of its produce. Among such industries are woollens, paper-making, shipbuilding (timber), distilling (cereals). Königsberg is the port of the short Pregel, and Memel, at the exit from the Kurisches Haff, is the port of the river Memel or Niemen.

ANCIENT & MODERN ROADS

Main, Rural, and Private Roads. Regulations for Quarries, Pits, and Pavements. Stopping and Diverting Highways. Road Sanitation. Maintenance

Continued from page 1858

By A. TAYLOR ALLEN

WHETHER in ancient times better roads and pavements were built than at present, or whether only the best ones remain, is uncertain; but it is certain that some of the remains of such structures found in Rome, for instance, evince engineering skill of high degree. These were laid out carefully, excavated to solid ground, or, in swampy places, made solid by piles. Then the lowest course was of small-sized, broken stones, none less than 3 in. or 4 in. in diameter; over these was a course, 9 in. thick, of rubble or broken stones cemented with lime, well rammed; over this a course, 6 in. thick, of broken bricks and pottery, also cemented with lime; upon this was laid the *pavimentum*, or pavement, composed of slabs of the hardest stone, joined and fitted together as closely as possible. This was costly—the Appian Way, extending from Rome to Capua, a distance of about 130 miles in length, having almost exhausted the Roman treasury—but it was as enduring as Nature's own work. In Peru and Central America similar remains, 1,000 to 2,000 miles long, were found by the Spaniards, which, as Prescott says, were built of heavy flags of freestone, and, in some parts at least, covered with a bituminous cement which time has made harder than stone itself.

Private Paths. In the very early periods of English civilisation the tract across the heath and the moor sufficiently answered their purpose. Yet, even in those districts unencumbered with wood, where the first settlements were made, stone tracts were laid down by the tribes between one village and another. Formerly no attempt was made to build a road, and most of the old English roads owe their present lines to particular circumstances—many of them were, doubtless, originally footpaths; others, perhaps, the tracks of the aboriginal inhabitants, these becoming the most convenient horse paths (referred to on maps as *bridle paths*). According as the lands of the kingdom were appropriated, the lines of road became fixed and unalterable, there being no other legal lines left for carriage roads, which accounts for the singular way in which many of our existing roads turn and twist in an apparently inexplicable manner. In the neighbourhood of London there was a *hollow way*, which now gives its name to a populous metropolitan district. Hagbush Lane was another of such roads. Before the formation of the Great North Road it was one of the principal bridle-paths leading from London to the northern parts of England; but it was so narrow as barely to afford passage for more than a single horseman, and so deep that the rider's head was beneath the level of

Early English Roads. In 1346 Edward III. authorised the first toll to be levied for the repair of roads leading from St. Giles in the Fields to Charing Cross (then a village), and from the same quarter to near Temple Bar. The footway at the entrance of Temple Bar was impeded by thickets and bushes, and in wet weather almost impassable, and the roads westward were so bad that when the sovereign went to Parliament, faggots were thrown into the ruts in King Street, Westminster, to enable the royal coach to pass along.

The first Act for paving and improving the City of London streets was passed in 1532.

The first turnpike road established by law was in 1653; this was made for taking toll of all but foot-passengers on the northern road through Hertfordshire, Cambridgeshire, and Huntingdonshire.

No very considerable improvements in the art of road-making took place till the Highland Rebellion of 1745, which gave a great impetus to the construction of roads for military as well as for civic purposes, as is evident from the fact that from 1760 to 1774 no fewer than 452 Acts regarding making, repairing, and improvement of highways were passed.

Macadam. Mr. John London Macadam, the great road-maker, was born on September 21st, 1756. During the early years of the nineteenth century he was travelling about the kingdom making inquiries into the systems of road-making. By August, 1814, he had travelled 30,000 miles, and had spent from his own private resources a sum equal to £5,019.

In 1823 he succeeded in getting an inquiry before a committee of the House of Commons as to his system, and had made a set of road-making implements, so that he might the more clearly explain the principles he advocated, and in 1825, having proved an expenditure of several thousand pounds from his own resources in carrying out his improvements, this amount was reimbursed to him by the Government, together with an honorary tribute of £2,000.

Mr. Macadam's system of road-making, to use his own term, was "to put broken stone upon a road which shall unite by its own angle so as to form a solid, hard surface." His practice was to lay flints or some other hard material broken to a uniform size of approximately cubical shape, 1½ in. to 2 in. in diameter to a depth of 10 in., the only preparation being the levelling of inequalities and the digging of side drains, the broken material being spread evenly over the road surface and left to be consolidated by the traffic. He used no admixture of binding material, and the stones were perfectly clean. This rule of Mr. Macadam, which in theory appears all right, in practice is found absolutely impossible to accomplish.

Telford's Highland Roads. About the same time that Macadam was busy engaged in his system of road-making and repairing, another pioneer, Mr. Telford, was equally busy constructing many miles of roads in the Scottish Highlands, but on an entirely different system. Mr. Telford did not believe it possible to construct a hard road by simply laying 10 in. of broken stones upon a soft natural foundation, his method being to keep the broken stones from the subsoil, and to ensure this he first laid down a "pitched foundation," consisting of pieces of stones or other hard substance placed upon the level bed by hand to form a close, firm pavement, and upon this foundation was laid a thickness of broken road metal.

Main, Rural, and Private Roads. The highways of England and Wales are divided among some 2,000 local authorities. All roads which had been dis-turnpiked between December 31st, 1870, and August, 1878, or were subsequently dis-turnpiked, became *main* roads under the Highways and Locomotive (Amendment) Act, 1878. Some of the existing roads or portions of roads although dignified by the term "main," are not "principal" roads, but being old turnpike roads, whose days of importance have passed away, have now very little traffic on them. By the Local Government Act, 1888, County Councils, who were previously only contributing authorities, were charged with *entire* responsibility of the maintenance of all main roads. In the provinces public highways are managed by City, Town, and Urban District Councils, while in the country they are managed by Rural District Councils.

Prior to 1835, so long as there was an intention on the part of the owner of the soil to dedicate a road to public use, which he signified by throwing open a road unreservedly, and an acceptance by the public signified by the using of the road, the two circumstances suffice to make a road a public highway; but now roads and streets remain private—*i.e.*, not repairable by the inhabitants at large—until they are formally dedicated to the public [see also under New Streets and Footpaths—Dedication as Public Highways].

Breaking Up. The opening of roads for the laying of new mains, repairs to existing ones, or other public services, is a continual cause of complaint, and one of the stock grievances of the public, and the damage caused to highways by openings made in them by builders, owners, and occupiers of property, and by gas, water, and other companies, is a source of much reasonable irritation and annoyance to Local Authorities who are responsible for their maintenance. A macadamised road opened for the construction of a trench can never be properly reinstated without showing some evidence of it, even when the replacement has been carried out by experienced roadmen; where, however, other workmen have been employed, as those engaged by builders or house owners, the damage is greater. The ramming of the materials in refilling the trench is most rarely executed in a sufficient manner; and instead of two men ramming being employed to one filling, which is necessary, and the materials being replaced in layers of not greater thickness than 6 in., ramming is generally performed in a most perfunctory manner—the material is replaced in large lumps, and as a consequence the trench subsides for weeks after. The substance of the sections giving statutory powers are collected into a short compress and in direct sequence.

Powers to Open Roads. The Gasworks Clauses Act, 1847, empowers the undertakers to open and break up any road, and lay down and place pipes, conduits, service pipes, and other works, and from time to time to repair, alter, or remove the same, subject to three clear days' notice being given to the clerk, surveyor, or other officer of the Local Authority before beginning such work.

The Waterworks Clauses Act, 1847 (incorporated with the Public Health Act, 1875, Sec. 57) provides similar power, and Sec. 52 gives power to a private individual to open or break up so much of the pavement of any street as shall be between the water-main and his house, building, or premises, after giving due notice. It has been decided by the courts that the word *pavement*, as used in this section, is not confined to the footpath only. Provisos are also contained in the Tramways Act, 1870; the Railway Clauses Consolidation Act, 1847; the Electric Lighting Act, 1882; Forrest Fulton's Act (the commonly known title of the Water Companies Regulation of Powers Act, 1887); and the Telegraph Acts, 1863, 1873, 1878, 1892.

Quarries, Pits and Pavement Regulations. Where any quarry dangerous to the public is in open or unenclosed land within 50 yards of a highway or place of public resort dedicated to the public, and is not separated therefrom by a secure and sufficient fence, under the Quarry Fencing Act, 1887, the Local Authority has power to deal with it. The term *quarry* includes every pit or opening made for the purpose of getting stones, slates, lime, chalk, clay, gravel, or sand, but not any natural opening.

The following can be dealt with by Local Authorities as obstructions in streets:

(*a*) Shop and sun blinds if fixed less than 8 ft. in height.

(*b*) Trees overhanging roadways.

(*c*) Doors and gates opening outwards on the pavements.

(*d*) Defective rain-water shoots from buildings.

Where the Local Authorities do not undertake or contract for the cleansing of footways or pavements adjoining any premises, they may make bylaws imposing this duty on the occupier of any such premises. This is the substance of an important provision in the Public Health Act, which may place occupiers under some responsibilities which have not, perhaps, been considered. Yet there is ocular evidence on the pavement day by day, opposite most greengrocers' and butchers' shops, of negligence in this matter. By the Public Health (London) Act, 1891, the City householders were relieved of this duty, which was thereupon cast upon the Sanitary Authority.

Stopping and Diverting Highways. It is the duty of a District Council, whether it be the Highway Authority or not, under the Local Government Act, 1894, to protect all public rights of way and to prevent, as far as possible, the stopping or obstruction of any such right of way, whether within their district or in an adjoining district in the county or counties in which the district is situate, where the stoppage or obstruction thereof would, in their opinion, be prejudicial to the interests of their district; and they may, for the purpose of carrying into effect the section, institute or defend any legal proceedings, and generally take such steps as they deem expedient.

Recovery of Public Rights. This section applies not merely to future obstructions or stoppages of rights of way, but to any past obstructions or stoppages which have been effected in recent times; and where there is clear evidence that the public have in past times enjoyed such rights the District Council will be entitled to take proceedings for the purpose of recovering them, or of putting an end to the obstructions. It is not necessary, however, to point out that it will not be expedient to rake up cases which have long been allowed to pass unquestioned; for, although there is no limit of time to the enforcement of public rights, there may be difficulty of proof in respect of rights which, in fact, have not been exercised for a length of time.

The Act also provides that where a Parish Council has represented to the District Council that any public right of way within the district, or an adjoining district in the county or counties in which the district is situate, has been unlawfully stopped or obstructed, it shall be the duty of the District Council, unless satisfied that the allegations of such representation are incorrect, to take proper proceedings accordingly.

Action by Public Councils. If the District Council refuse or fail to take proceedings in consequence of such representation, the Parish Council may petition the County Council of the county within which the way is situate, who are then empowered to take such proceedings as the District Council might have done. In view of this provision it will be necessary for the District Council to inquire carefully into any such case of obstruction or stoppage which is brought before them by a Parish Council, and to take action upon it, if it should be clear to them that the right of the public has been infringed. It may, however, be pointed out that the duties of a District Council are not limited to cases where they are set in motion by a Parish Council, but that, in any case where it is brought to their notice from any quarter that a footpath has been obstructed or stopped, it will be their duty to take steps to vindicate the right of the public, if fully satisfied of the validity of the claim.

These observations apply equally to bridleways as to footpaths. It not infrequently happens that the right of the public to use a way for horses is questioned, while that of its use for foot passengers is admitted. In cases of bridleways it will be the duty of the District Council to assert the right of the public to use the way for horses.

Proceedings by District Council. With respect to the proceedings to be adopted by the District Council where they are clearly of opinion that a footway or bridleway has been obstructed or stopped, there appears to be three courses open to them: (1) To direct the removal of the obstruction; (2) to indict the person who has caused the obstruction for a misdemeanour; (3) to proceed by way of action in the name of the Attorney-General, for which his "fiat" must be obtained in the usual way.

The last of these courses will, in many cases, be found preferable to that of indictment. As a general rule, however, where the public right appears to be quite clear, it will be better for the District Council to direct their surveyor to remove the obstruction to a footpath, leaving it to the person who has placed it there, if he wishes to raise a question of law, to do so by bringing an action of trespass. This course should be adopted only after due notice to the parties concerned.

Grounds for Stopping a Footpath. With respect to the legal diversion or stoppage of footpaths, it is to be observed that under the Local Government Act, 1894, the consent of both the Parish Council (or of the Parish Meeting where there is no Parish Council) and the District Council is necessary before justices in Quarter Sessions can give their sanction to such a course. The only ground on which a footpath can be wholly stopped without the substitution of another is that it is unnecessary, and this question will be for the consideration of both the Parish and the District Councils. Where it is proposed to divert a footpath, the question for consideration will be whether the proposed footpath is more commodious for the public than the existing footway [See Highway Act, 1835, 5 & 6 Will. 4, c. 50, secs. 84-92.]

The District Council may refuse their consent to the stoppage of a footpath even after the Parish Council has given consent.

Rights of Landowners. The owner of the land over which a public footpath lies has the right to maintain existing stiles or swing gates across it, provided they are of a reasonable kind, and are such that the public are not debarred from the use of the footway. But it will be the duty of the District Council to see that the use by the public of a footpath is not hindered by the erection of stiles or gates which are substantially less convenient than have existed in the past.

Now that our carriageways are being converted more or less into motor and engine tracks, the solitude of these paths forms a most pleasing contrast to the danger and flurry to which our highways are subjected, and it is a matter which reflects very severely on highway authorities that in many cases they take no steps whatever to prevent these footways and bridle-paths being closed, many of which are so overgrown with trees as to be perfectly useless.

Road Sanitation. The sanitation of roads is a question which has not received, by scientific and practical investigation, the attention as to its influence upon health demanded by its importance.

Dust from street surfaces contains bacteria generated from the excretal and other organic and vegetable matter which are more or less injurious to the throat, lungs, and eyes. The menace to health by the fouling of the surfaces of the roads of our cities and towns is an established fact, and this is now combated by scavenging and watering at a very considerable cost to the community.

In 1856 when the Metropolis Local Management Act came into operation there were no asphalt or wood-paved roads; steam-rollers were unknown, and the mud was up to one's ankles on a wet day.

Street Cleaning. The Public Health Act, 1875, contained provisions for the proper cleansing and watering of streets. The Public Health (London) Act, 1891, made it compulsory for every sanitary authority to employ a sufficient number of scavengers, or contract with any scavengers, for the execution of the duties of the authority under this act with respect to the sweeping and cleansing of the several streets within their district, and the collection and removal of street refuse.

Street sweeping by rotary brush machines drawn by horses is found to be 33 per cent. cheaper than if done by hand. It might be expected that, where streets have been paved to a very even surface with wood or asphalt, they should be kept much cleaner than they are, but the difficulty is that not only is mud and dust produced by the droppings on any particular street under observation, from the sanding that it receives to reduce slipperiness, but there is also a large amount of dirt from adjoining streets transferred by the wheels of vehicles; and in any wide-jointed paving such as granite setts, it is surprising what an amount of mud may be retained in the joints after the surface has been as effectually cleaned as ordinary processes can make it, for as soon as traffic begins to run over a road just swept, horses' feet and wheels at once begin to disturb the mud from the joints, and it soon appears as if nothing had been done to clear it.

Cost of Cleaning. Macadam must head the list as the most costly for cleansing; next to that granite paving must be placed. Very close after this comes soft wood, the disintegration of which is very rapid, and the spongy nature of its surface assists to accumulate mud. Hard wood paving can be placed at a considerable distance below soft wood, for if paved with close joints its surface is almost impervious, and it is easily cleaned. The road material costing the least for cleaning is asphalt.

Taking the whole of London within the limits of the London County Council and including the City to have just under 2,000 miles of streets, estimating the material to be removed on the present average of 980 cubic yards per mile, 2,000,000 cubic yards is removed per annum for the whole of London.

In comparing the cost of the work as done in European cities with New York, enormous discrepancies exist, but this is apparently due to the difference in wages. In Vienna, for instance, a sweeper works 10 hours for 1s. 8½d. In New York he gets 9s. 7d. for eight hours work. A mile of average streets in New York has been reported to cost—without including the treatment of snow—between £1,400 and £1,500, while in London the cost for the same work is between £240 and £260.

A large amount of the expense is accounted for by the droppings of the horse and the deteriorating influences of its hoofs.

With the introduction of motor vehicles, accumulations in centres of dense population will no longer assault our olfactory nerves and reduce our vitality by putrescent emanations, and the disintegrated fæcal matter, which is now pounded under the traffic, will no longer be distributed on the breeze to irritate pedestrians and poison exposed food-stuffs.

Maintenance. For economial and convenient traction, roads should be maintained in thoroughly good order. Roads well maintained cost less than bad roads. Experience proves that a road with sufficient strength, good surface, and thorough drainage, can be kept in first class order with a smaller quantity of material than an inferior, ill-kept road.

The cost of maintaining a macadamised road as compared with that of granite setts has been said to be as high as 5 to 1, and that this cost, if capitalised for 12 or 13 years, will equal the first expense, interest on money, and the necessary repairs for a granite-paved road.

Description of Pavement.	First cost of laying complete, per square yard.	Approximate annual cost of maintenance per square yard.	Cost of scavenging per square yard per annum.	Average Life.
	s. d. s. d.	s. d. s. d.	d. d.	Years.
Asphalt (compressed) ..	15 0 to 18 0	1 2 to 1 9	4 to 4½	18
Granite setts ..	16 0 to 17 6	5 to 9	2½ to 3	20–25
Macadam ..	3 6 to 5 0	1 9 to 3 0	10 to 12	2–3
Hard wood blocks ..	15 0 to 16 0	10 to 1 3	2 to 3	14
Creosoted deal blocks ..	9 6 to 11 0	1 0 to 1 6	2 to 3	8

The ancient method employed to meet the expenses for repairs and maintenance of the roads until after the restoration of King Charles II. was by a £1 rate on the landholders in the respective counties, and by the supply of carts and horses by parishes for a limited number of days. And in France they were, down to 1764, maintained by statute labour.

A SHORT DICTIONARY OF CIVIL ENGINEERING

See also A SHORT DICTIONARY OF BUILDING CONSTRUCTION, page 310

ABUTMENTS—Masses of masonry or natural rock, upon which the ends of a bridge are supported.

Adit—Subterranean passage or gallery.

Air-lock—Chamber with ingress and egress doors for workmen passing into workings where water is excluded by pneumatic pressure.

Ajutage—Tube fixed at the mouth of a hydraulic vessel to regulate water discharge.

Alignment—The setting of two or more planes, or three or more poles or points, in one straight line.

Alternate stresses—Stresses by which structures, or parts of structures, are placed alternately in tension and compression, as in counterbraced structures, subject to moving loads.

Anchor and Collar—Hinges employed in hanging lock gates.

Apron—A protection of concrete or other material to prevent the scouring effects of running water.

Ashlar—Blocks of stone cut to regular shapes, generally rectangular.

Attle—Any rubbish or stony matter.

BALANCE BOX—Box which counterbalances the load lifted by a crane, usually a cast-iron box loaded with small weights.

Banker—Bench or table on which masons prepare and shape their materials.

Bare—A term which signifies that a dimension is very slightly under the size preceding the term.

Barrage—The barring of a river or other watercourse to bank up the water behind.

Barring engine—An engine used for the initial turning of larger engines.

Barrow—Receptacle for carrying earth, etc.

Bascule—A bridge lifting in two leaves hinged to the abutments.

Bat—The half of a brick.

Battens—Sawn pine timber measuring not more than 7 in. by 2½ in. in cross section, or not less than 6 in. in width.

Batter—Face of a retaining wall when built in a leaning position.

Bay—In a lattice girder the space included between two adjacent apices is called a bay.

Beaumonteque (baum-antik)—Any mixture for stopping holes in stone or woodwork.

Beetle—Wooden mallet for driving small piles.

Benches—Platforms about 6 feet in width on the sides of cuttings.

Benching—Is cutting steps in the sloping surface of earth before filling-in behind a retaining wall.

Bench-mark—A recorded point in a survey, either marked on the ground or described in the field book or level book.

Berm—Narrow strip of level ground along the face of a slope.

Betty—An iron rod used as a crowbar.

Bight—The hanging loop of a chain or rope which falls below the pulleys in lifting tackle.

Block and fall—The rope tackle used in lifting heavy loads.

Bollard—Post of cast iron or timber, largely used for mooring vessels.

Bolster—Short piece of wood interposed horizontally between head of post and supported beam.

Boning Staff—Upright rod with a cross bar at right angles; used for levelling.

Bonnet—Hole formed in iron pipes and fitted with lid.

Boom—A term applied to the mast or girder of a derrick crane.

Booms—Pieces of timber connected with fender piles to protect cofferdams.

Bowstring girder—A girder in which the outward or horizontal thrust of a curved beam is sustained by a horizontal tie beam forming the chord of an arc.

Braces—Diagonal pieces used in the centre portion of a truss.

Break-up—Excavation commenced from an underground passage or gallery and carried upwards.

Breast wall—A wall at the foot of an embankment cutting off the toe, or any wall breast high.

Broach—A boring tool, employed for the purpose both of enlarging and imparting accuracy to tapered and parallel holes.

Brob—Wrought-iron spike driven into bars or sills, around the ends of props, to steady them.

CAISSON—Water-tight enclosure built up as required to surround foundations under water.

Camber—The bow or upward convexity of material to allow for sinkage.

Cantilever—A beam fixed at one end and loaded at the other end or loaded uniformly.

Cess—The space between the top of a railway embankment and the boundary fence.

Check—A joint composed of two portions, male and female, fitting one into the other, and so forming a guide or steady.

Chute—An enclosed trough which conducts the water to a water-wheel.

Cleading—Covering of planking or iron plates to strengthen tunnel sides in loose ground.

Cleat—A block of wood which furnishes a steady point of attachment for a part of a structure.

Closer—A brick cut in half longitudinally.

Coffer-dam—Water-tight enclosure of piling or of cast-iron plates bolted together; used in building piers to keep water out of work.

Continuous beam—A beam which rests on more than two supports.

Coping—A covering of impervious material on the top of a wall, or the curb at the edge of a dock.

Corbel—Short piece of wood interposed horizontally between the head of a post and a supported beam.

Counterbracing—Diagonal bracing introduced into a truss or girder for the purpose of giving additional support.

Counterfort—Projection from the back of a retaining wall, added to increase stability.

Course—A continuous range of stones or bricks, of uniform height, in a wall.

Crab—Small portable crane to raise material.

Cradle—The end girders of overhead travelling cranes which carry the running wheels.

Cramp—Metal tie used for uniting the several stones of a wall.

Creeper—Iron instrument, like a grapnel, with four claws, for dragging the bottom of a harbour or river to find anything lost.

Crib—A timber construction filled with rubble stone.

Crib work—Series of layers of logs, laid alternately lengthwise and crosswise, notched and pinned to each other at their intersections.

Cross bracing—Diagonal bracing introduced into a framed structure for the purpose of preventing lateral movement.

Crowbar—An iron rod flattened and bent at one end for use as a lever.

Crutch—Piece of timber in the shape of a bent knee.

Cuddy—Three-legged stand forming a fulcrum for lever in lifting stones or heavy weights.

Culvert—A drain carried under a road or railway.

Curb—Suitably formed ring of brickwork or cast iron at the base of a shaft, surmounting a circular orifice in the roof of a tunnel.

Cushion—Stone situated upon the top of a pier upon which an arch is built.

Cut and Cover—The operation of making a cutting, building a tunnel in the opening, and then replacing the covering material.

Cutters—Bricks of special quality for cutting to shapes.

Cutwater—Lower portion of a pier separating two arches of a bridge.

DAM—An earthen or masonry wall to retain a body of water as in an impounding reservoir.

Dead Neap—A very low tide.

Derrick—A form of crane in which the radius of the jib is rendered capable of alteration by means of chains or guys passing over the top of the mast.

Digger—Apparatus used for mechanically excavating earth, etc.

Dike—Term sometimes used in the same sense as embankment.

Distress—A beam or structure is in distress when it is subjected to undue or excessive stress, or to an amount exceeding the working stress.

Dog—Iron holdfast, or piece of round iron with the ends bent at right angles and sharpened.

Dolly—Intermediate short post of timber used in pile driving.

Double butt strips—Two covering strips employed in making a butt riveted joint, one strip being placed on each side of the abutting plates.

Dowels—Pins, either of wood or metal, used by pattern-makers to retain portions of patterns temporarily in position during the process of moulding, which portions, if firmly nailed or screwed, would prevent good delivery from the sand.

Dressing—Slopes of embankments and cuttings dressed to smooth and regular surfaces.

Drift—Small horizontal or inclined underground passage.

Drove—A narrow channel or drain.

Dumby—A floating barge connected with a pier.

EBB—The condition of a tidal river when running out. A falling tide.

Enrockment—Term applied to the stone filling upon breakwaters, banks of rivers, etc.

Extrados—The outside or upper surface of an arch.

FACE—Surface exposed by excavation in tunnelling.

Fair—Parts are said to be flush or fair when their surfaces are on the same level.

Female—The recessed portion of any piece of work into which a dowel or projecting piece fits is called the female portion.

Fender piles—Timbers placed in front of quay walls.

Fish-bellied—Girders and ribs are said to be bellied, or fish-bellied, when they are curved underneath, the depth of curve increasing towards the centre.

Fish-bolt—A bolt employed for fastening fish-plates and rails together.

Fished beams—Beams joined by fish-plates.

Fish pieces—Pieces of wood or iron connecting two pieces of a tie in a fished joint.

Flanks—The sides of an arch.

Flashes—A description of sluice.

Flitch-plate—A plate of metal bolted between two timber flitches to strengthen them.

Floating clough—Movable dam or machine used for scouring out inlets.

Floating derrick—A derrick crane placed on board a floating hull for transferring goods to and from vessels, independently of proper wharf and dock accommodation.

Flow—The condition of a tidal river when running up. A rising tide.

Fluffy—Timber is said to be fluffy when the sawdust is stringy and moist, or greasy instead of granular and sharp.

Flush—Parts are said to be flush or fair when their surfaces are on the same level.

Flush bolt—A bolt whose head is let into a recessed hole so that its top face stands level with the face of the material into which it is sunk.

Foot blocks—Flat pieces of wood placed under props to give a broad base.

Formation breadth—The width of the bed of a railway below the ballast.

Formation level—The level of a road or railway prepared for the road metal or ballast.

Four-foot—The space between a line of rails over which the traffic runs.

Full—A term which signifies that the dimension is very slightly over the size preceding the term.

Full way—A water-way is said to be full when the area of the opening in the valve or plug, as the case may be, is equal in extent to the area of the pipe.

GAD—Wedge of steel for driving into crevices or openings made by pick or chisel.

Gallery—Same as *Drift*.

Galletting—Small splinters of stone inserted in the joints of coarse masonry.

Gangway—A passage way or portable footbridge.

Gantry—The trussed beams, or girders, as the case may be, which carry the crab or crane in overhead travelling cranes; also the timber substructure.

Gibbet—The triangular framework of a crane consisting of post, jib, and strut.

Gin—A rude, portable, yet effective hoisting machine of the well-known tripod form, from whose apex the pulleys and gin-blocks for lifting are suspended for working heavy tackle. A barrel and winch are fixed between the two legs which form the shears.

Gin-block—A single-sheave pulley of a hollow-rim section, having its bearings in a skeleton frame suspended from a hook. A rope is passed over the pulley, one end of which is held by a man, the load being attached to the opposite end. There is thus no gain of power, but only an alteration in the direction of motion.

Goliath—A travelling crane supported on high trestles moving upon rails.

Grab—Machine used for excavations.

Gridiron—A simple framework of timber placed to admit of vessels being floated above it at flood tide and grounded upon it during the ebb for the purpose of examination.

Grillage—Term applied to sleepers and cross beams supporting a platform.

Groyne—A timber framework constructed across a beach between high and low water mark in order to prevent portions of the beach being washed away.

Ground moulds—A portion of the framework used in tunnelling to guide the bricklayers.

Ground square—Two straight-edged strips of board, the ends of which are so united as to form a right angle.

Grout—Liquid mortar used for running into dry joints in brick or stonework.

Gullet—Small preliminary working cutting about 15 feet wide.

Gusset—An angle-iron bracket used to stiffen an angular portion of a structure.

HAUNCH—That part of an arch between the keystone and the springing.

Header—A brick placed with its greatest length at right angles to the face of a wall.

Heading—Small horizontal or inclined underground passage driven in advance of the full-sized excavation.

Hedgehog—Machine for removing mud and silt from rivers and streams.

Heel—The thick or broad end of a wedge-shaped piece of wood or iron.

Heel post—The vertical member at the shore end of a lock-gate, with a pivot at top and bottom upon which it swings.

Hoggin—Small sifted gravel.

Hollow quoins—Cylindrical recesses in which gates of locks, etc., are hinged.

Horn plate—The upright frames in which axle boxes slide.

IMPACT—The sudden fall of a load upon a beam or structure. The deflection of beams varies nearly as the velocity of impact.

Impact wheel—A water-wheel which is driven by the percussive force of water acting at right angles to the floats and at a tangent to the circumference of the wheel. Turbines are impact wheels.

Imposed load—The load which is extraneous to a structure, and distinguished from that due to the structure itself.

Impost—A sort of capping at the top of a pier supporting an arch.

Impulsive load—A load applied suddenly to a structure. The structure is thus subject to the accumulation of energy due to the impact of the load, or that gathered in its motion, in addition to its actual dead weight.

Indifferent equilibrium—The equilibrium of a body which is neither stable nor unstable. If, when a body is moved longitudinally, the centre of gravity moves in a horizontal line, as in a sphere, the equilibrium is said to be indifferent.

Internal Stress—Stresses set up in the internal portions of castings and due to unequal contraction caused by differences in their mass.

Intrados—The under side of an arch.

Island platform—A railway platform with a track upon each side of it.

JIB—The strut or thrust member of the framing of a crane. It is always in compression.

Jib-legs—Timber legs pivoted to the jib pin of a crane. Reaching to the ground, they afford a firm and broad base to the jib when lifting, and so prevent the crane from overturning. When not in use they are shipped over the side frames.

Jim-crow—A portable rail straightener or rail bender.

Jogle—Keys of hard wood, or other material, used to resist shearing stress at the junction of two beams by being let into the surfaces, the beams being fastened together by vertical bolts in the spaces between the keys.

Journal—The portion of a rotating shaft which is in contact with its bearing.

Jumper—Long iron instrument with sharp steel point for making holes in rock or hard ground.

KENTLEDGE—The loose balance weights supplied with a balanced crane.

Key—The wedge used to fasten the rail in the chair on railways.

Keystone—Highest stone in the centre of an arch.

King post—The central upright in a roof truss against which the rafters abut, and which supports the tie beam.

King truss—A truss formed with a king post.

Knuckle joint—A joint in which an eye at the end of a rod is embraced by the forked end of a second rod, the two being connected with a joint pin.

LAP JOINT—A joint produced by the overlapping of contiguous faces of metal.

Lattice—Diagonal bracing forming struts and ties.

Lattice web—A girder web made by lattice bars, as opposed to a plated web.

Leading-frames—Framework formed to guide bricklayers in making brickwork tunnels.

Leat—Artificial channel for conducting water to water-wheels.

Lengths—Successive sections in which a tunnel is executed.

Lewis—Truncated iron wedge or dovetail, used with larger end downwards, for lifting stones by chains.

Life—Expressive of the total period during which a structure remains efficient.

Life-wall—Cross-wall of a back chamber in a tunnel.

Lining—Term applied to puddle clay reduced to a semi-fluid state, and laid along the bottom and sloping sides of canals, etc.

Lockage—Expenditure of water in passing boats from one level to another.

MALE—When a stud or a dowel fits into a recess it is said to be the male portion of that particular piece of work.

Meeting post, or mitre post—The vertical member of a lock-gate where it meets the other gate.

Metalling—Term applied to the covering of roads generally.

Mitre joint—A butt joint whose ends are cut at an angle of 45 degrees, the abutting sides therefore forming an angle of 90 degrees.

Monkey—The clip hook which lifts and releases the ram in pile driving.

Monkey-engine—Apparatus used in driving piles.

Monkey wheel—See *Gin-block*.

Mushroom—Horizontal single sheaves which act as leads for a rope to a capstan.

NEEDLE—Set of square bars of wood used for opening flood-gates in a weir.

OFF LETS—Pipes placed at the level of the bottom of a canal and fitted with sluices.

Ordnance datum—The base from which ordnance levels are measured. A mark cut on the wall at the entrance to the Mersey Docks, Liverpool. Mean half tide sea level.

Overshot wheel—A water-wheel which is turned by the gravity or weight of the water emptying itself into buckets at the top of the periphery.

PENSTOCK—A sluice or flood-gate.

Permanent load—A load which is constant and unvarying and a dead load, as the weight of a structure itself, or a load imposed thereon, or both taken in conjunction as distinguished from a live or a rolling load.

Permanent way—The road bed and rails upon which trains are run.

Pile hoop—An iron band, shrunk on the head of a pile to prevent splitting of the timber while being driven in.

Pinch bar—A bar of iron, or wood shod with iron, used to move heavy loads for short distances by "pinching" them along.

Pitch—Inclination which the sides of a roof make with the horizontal.

Polings—Planks or deal ends, by which the sides of an excavation are supported.

Proof load—A load imposed on a structure greater in amount than the working load, in order to test its capability or margin of safety. The deflection of a structure, when under its test load, is carefully noted and its capability deduced therefrom.

Props—Struts or posts, either vertical or raking, used as supports in tunnelling.

Puddle—A mass of tempered clay, to prevent the passage of water.

Punch—Same as *Dolly*.

Purlins—The members which unite the trusses of roofs in longitudinal directions.

Putlogs—Short poles used for scaffolds.

QUEEN POST—A roof member which fulfils a similar function to that of the king post, its position only being different.

RABBET, or REBATE—A shoulder or recess on the edge of a piece of wood or metal for the reception of the edge of another similar piece.

Race—Cut along which water is conveyed to and from a water-wheel.

Rail gauge—The width in the clear between the two adjacent sides of the top flanges of the rail upon railways.

Rakers—Same as *Props*.

Ram—Heavy weight dropped on to piles when they are being driven.

Ranging—Laying out the line of a tunnel.

Retaining wall—A wall to hold up a bank of earth, usually battering on the face.

SCARFING—Method of connecting ties or beams, the ends of the two pieces overlapping.

Scouring power—Stream of water employed in connection with harbours to carry away the shingle, etc., to prevent its accumulation at the mouth.

Scuttling—Method of stirring up deposits by mechanical means.

Semi-beam—A beam fixed at one end and loaded at the other or loaded uniformly.

Shearing stress—The stress to which a body is subject when force is applied to it in a direction parallel with its section. Its mean intensity is equal to the shearing force divided by the area of the section.

Shear legs—A rude but strong form of crane, having three legs or pillars of timber or iron, set leaning at an angle towards each other for supporting the lifting tackle. The gear wheels may be attached to one of the legs, or be fixed independently, and hand or steam power may be employed.

Sheet-piling—Row of timbers or piles driven firmly, side by side, into the earth.

Shoe—A cap, or socket, which receives the end of a piece of timber and which sustains the end pull of a truss rod, or takes the thrust of the legs of shears, or carries a pivot or bearing as in pillars of wooden cranes, or acts in a general way as a protection to timber ends, as in pile shoes.

Shore—Pieces of timber placed diagonally against walls, to support them.

Shoulder—That portion of a shaft or a flanged structure where an immediate increase of diameter occurs.

Sills—Strong timbers of large dimensions, placed horizontally across the line of a tunnel to support the props, etc.

Side width—The distance required from the centre line to form a road or railway.

Silt—The alluvial soil washed down and deposited on the bottom and sides of rivers by the action of the tides.

Six-foot—The space between two railway tracks.

Skew-back—Large stones cut to an angle to receive the end of an arch.

Skew-bridge—A bridge formed with an oblique arch, usually constructed with spiral courses.

Skin-dam—A dam consisting of a single row of sheeting piles of whole or half timber, with tiers of horizontal wallings or planks.

Slurry—Liquid mud or cement mortar.

Soffit—The under side of an arch.

Sough—A small drain, situated at the top of an embankment.

Span—The clear width between the supports of a girder or arch.

Spandril—The portion on the top of a pier between one arch and another.

Spider wheel—A wheel or pulley having light arms of wrought iron or steel.

Spoil, or spoil bank—The surplus material excavated, which is laid by the side of a railway or canal.

Spoon and bar—Tool used in hand-dredging.

Springing-line—The line in which the soffit of an arch intersects the pier.

Staiths—Short tongues or jetties used for coaling.

Starling—The angular form of a pier-head in bridge work.

Stirrup—A strap which supports a beam or sustains the thrust from one end of a strut.

Strain—The change of form produced in a body by a stress.

Stop-planks—A description of dam employed on canals.

Stress—When materials and structures are subjected to straining forces those forces are resisted by internal molecular actions called stresses, transverse, shearing, or torsional.

Stretcher—A brick with its greatest length placed parallel with the face of a wall.

Striking-plate—The apparatus by which the centre is lowered after the arch of a bridge has been completed.

Struts—These may be vertical or diagonal and connect a beam with a truss rod. Through them the strains due to deflection of the beam are translated into those of tension in the rod. In roof trusses those members which extend diagonally from the beam or from the foot of the king post or queen post either to the rafters or to the shoulders of the queen posts.

Surcharged wall—A retaining wall to hold back a bank of earth sloping upwards above the top of the wall.

Sump—Hole at the bottom of excavations into which water is drained, and in which the end of the suction pump is placed.

TAIL—The hinder part of a portable crane upon which the balance box rests.

Tee-irons—Rolled wrought iron bars whose section is that of a letter T. They are employed in engineering constructions such as bridges, girders, and roof work.

Teeming—Depositing earth in an embankment.

Temoin—Earth pillar left in excavations.

Tenon—A tongue projecting from the end of a piece of timber, and which, with the mortice into which it fits, is one of the common joints in woodwork.

Terring—Scotch term for soil removed in clearing the top of a quarry.

Thimble—Ring attached to a buoy.

Thirl or thirling—Meeting of workings approaching each other from opposite directions in tunnelling.

Thorough—A term applied to the heading stones forming a wall.

Thrust—The compressive force exercised by a body transmitting pressure.

Tine—An iron or steel claw used in dredging operations.

Toggle—A bar of iron or wood used to tighten a chain or rope by twisting two lines together.

Tongue—This is a short piece of metal or wood projecting from one portion of a structure and entering into another, in order to ensure steadiness and to prevent overlapping of joints.

Transom—Horizontal framing in bridge work.

Traveller—A framework carrying a lifting crab and able to travel along elevated rails.

Trenail—Wooden pins of large diameter used as fastenings for joints.

Trig station—A place where a theodolite is set up for the purpose of taking an observation.

Truss—Triangular frame in bridge and roof work.

Tunnel—A passage lined with brickwork or masonry, excavated through a hill or below the surface of the ground.

ULTIMATE STRENGTH—The load which produces actual fracture in a structure.

Underpinning—Additions and repairs to foundations and walls in which the latter are first supported by strong timber shores and needles.

VOUSSOIRS—Wedge-shaped blocks in bridge-building.

WALES—Horizontal braces.

Waling—A horizontal piece of timber used to hold vertical pieces in place either in an excavation or against a jetty.

Warren girder—A lattice girder in which the struts and ties form triangles or triangular bays, the struts leaning inwards or towards the centre of the girder, and the ties leaning outwards. A Warren girder consists of a single system of triangles, while lattice girders contain two or more systems of triangulation.

Web—The plated or central portion of a structure as distinguished from its flanges and bosses. Thus, a crank web is the plate which carries the shaft and pin bosses; a girder web is the main vertical plate which becomes the connection between the top and bottom flanges.

Weep-hole—A hole for drainage made through a retaining wall or bridge abutment.

Weir—A wall to hold back a certain head of water and allow the remainder to pass over the top.

Wrinkling—The failure of thin unstayed or improperly stayed plates, by wrinkling up or becoming corrugated under pressure.

STABILITY OF STRUCTURES

General Conditions. Beams. Bending Moments. Moment of Inertia. Rolled Joists and Girders. Shearing Stresses

By Professor HENRY ADAMS

THE varieties, characteristics, and strength of the various materials used in forming structures having been dealt with seriatim and the elements of structural mechanics explained, the stability of the structures themselves will now be considered. The subject may be approached from several distinct points of view, but the study will perhaps be facilitated by commencing with a simple beam of timber supported over an opening and carrying a load on its upper surface, as in **116**.

Strength of Beams. The width of opening beneath the beam is called the span, or the clear span, and for ordinary purposes may be assumed to be the effective span ; but the latter is more correctly taken as the distance from centre to centre of the bearing surfaces. The use by architects of the term *bearing* instead of span should be discountenanced, as the bearing is the portion in contact with the support at each end. In making investigations of stability it is convenient to eliminate all unnecessary details and to show the forces in action by lines, so that the beam may be drawn as **117**.

Concentrated Loads. The first effect of the load is to put pressure on the supports. When the load is in the centre it is self-evident that the pressure on each support, and the consequent reaction of each support, will be equal to half the load; but when the load is placed out of the centre as in **118**, it will be necessary to take it as a question of leverage. The reaction at A will be $W \times y \div L$, and the reaction at B will be $W \times x \div L$. Let $W = 5{,}000$ lb., $L = 10$ ft., $x = 6$ ft., $y = 4$ ft., then the reaction at A

$$= \frac{5000 \times 4}{10} = 2000 \text{ lb.,}$$

and at B

$$= \frac{5000 \times 6}{10} = 3000 \text{ lb.,}$$

and as the maintenance of equilibrium depends upon the vertical load being resisted by equal and opposite reactions the result is proved correct by the equation $2000 + 3000 = 5000$.

Bending Moments. The next effect to consider is the bending of the beam—not so much the actual bending, but what is called the bending moment (M), which is the measure of the effect of the load in producing stresses in the beam. This, again, is a question of leverage ; it is the reaction at one end multiplied by the distance to the load, reaction at A multiplied by x, or reaction at B multiplied by y. Thus, 2000 lb. × 6 ft. = 12000 lb.-ft., or, working from the other end, 3000 lb. × 4 ft. = 12000 lb.-ft., or 12000 × 12 = 144000 lb.-in., the accuracy being proved by the agreement of the results obtained from opposite ends.

Moment of Resistance. Opposed to the bending moment is the moment of resistance (R), or, in plain language, the strength of the beam. This is made up of the natural strength of the material, the area of the cross-section and the disposition of that area in the directions of breadth and depth. The natural strength of the material is given in the tables of strength, page 1396, as modulus of rupture (C).

Modulus of Rupture. The *modulus of rupture* is the virtual stress in pounds per square inch which the extreme fibres will bear under a transverse load. It is eighteen times the load in pounds which placed in the centre will just break a beam 1 in. square when resting on supports 1 ft. apart. If we assume the beam to be Memel fir, the modulus will be 8,000. This breaking load upon the unit beam may be distinguished as *the coefficient of transverse strength*.

Modulus of Section. The remaining elements of strength—*viz.*, the area and its disposition—are called the modulus of section (Z), so that we have the equation $M = Z \times C$. For a rectangular beam of breadth b and depth d, the modulus of section (Z) is $\frac{bd^2}{6}$, and it will be shown presently how this is arrived at. If the load be insufficient to break the beam, the value of resistance (ZC) will exceed that of bending moment (M), and the former divided by the latter will give the factor of safety, or the number of times the actual strength of the beam exceeds the strain put upon it by the load.

Assume the beam to be 6 in. wide and 12 in. deep, then

$$Z = \frac{bd^2}{6} = \frac{6 \times 12^2}{6} = 144,$$

and as $C = 8000$ and $M = 144000$,

$$\frac{ZC}{M} = \frac{144 \times 8000}{144000} = 8,$$

factor of safety. It will now be desirable to see how the modulus of section is made up. The beam in bending will have the lower portion extended and the upper portion compressed, the stresses diminishing gradually towards the centre of the depth where they disappear, and the change takes place from one kind to the other. This line of no stress is called the *neutral axis* when considering the cross-section and the *neutral layer* when considering the whole beam.

If diagonal lines be drawn upon the section of the beam, as in **119**, the horizontal line through their intersection will be the neutral axis. Bearing in mind that the extreme fibres at the top and bottom are those subject to the greatest strain and that the strain reduces towards the neutral axis, it is possible to conceive that the same total strength would result if the resistance spread over the width of each successive layer could be gathered into a narrower space, so that all the fibres within the narrowed space would be under uniform stress.

Inertia Area. This would give the effective area indicated by the shaded portion, and the fibres within it are assumed to be all equally strained. It forms what is called the *inertia area* of the beam section, and the resistances of the fibres to compression or extension may be considered as a series of parallel forces acting at their centres of gravity, shown by the dot in a circle. On the principle of couples explained in the last chapter, the area (A) of one shaded triangle represents a series of parallel forces which may be replaced by their sum, whose centre of effort is at the distance g from the neutral axis, or the *arm of the couple* will be $2g$. Then the moment of the couple, or the *modulus of section*, will be $A \times 2g$. But A by inspection

$$= \frac{bd}{4} \text{ and } 2g = \tfrac{2}{3}d,$$

therefore,

$$A \times 2g = \frac{bd}{4} \times \tfrac{2}{3}d,$$

whence, the modulus of section Z

$$= A \times 2g = \frac{bd^2}{6}.$$

Moment of Inertia. The moment of inertia (I) is very closely allied to the modulus of section (Z); it will be obtained by multiplying Z by the distance from the neutral axis to the furthest edge of section, y, so that $Zy = I$, or, as it is more generally stated, $\frac{I}{y} = Z$. The moment of inertia (I) is really the basis of the modulus of section (Z). It is made up by the summation of the quantities obtained by multiplying the area of each individual fibre by the square of its distance from the neutral axis, and although the moment of inertia enters into many formulæ, we may for the present postpone its further consideration.

Graphic Representation. With a central load, as **117**, the maximum bending moment is half the load multiplied by half the span, or $\frac{WL}{4}$, which, in this case,

$$= \frac{5000 \times 10}{4} = 12{,}500 \text{ lb.-ft.};$$

and if a triangle be drawn to scale below the beam, as in **120**, the vertical distance between the beam and the outline of the triangle will give the value of the bending moment at any point of the beam. It will thus be seen that it varies from a maximum in the centre to nil at the ends. When the load is shifted out of the centre, as in **118**, the maximum bending moment

$$= W\left(\frac{x \times y}{x + y}\right),$$

occurring directly under the load, so that the triangle of bending moments will now become as **121**.

Distributed Load. A uniformly distributed load acts as an infinite series of concentrated loads giving a maximum bending moment in the centre of $\frac{WL}{8}$, or half that due to a concentrated central load, but the diagram will now be a parabola, as **122**.

Two or More Concentrated Loads. When two loads W and W′ act upon a beam, as **123**, the maximum bending moment for each must be found separately, as shown, and the overlapping parts must be added outside to make the complete diagram, as **124**.

Partial Distributed Load. When a distributed load occupies only part of the span, as z in **125**, the triangle must be found as for a concentrated load at the centre of gravity of the distributed load $\frac{WL}{4}$, and then, dropping vertical lines from each end of the load to meet the triangle, a parabola must be set out from the line joining the points so found $\frac{Wz}{8}$. Bending moment diagrams may be drawn in a similar way for any other combination of loading, and in any beam or girder it is always the greatest depth of the shaded figure that gives the maximum bending moment, which the moment of resistance has to balance. A very simple formula for the practical use of fir beams is $W = \frac{bd^2}{L}$, where W = safe load in cwts. distributed, b = breadth of beam in inches, d = depth in inches, and L = clear span in feet. This allows a factor of safety of 7, which is a suitable one for ordinary work. Also, if w be the load in cwts. per foot super. to be allowed on a floor, and c the distance in feet between the centres of joists, bd^2 must equal cwL^2.

Use of Tables. The modulus of rupture for transverse strength is C in the formula $M = ZC$, and is given in the table on page 1396. The coefficient of transverse strength is another figure used as a substitute for the above in ascertaining the strength of beams; it is c in the formula $W = \frac{cbd^2}{L}$. It is usually given in cwts., when L is in feet, as quoted by Hurst and others. In general, $C = 18c$.

Rolled Joists. Rolled iron joists of the present pattern were first made in 1849 in

Belgium, and about 1851 in England. Similar sections in mild steel came into use about 1880, and the rolled iron joists went out of use about 1896. In 1902, the Differdange wide flange beams were introduced, and in 1903 the British Standard Sections were formulated. Within the limits of their capacity, rolled steel joists form the most perfect girder obtainable, and the disposition of the metal in the flanges and web conduces to the greatest economy of material, as well as of weight and cost.

Advantage of Flanged Beams. A flanged beam carrying a load has the same general distribution of stress as a rectangular beam, but the material is more efficiently placed. In the rectangular beam the material is uniformly disposed throughout the depth, but the stress being reduced towards the neutral axis, only the extreme fibres can be strained up to their capacity. In the flanged sections, as much of the material as possible is put at the upper and lower extremities, so that what there is of it is under nearly the maximum stress, the web being used to keep the flanges apart. Or, putting it another way, the central portion of the depth of the rectangular beam has so little leverage to resist the bending moment that it is comparatively useless, while in the flanged beam the greater part of the material has the maximum advantage in the way of leverage. The bending moments are independent of the shape of the cross-section of a beam, but, as already stated, the moment of resistance depends upon the shape and disposition of the material in the cross-section.

Principle of Flanged Beams. The strength of a flanged beam may be shown approximately in a very simple manner by a pair of "couples." The elevation of a flanged beam supported at the ends and loaded in the centre is shown in **126**. Taking the right-hand side, the couple formed by the half-load and reaction on that side, with the leverage arm of half the span, produce a bending moment of $\frac{1}{4}Wl$, with positive or anti-clockwise rotation. This is resisted by the couple formed of the tensile strength multiplied by the area of bottom flange, and the compressive strength multiplied by the area of the top flange, the lever arm being the mean depth centre to centre of flanges, producing a resisting moment of cAd or tAd. Mild steel has practically the same resistance to compression as to tension, and 8 tons per square inch may be taken as the maximum working allowance. Taking a 12 in. by 6 in. by 54 lb. per foot rolled steel joist, the sectional area of each flange is 5·22 sq. in., then the safe central load on a span of 20 ft. will be given by the equation

$$\frac{Wl}{4} = tAd,$$

or

$$W = \frac{4tAd}{l} = \frac{4 \times 8 \times 5{\cdot}22 \times 11{\cdot}63}{20 \times 12}$$

= say, 7·65 tons. A beam of uniform section will carry twice the load distributed that it will carry with the same effort in the centre, so that this joist will carry 7·65 × 2 = 15·3 tons distributed. The published tables issued by manufacturers give the strength as 16 tons, the slight difference being due to the assistance given by the web, which has not here been taken into account.

Strength by Moment of Inertia. The true strength of a rolled joist will be obtained by using the moment of inertia, in the formula

$$\frac{Wl}{8} = \frac{I}{y}C.$$

The actual section of a rolled joist is as shown in **127**, but for purposes of calculation it may be simplified to **128**. Then the moment of inertia will be

$$I = \frac{bd^3 - h^3(b - t)}{12};$$

also, it will be seen that $y = \frac{d}{2}$, and as the modulus of section $Z = \frac{I}{y}$, it will be given direct by the formula

$$Z = \frac{bd^3 - h^3(b - t)}{6d}.$$

Taking the 12 in. by 6 in. by 54 lb. rolled joist

$$I = \frac{6 \times 12^3 - 10{\cdot}25^3(6 - {\cdot}5)}{12} = 376{\cdot}5,$$

and the other conditions being as before,

$$W = \frac{8CI}{ly} = \frac{8 \times 8 \times 376{\cdot}5}{20 \times 12 \times 6} = 16{\cdot}73 \text{ tons}$$

distributed, as against 15 found by simple leverage.

The published tables of rolled joists, such as those by Dorman, Long & Co., give the exact moment of inertia, in this case 369·91, and what they generally call the moment of resistance in square inches, which is really the modulus of section (Z) in inch units. They also give a value for the distributed load in tons that 1 ft. will carry under different factors of safety. The tabular value divided by the span in feet gives the safe load in tons, and it is useful to know that with any kind of loading when the maximum bending moment in ton-feet is ascertained, eight times the amount gives the tabular equivalent. For example, in the above beam the bending moment

$$\frac{Wl}{8} = \text{say, } \frac{16 \times 20}{8} = 40 \text{ ton-feet,}$$

and 40 × 8 = 320, while the table gives 328·8; and the span being 20 ft. the tabular value 328·8 ÷ 20 = 16·44 tons safe load distributed.

Finding Moment of Inertia Graphically. The principle applied to finding the inertia area of the rectangular beam can be applied to the rolled joist. Draw the upper half of joist, above the neutral axis NA [**129**], to a large scale—full size or half full size is best. Draw horizontal lines *a-a*, *b-b*, etc., across the section wherever the direction of the outline changes. Join *a* with the centre O cutting

STRENGTH OF BEAMS UNDER VARIOUS CONDITIONS OF LOADING line *b-b* in *f*. From *c* draw a vertical line to meet *a-a* in point *g*, and join *g*O, cutting *c-c* in *h*. Draw a vertical line from *d* to meet *a-a* in *i*, and join *i*O, cutting *d-d* in *k*. From *e* draw a vertical line to meet *a-a* in *m*, and join *m*O, cutting *e-e* in *n*. Then *afhkn*O will be one half of the outline of the inertia area. Do the same on the other side of the centre line, when the complete inertia area for one half the depth will be as shown by the shaded portion. Cut this figure out and suspend it from two points to obtain the position of its centre of gravity, marked × at a distance G from neutral axis. Trace the outline of the figure by a planimeter and find its area A, of course, allowing for the scale to which the figure is drawn. Then 2DAG will be the moment of inertia of the whole section.

By experiment it is found that for the 12 in. by 6 in. by 54 lb. rolled steel joist D = 6 in., A = 6 sq. in., G = 5·15 in., then 2DAG = 2 × 6 × 6 × 5·15 = 370·8. The moment of inertia of any irregular figure can be found in a similar manner, but the neutral axis must pass through the centre of gravity of the whole section, and the inertia area found for each side separately, adding the two areas together for the final result and omitting the prefix 2.

Shearing Stresses. Before leaving the rolled joist reference may be made to shearing stresses. When a central load is carried by a beam, the shearing stress is of uniform value throughout the length, and is equal to half the load, or one of the reactions—that is to say, starting from one abutment and calling the shear positive, it retains its value unaltered until it meets the load, the load being deducted then gives a negative shear stress of the same value, ½W, as in **130**. When the load is out of the centre, the same method must be followed as in **131**. With two equal loads symmetrically placed between the abutments, as in **132**, it will be seen that the shearing stress vanishes between the loads.

With a uniformly distributed load, adopting the same general principle, the graphic diagram will appear as **132**. The flanges of a rolled joist are assumed to take the whole of the bending moment, and the web the whole of the shear stress. Generally, there is ample strength in the web, so that it is usual to omit calculation for shear, but there are cases, such as short, deep joists with heavy loads, where calculation is desirable.

The effective depth of web may be taken as five-sixths of the total depth of joist less mean thickness of two flanges—*e.g.*, in the 12 in. by 6 in. by 54 lb. joist, the mean thickness of flanges being ·87 in. each, the effective depth of web will be ⅚(12 − 2 × ·87) = 8·55 in. The thickness is ·5, making the sectional area 8·55 × ·5 = 4·275 sq. in. The maximum shear with a distributed load of 16 tons = 8 tons, and the working allowance for shear stress being 6 tons per square inch, the safe capacity of the section to resist shear will be 6 × 4·275 = 25·65 tons, against the actual maximum of 8 tons. Had the joist been only 6 ft. span, the safe load, regarding only the flange stresses, would have been $\frac{328 \cdot 8}{6} = 54 \cdot 8$ tons, giving a maximum shear of $\frac{54 \cdot 8}{2} = 27 \cdot 4$ tons, against a safe capacity of 25·65 tons, or just beyond the limit of safe strength. In such a case it would be necessary to fit a vertical angle, or tee, or even flat plate, between the flanges, and bolt or rivet it to the web just over the edge of the bearing surfaces.

Relative Carrying Capacity. The relative carrying capacity of cantilevers, beams, and girders, according to the method of loading and supporting, is shown very clearly by the illustrations **134** to **139**. The first two and last two are not well suited for timber, as it has to be built in the wall so deeply that it tends to decay from want of ventilation. The last two beams are in very much the same condition as a girder continued over several spans, the ends, at the limit of each span, being "fixed" by continuity with the next span.

Strength of Structures. The strength of structures varies as the square of the linear dimensions of similar parts, excluding the effect of weight, but the weight varies as the cube of the linear dimensions. The strength of a structure of any kind is not, therefore, to be determined by that of its model, which will always be much stronger in proportion to its size. All works, natural and artificial, have limits of magnitude which, while their materials remain the same, they cannot surpass (Lardner).

Safe Load on Structures. Common ratios for safe working load to breaking load are as follows :

Cast-iron columns Cast-iron girders for tanks Wrought-iron structures Mild steel structures	.. = ¼
Cast iron for bridges and floors	.. = ⅙
Stone and bricks	.. = ⅛
Timber under live loads ..	.. = 1/10
Timber under dead loads and temporary structures	.. = ⅕

The safe loads allowed on floors are :

Dwelling-houses ..	.. 1¼ cwt. per sq. ft.
Churches and public buildings	.. 1½ ,, ,,
Warehouses ..	.. 2½ ,, ,,

including the floor itself when of timber, but excluding it when of concrete-steel.

Continued from page 1898

COAL-DEALERS

Although not "shopkeeping" in the commonly accepted sense of the term, coal-dealing depends largely, especially in suburban neighbourhoods, on the way in which the wares are displayed. Indeed many coal offices have samples of coal neatly ticketed in their windows, and samples of stock are to be examined inside. But the relations of the coal-dealer and his clients are at first usually the reverse of those of the ordinary shopkeeper and his customer, inasmuch as the dealer goes to the customer direct to solicit his order instead of the customer coming to the shop. The coal-dealer proclaims his goods in the public street, either personally or by deputy, and the particular branch of this large and important business that we are now to consider is the small merchant—the beginner.

The Working Coal-dealer. First of all there is the man who, either by serving as carman or wharfman to a large coal merchant, has acquired a certain knowledge of the trade. He has ambitions beyond a weekly wage and a small commission, and he decides to start for himself. He has enough capital—say, £30 or £40—to buy an indifferent horse and a second-hand van, and he starts on an adventurous career with two tons of coal for which he has paid money down. This man will, of course, drive his own horse and find his own customers by the usual method of shouting his wares aloud. He will require a strong lad to help him to load and unload, and an industrious, sober man may get together a decent business. Many of the large coal businesses of to-day have been started with £40 to £60 capital, but the day of the small trader, especially in the metropolis and in large centres, is not of the present.

The Minor Capitalist. For our present purpose, perhaps it will be more useful to imagine a young man who has acquired a good all-round knowledge of the outs and ins of the coal trade, with a desire to become a coal merchant. He has been boy and wharf clerk successively to one or several big firms of coal-dealers, has kept his eyes and ears open, and has a capital of from £200 to £500. He selects a promising suburb, preferably where he is well known and where his family resides. If it be a London suburb, or the suburb of some large manufacturing centre, he will find some difficulty at the outset in getting the grant of a wharf, as it is called—a piece of ground by a railway siding—on which to store his stock of coal. In London particularly there is such competition for wharves that the railway companies have generally far more names on their list than they can supply. This makes them captious, and a new man with small capital, unless he has exceptional credentials, is passed over for the huge concerns that are ever eager for new wharves, and who may be depended upon to bring business to the yard and to pay promptly. In country districts, and especially at new stations, the reverse of this is the case. The companies are often glad to get men to use their sidings, and this is the young dealer's opportunity. The rents charged for wharves, even in London, are merely nominal; a sum of £20 to £30 a year will usually secure a wharf and an office—a box on wheels, which generally serves as the shop or office. The office should be fronting the main road to the railway-station, and should communicate at the back with the railway yard. It should be remembered that the railway companies usually lease these wharves (supposing our young friend is fortunate enough to get one), subject to termination at very short notice.

Working Necessities. The first and most expensive part of the coal-dealer's equipment is his horse. A good, sound, heavy horse should be purchased, and £40 would be a fair price to pay. The coal van, including weights and scales (which are a compulsory part of each coal van from which coals are sold retail) would cost another £30 or £40. At the wharf there must be a wooden shanty—the "men's lobby," it is called, for sheltering the workmen and for storing their tools. If there be no "lobby" already erected, a few shillings will build a new one.

A handy kind of weighing machine, known as a "Redeo," is necessary at the wharf for weighing the coals into the sacks after screening, and prior to loading the van. This costs about £4 10s., and needs "a gang" or three men to work it. Another machine called the "combined weighing machine" is largely used in the country, as one man can load and weigh with it. The sacks are simply hung on hooks, and thus a man to hold open the sacks is done away with. The sacks for this machine must be specially fitted with eyelet holes. For small businesses this machine is found very useful, and the cost is about £5 15s. Loading steps, or dolls, cost £2 10s. each; a sack barrow (used by the carman to pull back the front sacks on the van) may be bought for 10s. 6d., while a landing barrow for wharf use costs £1 10s. Other yard necessities are a 5s. tomahawk (for breaking abnormal lumps of coal, and for opening truck doors, etc.), a screen and three shovels (one for the carman and two for the yard). Bags and sacks are important items. The beginner will want at least 24 sacks, 20 1-cwt. bags, and 40 ½-cwt. bags, sufficient for a load of coal, which is usually reckoned at two tons. These sacks and bags will cost new probably about £9 10s. to £10, but they may be hired at about 35s. per month, which includes repairs. In some districts it may probably be found necessary to do a considerable amount of trolley-work if a small general shop is also kept. That is to say, a man is sent out with small orders on a hand-trolley. There may be orders for cwts. and ½ cwts., or even smaller, quantities in the poorer neighbourhoods, and it all brings grist to the mill. Some hucksters in lower working-class neighbourhoods keep coals as one of their staples, selling out to their customers in pennyworths, and those shopkeepers are likely customers to the coal merchant for ½-ton or 1-ton quantities.

Stabling for one horse may cost anything from 1s. 6d. to 3s. per week, according to locality and accommodation provided, and horse-keep in the neighbourhood of London amounts to from 14s. 6d. to 15s. per week. A new man feeling his way will work at first with a carman and a loader only. He would probably pay the carman from 21s. to 25s. per week (with perhaps 1s. commission on every ton he sells), and the loader would receive a weekly wage of 21s. or 22s. The usual practice, however, when a business is well under way, is to pay Union rates of wages to the men. Besides the workmen, either a boy (5s. or 7s. per week) or a junior clerk (12s. 6d. a week) is necessary for the office.

Yard Work. Should the young dealer be able to get into direct touch with the collieries, which is seldom, he will probably want to have a railway truck of his own. The average price of these trucks is about £70, but they may be acquired on the hire-purchase system, with payments extending over seven years. The cautious way, however, is to hire the trucks from the collieries or railway companies. Trucks may be hired at about £8 a year, including repairs. This includes painting. The disadvantage of having no wharf is shown in the fact that the railway companies insist on the trucks being cleared in six clear days—counting the day of arrival and despatch day—otherwise demurrage is charged. All the coal is "screened" before delivery to customers. This is done by the men in the yard, the small coal passing through the screen being sold separately for ballast burning or for the furnaces at large factories. After screening, each sack is weighed before being put on the van, and skilled coal-heavers are very expert, unloading a truck into vans in a surprisingly short time.

The Middleman. In the metropolis and in big provincial centres, the beginner will probably find it most advantageous to make an arrangement with some large firm of coal merchants of known repute for a steady supply. In this way he will avoid all snubbing by the lordly colliery owners, who prefer to deal with the big men, and may neglect the orders of the small buyer. By this means also the absolute necessity for a wharf may be avoided, or postponed. As a matter of fact, unless a man has a wharf of his own he *must* buy from the merchants, and, as we have already indicated, the big coal companies block the small man at every possible corner, possessing as they do all the advantages that large capital has over small. On the whole, in London at least, the small man will find many advantages in the middleman, particularly when it is remembered that the coal companies only charge the smaller dealer a matter of 1d. to 3d. per ton more than the colliery price, plus, of course, the carriage to station.

Interesting the Public. The usual method of advertising, and one which is said to bring the best results, is by house-to-house distribution of coloured cards. These are familiar to most householders, and something in that line different from other dealers is advisable. An advertisement in the local newspaper is always politic, and the name and wares of the coal-dealer should always appear on the local time-tables issued by suburban printers. Local literature, such as bandstand programmes, chair tickets (if there is a park with a bandstand in the neighbourhood), concert programmes, and such like are all amenable to the insidious instillation into the public mind that "So-and-So's nuts" are the finest and most desirable obtainable, and his prices are the lowest. A sum of £5 spent in judicious advertising of this sort gives a fillip to a new business. Moreover, the advantage of the shop window display is now becoming more and more recognised among coal owners. A matter of £15 or £20 spent in erecting an attractive office, with glass facias, gold-block lettering, and a profusion of electric lights is in itself an advertisement which compels attention.

Buying. The best time to buy largely is in June, July, and August. Then coals are at lowest summer prices, as there is less demand than at almost any period of the year. The man with a wharf or yard, therefore, should endeavour to lay in his winter stock at that time, so that he will have something to fall back on when winter prices are ruling. The prices are usually regulated by the leading merchants, or colliery agents, on the coal exchanges all over the country. The dealer has first to aim at discovering what kind of coal is likely to sell most quickly in his neighbourhood. He should not be too greedy for profits at first; the primary obligation is to please his customers, so that he may get repeat orders and, therefore, a *clientele*. And providing he has bought cheaply, judiciously, and with foresight in the summer, he may expect to reap his harvest, if prices are closely watched, between January and March.

Varieties of Coal. There are only six classes of coal necessary. These are "best silkstone," "best Derby brights," "best kitchen," "best nuts," "kitchen cobbles," and "kitchen nuts." Experience will guide the buyer in making a selection of these to suit his particular neighbourhood. If he buy from the large companies locally he will be able to select and to make his terms without much trouble. If he own a wharf travellers from the various firms will call on him regularly, and prices (usually net at one month) are easily arranged. All the collieries, excepting the Welsh, allow 2 cwt.

extra per truck, which the railway companies carry free of charge, as allowance for occasional short weights. Coke nowadays is scarcely worth dealing in, especially in the metropolis, for the gas companies charge something like 10s. per chaldron for coke to the merchant and deliver free to the actual consumer for 6d. or 1s. per chaldron more. This is a standing grievance with the coal-dealers and the gas companies, and so far as the coalmen are concerned, the game is scarcely worth the candle under present conditions.

Prices and Profits. Three factors have to be considered in order to arrive at the net price of coal. These are the price at the pit's mouth, the carriage and the waggon hire. In the following table we give (1) the kinds of coal usually sold in London ; (2) the district from which they come ; (3) the average price per ton at the pit's mouth in summer ; (4) the rate of carriage per ton ; (5) waggon hire ; and (6) net cost in London :

		Average Price at Pit.				
Best Silkstone ..	Yorkshire ..	9	0	7	2	1
Best Derby Brights ..	Derbyshire .	8	3	6	0	1
Best Kitchen.. ..	Nottingham ..	7	9	6	3	1
Best Nuts	Derby	8	0	6	0	1
Kitchen cobbles ..	Leicestershire .	7	3	5	3	1
Kitchen nuts.. .	do. ..	7	0	5	3	1

In addition to these prices the cost of loading and cartage must be added. This works out at about 4s. per ton.

In retailing, fair summer and early autumn prices would average for these kinds 24s., 23s., 22s., 21s., 18s., and 18s. per ton respectively. After deducting ordinary working expenses, an average profit of from 10 to 20 per cent. may be reckoned on house trade in a carefully-watched business. When the business is of the select class, it will probably be necessary to stock the Durham coals, known in the trade as "Wallsend," but there is not so much of this now used in ordinary trade. The original Wallsend pits were worked out years ago. "Flockton Wallsend" and "Park Hill Wallsend" obtained from collieries in the district are recognised in the trade as "best Wallsends," mostly described as "best." These are the most expensive of all.

Provincial Trade. It will be understood, of course, that the prices and conditions are modified considerably in country districts and vary according to the season and the state of the market. Expenses generally will probably be less in many parts of the country, and in towns near the colliery districts less carriage will be demanded. But, of course, retail prices are proportionately smaller, and a fair average may be worked out all over the country at the profit on capital mentioned. The Scotch and the Welsh dealers have supplies from the collieries in their respective counties. Scotland is supplied by the coal-mines in the Glasgow district, in the Lothians, in Fife, and in Ayrshire, and the pit-mouth prices are much the same as those of the English collieries. Cardiff and Swansea are the great centres for the Welsh coal trade, and an enormous quantity of sea-borne coal is exported from these ports to all parts of the world.

CORN-CHANDLERS

The development of the side line, which seems to be the unavoidable issue in every kind of modern shopkeeping, is exemplified better, perhaps, in the establishment of a corn-chandler than in any other business. The original purpose of the corn-chandler was to deal in corn, fodder, etc., for horses and cattle, but nowadays, as the windows of any corn-chandler in a town of any size will show, proprietary foods, biscuits, mustards, rices, tapiocas, and other things naturally associated with the grocer, are almost the only articles shown. These things, although probably serving as an attraction, are still subsidiary to the main business—at least, so far as profits are concerned—for the backbone of the trade is the oats, wheat, flour, hay and straw that form the unobtrusive profit makers.

Experience. The successful corn-chandler usually emanates from agriculture or from an agricultural community. The son of a farmer, or of a miller, or the scion of some family interested in agricultural pursuits, has most often the proper natural bent for the business. But experience may be obtained, and, of course, has in all cases to be obtained, preferably by serving in the busy shop of some corn-merchant in a country town or in the suburbs of a large town with an agricultural district. To make a success of it the young man must set himself diligently to distinguish between the various kinds and qualities of oats, wheats, barleys, and so forth, to learn how and when to buy, and—as a doyen of the trade has observed—"there is a great art in learning how to measure." A little too much in the scale means loss of profit to the retailer ; on the other hand, short weight in a bag of oats raises the ire of the customer, and breeds suspicions difficult to allay. The successful corn-dealer must know the kinds and qualities of beans, peas, maize, and flour ; the way to cut and mix chaffs, the weight of trusses of hay, straw, etc., and the purpose and prices of the innumerable packed proprietaries that abound in the business.

Neighbourhood and Shop. Having acquired a thorough practical knowledge of these things, a man of good character and with £200 in the bank may bethink him of starting *on his own account*. He should be careful to select, if possible, a district where there are plenty of stables. He should make it his business to get acquainted with all the coachmen, livery-stable keepers, and team owners in the neighbourhood, regarding them as future sources of profit. The shop for the man with so limited a capital would be a small one, and should have a covered yard, or a store-room in connection.

for stocks of hay, straw, and other necessities that cannot well be kept in an open shop. In the suburbs of large towns like London, such premises would probably be obtained at from £50 to £70 a year rent, but in country towns a much smaller rental would suffice, and there would be other facilities which would make it easier for the beginner. But, taking a London suburb as an example, the rent mentioned would be a fair one, and as the fittings required —a few large bins, some shelving, a counter, etc. —are not elaborate, £25 would cover the preliminary preparations for stock.

Shop Requisites. There are, however, two sets of scales necessary—one of large size for weighing sacks, and smaller counter scales and weights. The former would cost, with weights, about £5 10s., and the latter £2 10s. Another £3 would be spent on measures and scoops of various sizes. The measures used are the bushel, half-bushel, peck, half-peck, two-quart, quart, pint, and half-pint. If particularly adventurous the beginner might also invest in a chaff-cutting machine, but he will probably find it preferable at first to buy his chaff ready cut. A supply of bags to hold about two bushels is also needed for displaying stock. These may be obtained from the wholesaler who supplies the goods, but they are usually charged sixpence each, and the careful man will lay in a stock of bags for his own use, buying them from a baker at a cost of about 1s. 6d. per dozen. Then he would require 40 corn-sacks (all with his name and address stamped on the side); these would cost on an average from 7d. to 8d. each. A like number of chaff-sacks, costing about 6d. each, are also necessary. This sack business is a serious matter in the corn trade if not carefully watched. Large numbers of sacks get lost in various mysterious ways, and as there is no recognised system of charging the customer for the sack in which he gets his corn, flour, or what not, the retailer often loses money in this way during the course of the year's trading. Paper bags of different sizes for small retail sales are obtainable with name and address printed on from any wholesale stationer at a few shillings per thousand.

Stock. An opening order would include a load of hay, £3 to £3 10s.; a load of straw, £1 10s. to £1 13s.; and a load of clover, £4 to £4 4s. A ton of chaff would likewise be needed, and five quarters of various qualities of oats, the cost price averaging about 18s. per quarter, except in the case of English oats, which would probably cost £1 3s. to £1 5s. Three or four sacks of various kinds of flour would be requisite, and one sack each of barley, maize, buckwheat, darii, wheat and barley. Then the buyer would have to make a careful selection from the innumerable proprietaries on the market, which it is necessary for him to stock, especially in a populous neighbourhood. He would probably mix his own poultry food and cattle foods, but there are many well-known brands of bird foods, poultry mixtures, dog biscuits, mustards, rolled oats, self-raising flours, and so on, that are in fairly frequent demand, and £20 judiciously laid out on these lines will make a good window show and lend a prosperous appearance to a new concern. Then there are supplies of oatmeal, rice, tapioca, mustard, butter beans, haricot beans, marrowfats, peas and lentils to be thought of, all of which would consume another £10 at least. In many country businesses corn and coal dealing often go together, but the combination is rarely, if ever, seen in big towns.

Credits and Profits. It must be understood that the inception of a business such as we have sketched can be undertaken with the capital named only on strictly cash prices for retail. The retailer will not be able to give any credit to his customers until he has a larger capital and a safe business, but he will, by careful management and intelligent buying, carry on business very well on cash lines. He will have no difficulty in getting supplies, as the representatives of corn-factors and grain merchants are as numerous and as eager for business as in other trades. The usual credit given by corn-factors is one month on the market prices, but no discount is allowed except in the case of some proprietaries. In the case of the latter a discount of 2½ per cent. off cost is in some cases obtained on goods paid for on delivery. The average gross profit cannot be reckoned at more than 20 per cent. on the return. There are no arbitrarily fixed retail prices for grain, fodder, etc., and the shrewd man adapts his prices to his environment. He will, of course, keep a keen eye on the corn markets, and there are many ways in which a skilful man will increase his profits. As business progresses he will be able to buy a chaff cutter, and perhaps even a pony and trap; and an intelligent interest in the needs of his neighbourhood, a strict attention to business, and fair dealing will secure him very soon a competence, if not an independence.

Simple Brackets. Simplifying Expressions in Brackets. Multiplication of Simple Expressions. Examples and Answers to Examples

continued from page 1820

By HERBERT J. ALLPORT, M.A

SIMPLE BRACKETS

18. As already explained, an expression that is to be treated as a whole is put between brackets. If we wish to *add* the expression to some other expression, we may enclose it in brackets and put the sign + before the brackets.

Thus, $a + b + (2a - b)$ means that $2a - b$ is to be added to $a + b$. But we know that to add an expression to another, we simply write down all its terms, with their signs unchanged, after the other expression.

It follows, then, that *if a pair of brackets is preceded by the sign +, the brackets may be omitted.*

Again, if we wish to *subtract* an expression, we may enclose it in brackets and prefix the sign −. But, to subtract an expression, we write down all the terms, with their signs changed [Art. 16]

Therefore, *when a pair of brackets is preceded by the sign −, the brackets may be omitted if we change the signs of all the terms between the brackets.*

Thus, $a + b - (2a - b)$ is equivalent to $a + b - 2a + b$. For, the terms in the brackets are $+ 2a$ and $- b$, and, if we omit the brackets, we must change these into $-2a$ and $+ b$.

19. Conversely, we have

Any number of terms of an expression may be enclosed within brackets with the sign + prefixed, the sign of every term remaining unaltered.

Any number of terms of an expression may be enclosed within brackets with the sign − prefixed provided the sign of every term put between the brackets be changed.

20. In simplifying an expression which has brackets placed within brackets, it is best to begin with the innermost pair, applying the rules given in Art. 18 to the removal of each pair.

Example. Simplify the expression

$$2b - [a - \overline{2a + b} + \{b - a - (-2b + 3a)\}]$$

The expression

$$\begin{aligned} &= 2b - [a - 2a - b + \{b - a + 2b - 3a\}] \\ &= 2b - [a - 2a - b + b - a + 2b - 3a] \\ &= 2b - a + 2a + b - b + a - 2b + 3a \\ &= \underline{5a \; \textit{Ans.}} \end{aligned}$$

Explanation. The vinculum and pair of brackets ( ) contain no other brackets, so we remove these first. The sign before the vinculum is −, therefore the terms under the vinculum, *viz.*, $+ 2a$ and $+ b$, will become $- 2a$ and $- b$ when the vinculum is removed. Similarly, since there is a − sign before the brackets ( ), the terms $- 2b$ and $+ 3a$ will become $+ 2b$ and $- 3a$ when the brackets are removed. We next take the pair { }, simply having to write down all the enclosed terms, with their signs unaltered. We now remove the pair [ ], by changing the signs of the enclosed terms, since a − sign precedes the bracket. Finally, we collect the like terms.

EXAMPLES 3

Simplify, by removing the brackets and collecting like terms

1. $2a - [b - \{a - (2b + a)\}]$
2. $3x - [1 - \{3x + (1 - \overline{3x - 1})\}]$
3. $a + b - [-(c - a) + \{2b - \overline{a + c}\}]$
4. $-\{-(1 - \overline{1 + 2})\} - [2 + \{1 - (2 + 3)\}]$
5. $x^4 - \{x - 3x^3 - (x^2 + x - 1)\} - [-3 - \{-x^4 - (3x^3 + x^2 + 1)\}]$
6. $\frac{1}{2}x - (\frac{3}{2}y + \frac{1}{3}z) - \{\frac{1}{2}x + (\frac{1}{2}y - \overline{\frac{1}{3}z + x})\}$.

MULTIPLICATION

21. In Arithmetic [Art. 15] the multiplication of one whole number by another was defined to be the sum of as many repetitions of the one number as there are units in the other number. 12×5 means that we are to add together 5 repetitions of the number 12. We saw, however, on reaching fractional quantities [Art. 82] that we had to put the definition in another form, *viz.*, to multiply one number by another we do to the one what we do to the unit to obtain the other. Thus, if we multiply 3 by 4, the definition states that since 3 is $1 + 1 + 1$, therefore, 3×4 is $4 + 4 + 4$.

By means of this definition we can find a meaning for multiplication by a negative quantity. Suppose we wish to multiply 3 by −4. To subtract 4 is the same as subtracting four units in succession, *i.e.*,

$$-4 = -1 - 1 - 1 - 1.$$

Hence, by definition, to multiply 3 by − 4, we must subtract 3 four times in succession, *i.e.*,

$$3 \times (-4) = -3 - 3 - 3 - 3 = -12.$$

Similarly, we can multiply − 3 by − 4.

For

$$-3 = -1 - 1 - 1.$$

Therefore,

$$\begin{aligned} (-4) \times (-3) &= -(-4) - (-4) - (-4) \\ &= +4 + 4 + 4 \text{ [Art. 18]} \\ &= +12. \end{aligned}$$

We can proceed in the same way with any other quantities, whether whole numbers or fractions, positive or negative. Hence, we see that

(i.) $a \times b = ab$,
(ii.) $a \times (-b) = -ab$,
(iii.) $(-a) \times b = -ab$,
(iv.) $(-a) \times (-b) = +ab$.

These four results are usually stated thus: *Like signs give +, unlike signs give −.* This is the *Law of Signs.*

22. It was proved in Arithmetic that $4 \times 5 = 5 \times 4$, and that $\frac{3}{5} \times \frac{4}{11} = \frac{3 \times 4}{5 \times 11}$. But $3 \times 4 = 4 \times 3$, and $5 \times 11 = 11 \times 5$. Hence

$$\frac{3}{5} \times \frac{4}{11} = \frac{4 \times 3}{11 \times 5} = \frac{4}{11} \times \frac{3}{5}.$$

Therefore, for *positive* values of a and b, whether a and b are whole numbers or fractions, we have

$$a \times b = b \times a.$$

But the result of Art. 21 showed that the *absolute* value of the product is independent of the signs, so that $ab = ba$ is true for *all* values of a and b, positive or negative.

It easily follows that

$$abc = a \times b \times c = (a \times b) \times c$$
$$= (b \times a) \times c = b \times a \times c = bac.$$

In the same way we get $abc = acb$, and so on. Hence, *the factors of a product may be taken in any order.* This result is called the *Commutative Law.*

23. From our definitions of *power* and *index* we have

$$a^3 = aaa \text{ and } a^4 = aaaa$$
$$\therefore a^3 \times a^4 = aaaaaaa = a^7 = a^{3+4}.$$

Again,

$$5a \times 3a^2$$
$$= 5 \times a \times 3 \times a \times a$$
$$= 15aaa, \text{ since the factors can be taken in any order}$$
$$= 15a^3 = 15a^{1+2}.$$

Thus, *the index of the product of two powers of the same letter is equal to the sum of the indices of the factors.*

This result is called the *Index Law.*

24. Making use of the law of signs, the commutative law, and the index law, we are now able to find the product of any *simple* expressions, *i.e.*, expressions which contain only one term.

Example 1. Multiply $4x^2y$ by $3x^4y^2$.

$$4x^2y \times 3x^4y^2 = 4 \times 3 \times x^2 \times x^4 \times y \times y^2, \text{ by the commutative law}$$
$$= 12x^{2+4}y^{1+2}, \text{ by the index law}$$
$$= \underline{12x^6y^3} \textit{ Ans.}$$

Example 2. Multiply $7xyz^2$ by $-2x^2y$.

$$7xyz^2 \times (-2x^2y) = -(7xyz^2 \times 2x^2y), \text{ by the law of signs}$$
$$= -7 \times 2 \times x \times x^2 \times y \times y \times z^2, \text{ by the commutative law}$$
$$= -14x^{1+2}y^{1+1}z^2, \text{ by the index law}$$
$$= \underline{-14x^3y^2z^2} \textit{ Ans.}$$

We see, then, that the result can be written down at once, without putting down all the steps shown above. We (i.) write down the sign of the product; (ii.) multiply together the numerical coefficients; (iii.) write each letter that occurs, the index of its power being found by adding the indices of that letter in the factors.

Example 3. Find the continued product of $-3a^2b$, $2bc^3$, and $-4ac$.

$$(-3a^2b) \times 2bc^3 \times (-4ac) = \underline{24a^3b^2c^3} \textit{ Ans.}$$

In determining the sign, we see that the sign of the product of the first two terms is $-$. The sign of the product of this result and $-4ac$ will therefore be $+$.

EXAMPLES 4

Multiply

1. $4a^3$ by $7a^6$.	5. $-11ca$ by $-4ab$.
2. $-3x^3$ by $-4x$.	6. $2a^4b^6c$ by $-abc^3$.
3. xy by $-2xy$.	7. abx by bcy.
4. $3abc^3$ by $-2a^4c$.	8. $5cx$ by -4.

Find the continued product of

9. $4ab, -3ca, 5bc$.
10. $-a^3bcx, 2b^2x^2, 3ac$.
11. $-x^2yz, -y^3z^2, -x$.
12. $6byz, -4c^2xy, 2bz^2, ax^2$.

If $x = -2$, $y = 3$, $z = 0$, $a = -1$, find the value of

13. $2ax^2y$.
14. $5a^2y^3$.
15. $3xy + 4y^2z - 5a^3$.
16. $(2x + 3y)^2 - 3(a^2 + z^2)$.
17. $2ax - \{3x^2y - \overline{4xyz - a^3}\}$.
18. $\sqrt[3]{6ax^2y^2}$.
19. $\sqrt[3]{\frac{a^2 + xy}{5x^3}}$.
20. $\sqrt{6ax^3y} + \sqrt[4]{12a^2x^2y^3}$.

Answers to Algebra

EXAMPLES 1

1. $3a^2 = 3 . 3 . 3 = 27$ *Ans.*

2. $4abc^2 = 4 . 3 . 1 . 2 . 2 = 48$ *Ans.*

3. $a^3 + b^3 + c^3 - 3abc = 3^3 + 1^3 + 2^3 - 3 . 3 . 1 . 2 = 27 + 1 + 8 - 18 = 36 - 18 = 18$ *Ans.*

4. $\frac{a + b - c}{a + c - b} = \frac{3 + 1 - 2}{3 + 2 - 1} = \frac{2}{4} = \frac{1}{2}$ *Ans.*

5. $\frac{1}{2}a^2b^2c^3 - \frac{1}{3}a^3bc = \frac{1}{2} . 9 . 1 . 8 - \frac{1}{3} . 27 . 1 . 2 = 36 - 18 = 18$ *Ans.*

6. $\sqrt{2x^2 + 3y^2 + 4z^2} = \sqrt{2 . 36 + 3 . 9 + 4 . \frac{1}{4}} = \sqrt{72 + 27 + 1} = \sqrt{100} = 10$ *Ans.*

7. $\sqrt[3]{\frac{3xy}{z^2}} = \sqrt[3]{\frac{3 . 6 . 3}{\frac{1}{4}}} = \sqrt[3]{3 . 6 . 3 . 4} = \sqrt[3]{3^3 . 2^3} = 6$ *Ans.*

8. $\sqrt{x + y} . \sqrt[3]{x + 4y^2 + 7z^3} = \sqrt{6 + 3} . \sqrt[3]{6 + 4 . 9 + 7 . \frac{1}{8}} = \sqrt{9} . \sqrt[3]{6 + 36 + \frac{7}{8}} = 3 . \sqrt[3]{42\frac{7}{8}} = 3 . \sqrt[3]{\frac{343}{8}} = 3 . \frac{7}{2} = 10\frac{1}{2}$ *Ans.*

9. When $x = 3$, $x^2 - 7x + 12 = 9 - 21 + 12 = 21 - 21 = 0$. When $x = 4$, $x^2 - 7x + 12 = 16 - 28 + 12 = 28 - 28 = 0$. When $x = 5$, $x^2 - 7x + 12 = 25 - 35 + 12 = 37 - 35 = 2$.

10. $(ad + bc)^2 - 2(2a^2 - 3b^3) + (c^2d - 2b)^2 = (0 + 2)^2 - 2(32 - 24) + (0 - 4)^2 = 4 - 16 + 16 = 4$ *Ans.*

EXAMPLES 2

1. $ab + cx + bc$.	6. $-x^3 - 8x^2y + 5xy^2 - y^3$.
2. $-2x^3 - x^2 + x + 2$.	7. $-\frac{1}{4}a - \frac{7}{12}b + \frac{3}{4}c$.
3. $\frac{1}{2}x - y + \frac{1}{2}z$.	8. $-7a^4 + 3a^3 + a^2 + 3a - 4$.
4. $-2ax^2 - 2a^2x$.	9. $x^3 + 4x^2 + 2x - 2$.
5. $2ab - 3cd + 4bd$.	10. $4 - 3y - 4y^2 + 5y^3$.

NOTE. The answer to Examples 12, No. 2 (page 886), should read as follows: $21{\cdot}923636 - 9{\cdot}3893 = 12{\cdot}534297702743247$.

THE MAKING OF FELT

Varieties and Uses of Felt. The Needs of the Industry. Felt Wools and their Treatment. Felting Machines and their Operation

By W. S. MURPHY

FELT is a cloth which is not woven; felting may be described as the short cut to cloth manufacture. If all our fabrics were made by felting, we should have no spinning, no warping, no weft, no weaving. Felt cloth has neither warp nor woof; it is a solid layer of wool. Compare a piece of felt with a piece of woven cloth. Break up the structure of both, and note the differences between them. From the woven cloth threads come away from other threads with which they have been woven. In some cloths the combination of warp and weft has been so cunningly formed that we can separate them with difficulty; but, ultimately, they come apart as two sets of threads.

Distinctive Properties of Felt. If the felt be of good quality, you will not be able to fray it in the way the woven cloth has been done; but by pulling hard and perseveringly you get away something. It is not thread, but a little tuft of wool, with fibres irregularly displayed all round it, and the cloth shows a ragged hole. One peculiarity of felt is that you may break it, or cut it, but it can never be opened out. The fibres combine in ways designedly irregular, twining and twisting in all directions. Each fibre is warp and weft in one. Examining the tuft riven out, we see how the crinkled fibres of wool cling and mingle, the edges of the one holding on to the edges of the other. When studying the structures of wools, we noted the serrated edges characteristic of true wool. Useful in the making of yarns and threads, this quality is indispensable to the felt-maker. Whatever may be the quality of the wool used for making felt, it must possess that characteristic. Crinkling, curling wools are the best wools for the felt-maker; if they are also soft, lustrous, and sound, so much the better.

Varieties of Felt. Few fabrics have so wide a range of usefulness as felt. It enters into many departments of life. First, we view it as a headdress. The turban of the East seems to have been originally a mass of fine wool beaten so as to fit the shape of the head, and protect it from the rays of the sun. Thence sprang felt caps, bonnets, and hats. [See HAT MANUFACTURE.] Another original felt was the blanket robe, of which the Roman toga was a refined survival, and the heavy robes of the American Red Indian actual examples. It is practically certain that the tent cloths of our nomadic ancestors were made of felted wool, and when the nomads settled down the fabric became mats for the floors and hangings for the doors of the dwellings. On these three lines the felt industry has developed—headdress, body apparel, and household garniture—ever growing with the expanding needs of civilised life.

Dress Felts. Leaving out for the moment the felt-hat industry, which is dealt with elsewhere, we look at the felts used in wearing apparel. Men do not use a large variety of felts. About the latter end of the nineteenth century, when an attempt was being made to break away from the prevalent sombreness of male attire, some fine felt coatings in various colours were put on the market, and enjoyed a short run of popular favour; but the dress reform movement died out, and the felt coatings passed out of fashion. For some classes of heavy overcoats, however, used principally by 'bus drivers, coachmen, and others working in all weathers, felt is largely used.

For the finer classes of felts the fair sex are good and constant customers, though fashion in the past favoured it more than at the present time. Felt drapes better than any other kind of heavy fabric, and hence it is a favourite material for riding habits, winter walking-skirts, long winter cloaks, and heavy jackets.

Household Uses. Foremost among the household uses for which felt is made comes the carpet. For one thing, felt carpets are cheap; a high quality can be produced at less cost than an inferior quality of woven carpet. They are artistic, easily laid and lifted, soft to the foot, and wear well. On the other hand, felt carpets lack the solidity and richness of the Brussels or Wilton, and do not imitate so closely the merits of the highest class of carpet as do the tapestry carpets.

Carpet felts perform a humbler, but not less useful, function than felt carpets. These are plain felts, generally of the natural colour of the wool, for laying under fine carpets and costly rugs. As a pad and protection, the felt is highly serviceable, and a very large trade is done in that line.

As a material for hangings and draperies, felt is greatly in demand. Still higher, and calling for more artistic ability, are the tablecloths, sofa rugs, mantel, and other draperies, made of felt, which have to compete with the fine products of the higher fabrics. Felt has a peculiar merit of its own for these purposes, having a fine, soft richness, combined with plainness, very attractive to the artistic eye.

Industrial Uses. Being in such demand as a household fabric, felt naturally comes into the hands of the upholsterer, and is utilised by him for all kinds of drapings, hangings, and coverings. Some of our very best work is done

felt manufacturers, therefore, found it advisable to send their goods over to the Rossendale district of Lancashire, across the hills, where the dales are saturated with rain and intersected with rushing streams, there to be bleached, or dyed, or printed.

For a considerable period this division of labour worked very well; but when the railways began to cut into the lonely vales of East Lancashire, skirt round the mouths of the deep valleys, and even cross the wildest of them, a new spirit awoke. It occurred to one dyer and printer that wool might be as easily felted at Waterfoot as at Leeds, and the whole process carried through on one spot. The saving in carriage was something, the lower cost of living for the operatives another thing, and, in addition, and most important, the delays and inaccuracies inevitable in the best system of transit were wholly obviated.

The Centres of the Felt Industry. What happened was inevitable. By force of economic gravity the industry was drawn from Leeds into Lancashire, till Whitewell Vale and the neighbouring dales changed from lonely seats of isolated dyeing and printing establishments into scenes of busy manufacture. From Rawtenstall up to beyond Waterfoot the valleys are studded with felting factories, the works and the villages straggling for miles in every direction. In the higher classes of fine felts Leeds still enjoys a fair share of the trade, and Lancaster keeps hold of the old baize-cloth manufacture for which it made an enviable name in days gone by; but the bulk of the felt industry is carried on in the deep, rocky valleys which lie amid the hills bordering Lancashire and Yorkshire.

Outsiders may not see much difference between having raw material and goods carried to the factory and goods being taken to and from the finishers; but practical men know the difference.

In the first place, we have the stoppage of the process in mid-career, so to say, and the loss of impetus entailed in making a new start. Next, there are the repeated packings and unpackings. Add the accidental delays, entailing sometimes the loss of a day or more, and you have a fair idea of the disadvantages the Leeds felt-maker, who sent his goods to be dyed and printed in the Rossendale Valleys, had to combat.

As a rule, only one carding is given felting wools, and the sliver-forming apparatus is conspicuously absent. Instead, the carded wool is drawn off in the filmy web made by the doffing blade and wound round a roller. Felt wool never takes the form of a thread, not even such a remote semblance of a thread as a sliver.

Felt Wools. For making heavy felts and carpets we use large quantities of the short, crisp, and deeply-serrated wools of the East Indies. Carpet manufacturers of all classes find these wools almost indispensable; carpet weavers, as well as carpet felters, use them largely. Looking only at the low counts to which they can be spun, the inexperienced buyer might expect to buy them at his own price, but the market quickly clears his mind of that delusion. Harshness is certainly a characteristic of the Indian wools, and partly on that account, partly on account of the comparative costliness of the material, it is seldom used pure, except for special purposes. Some of the home wools, such as Highland, Blackface, and the coarser Leicesters, make a very good mixture with them, for either felts or carpet yarns. Nearly all the British wools felt well, and may be used pure or mixed, according to the kind and quality of wool felt designed.

We are about to touch on a matter regarded with some bitterness by many felt-makers, and even resented as a false imputation, though we have not been able to discover any reason for the feeling, nor any felting establishment where the imputation, if such it be, could be truthfully denied. Roughly put, the fact is that felt-makers utilise wools found unsuitable by worsted cloth manufacturers. This may sound a little harsh, but look at the facts. Weavers of high-class worsteds, broadcloths, and serges cannot utilise the higher sorting numbers of even fine merino fleeces. From No. 11 to 14 the wool is absolutely useless to them, and yet it is good and dear wool, useful in its way. What can they do but sell it, if they can find a market? The wool is sold, and it is bought by wise felt makers, who have fine felts to make.

Noils. These wools are specially remarkable for high felting quality—that is to say, the material is better than even the wools designated the raw material of the felt manufacturer in the wool market. But this does not wholly describe the debt of the felt industry to worsted manufacture. In studying the combing process, we saw that a refuse called noils was left after the sliver had been formed. This remainder was carefully collected, not only to clear the combs, but for other purposes. We hesitate to call noils refuse, though rejected. The wool had already been selected by experts and put in the class of fine combing wools; but these fibres were rejected for one fault only—*viz.*, shortness. Comparatively little noil comes into the open market; as a rule, it is either utilised in another department of the factory or supplied by contract to a woollen cloth, a hosiery, or a carpet manufacturer, if the felt maker is not smart enough to pick it up.

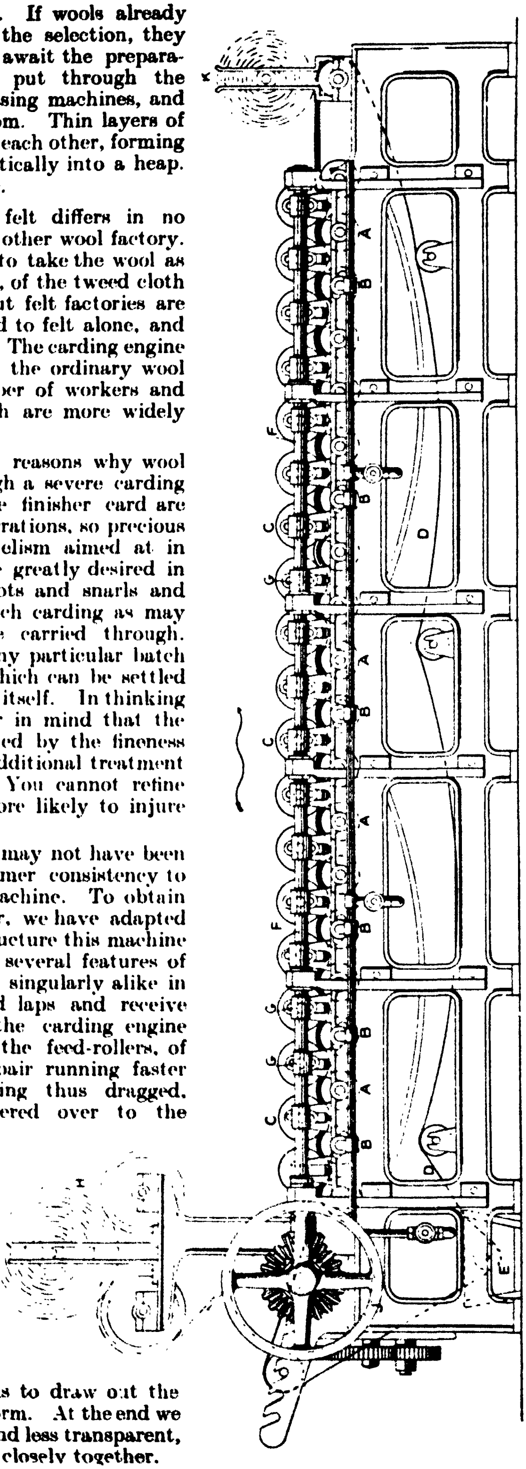
Perhaps the fact which felt-makers most desire to conceal is the function the industry plays to the sorting departments of the woollen factories. There are certain parts of the fleece which it would not pay to spin into yarn, but which make good felt. These wools are therefore bagged and sold to the felt-maker, but we can see nothing derogatory in that. On the contrary, we think it a noble act to make good felt out of what were otherwise waste material.

Preparatory. In felt manufacture the end of the process is designed from the beginning. Whatever may be the product aimed at—habit cloth, blanket, carpet, or paper-making felt—when we select the wool from the stores, we have it in mind, and make the selection accordingly. Once the process has begun, there is no turning back, no correcting of error, except at great cost of time, labour and thought. If wools already prepared, such as noils, are included in the selection, they are sent on to the mixing room, there to await the preparation of the raw fibres. The latter are put through the scouring, drying, opening, burring, and teasing machines, and arrive, white and fluffy, at the mixing room. Thin layers of each material are piled horizontally above each other, forming a stack ; then the whole is raked down vertically into a heap. Now it is ready for the carding machine.

Felt Carders. Carding wool for felt differs in no essential respect from the carding in any other wool factory. Indeed, it would be quite good practice to take the wool as it comes from the first carder, or scribbler, of the tweed cloth manufacturer, and make it into felt. But felt factories are usually individual establishments, devoted to felt alone, and the machines naturally take special forms. The carding engine of the felt-maker is generally larger than the ordinary wool carder, and equipped with a greater number of workers and strippers ; sometimes, too, the card-teeth are more widely set, and do not slant so sharply.

Limit to Carding. There are two reasons why wool designed for felt should not be put through a severe carding process. First, the keen teeth of the fine finisher card are apt to tear away the imbrications, or serrations, so precious to the felt-maker. Secondly, the parallelism aimed at in the higher carding processes is not to be greatly desired in felting. Of course, we want all the knots and snarls and little mats to be taken out, and as much carding as may be necessary for that purpose must be carried through. What amount of carding is needed for any particular batch of wool is a purely practical question, which can be settled only on the spot and in view of the stuff itself. In thinking out that question, the worker should bear in mind that the fineness of the felt is primarily determined by the fineness of the wool of which it is composed, and additional treatment affects the ultimate result very little. You cannot refine coarse wool by fine carding ; you are more likely to injure it and reduce its value.

Scutching. The mixing of the fibres may not have been thorough, and we may wish to give a firmer consistency to the wool before laying it on the felting machine. To obtain a finer mixture and bring the fibres closer, we have adapted the scutcher to our need. In its main structure this machine is simply the cotton scutcher, but it has several features of its own. Feed end and delivery end are singularly alike in appearance ; the reason is that we feed laps and receive laps. The filmy laps are taken from the carding engine and hung in tiers of four in front of the feed-rollers, of which there are two pairs, the second pair running faster than the first, or outermost, pair. Being thus dragged, the wool is torn asunder, and delivered over to the beaters revolving within the machine over the slanted or curved grid, dropping out the remaining dust and rubbish. Underneath stretches a moving lattice, inclined up towards the lapping rollers. Blown flat upon the lattice by the exhaust fans, the wool is carried forward to the lapping rollers, similar in action to those of the cotton scutcher, but revolving more rapidly, or, being larger in circumference, having a quicker surface speed. The object of the lap machine, in the present instance, is to draw out the wool to its former fineness, but in a firmer form. At the end we have again four webs, or laps, but thinner and less transparent, because the fibres have been pressed more closely together.



74. SIDE ELEVATION OF ROLLER FELTING MACHINE. (Wm. Bywater, Leeds)

Making the Finest Felts. This method produces the very finest of felts; those laps could be formed into felts as fine as the finest calico. It is not often we are called upon to make felts of that quality, however. But the scutcher, or *bat-engine*, as it is named in the felting trade, can be adjusted to form laps as thick or as thin as may be required. Lower the speed of the lapping rollers by a half, and we get a lap equal in thickness to two of the four fed in at the beginning; make the speeds equal, and the lap will be equal to all four put together. Add to the number of carded laps, and the thickness will be greater; slacken the draft of the lapping rollers till it becomes negative instead of positive, and the lap grows correspondingly thick.

The Common Batt Frame. We have already hinted that present-day practice tends towards shortening the felting process. In 73 we show one of the latest methods of forming what is called the "batt," or thick sheet to be felted. By this method, the wool is formed into a sliver on the second carder, and run direct on to the batt-forming frame. From the scribbler, the wool comes on to the feed sheet A of the second carder, and passing through, comes out on the doffing roller, B, to be formed into the sliver C. Round the rollers of the batt frame, E, runs an endless canvas web, D, driven from the carder by the belt F. Upon the web the sliver travels round and round, gathering layer on layer, till a thick sheet is formed and wound on the rollers, G, whence it is made into the roll, or batt, H, and ready for the felting machine.

Felting. Anybody can make a piece of felt. Take a handful of damp wool, spread it out in a thick layer on a board, and knead it together with the hands. After a short time, the fibres which were formerly a loose mass will be found combined into a flat cake of wool more or less coherent. By diligent practice and experiment, careful observation of the manner in which the fibres act under the rolling pressure of the hand, and acquirement of the deftness in adjusting the pressure needed, one might make a piece of real felt. Our privately made felt would not be of much use; but the experiment is useful, as teaching the primary basis of a very important industry. Advance a step further. The early felt-makers used a mallet and a piece of raw hide in the following way. Spreading the heap of washed wool on a flat stone, and covering it over with the hide, the felter beat upon the wool with the mallet. The hide gave an obliquity to the strokes, which the worker aided by giving it a rolling movement. Between the strokes of the mallet and the rubbing movement, the wool was spread flat and wrought together in quite a wonderful manner, forming an even piece of cloth. We have no need to go back to such primitive methods; our wool is already formed into a fine, flat web; but our aim is just the same as that of the early felt-maker with his stone, raw hide, and mallet, and if he could produce good felt, as he did, surely we may hope to achieve that purpose too.

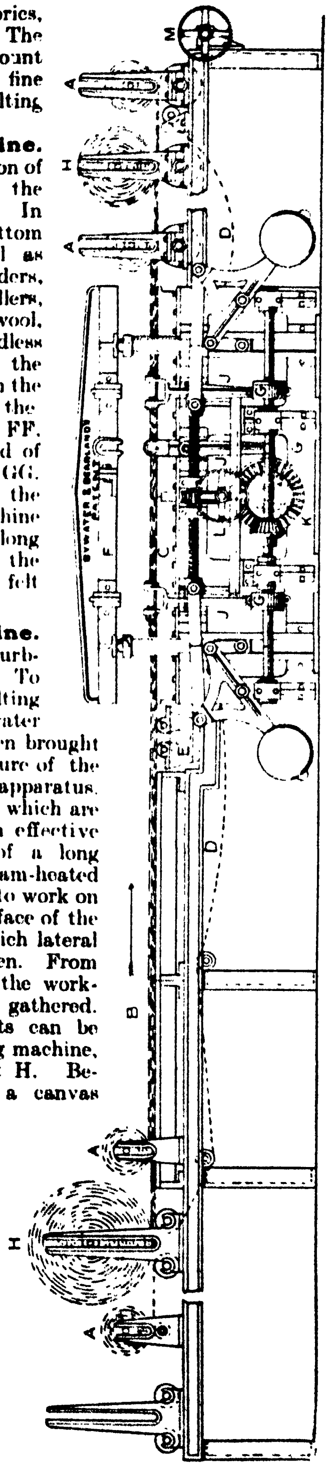
A Simple Machine. One of the simplest machines in the felt factory is the water felter. A shallow trough, nearly full of warm water, heated by steam coils laid along the bottom, forms the main body of the machine. At one end are the feed-rollers, and geared within the sides of the trough are two sets of rollers, the under set being wholly submerged in the water, and the upper set merely touching the surface. The submerged rollers are hollow tin or copper cylinders, filled with steam, and those above are heavy wood rollers. It is important to note the relative positions of the rollers. The upper set do not lie directly above the lower set, but each wooden roller rests between two cylinders, touching the sides rather than the tops of the cylinders. The gearing of the rollers is also peculiar. The sockets of the spindles are movable, and geared on an eccentric apparatus which imparts to them a backward and forward motion. Naturally, a roller slung on these sockets is bound to have a transverse action, no matter at what speed it may be run. These are the main features of the machine, and, having got a fair notion of the structure and mechanism, we are ready to work it.

Working the Water Felter. The web of wool is slung on the end of the machine, and the end gently led forward by the endless web of canvas, falls on a cylinder, which bears it round to meet the heavy wooden roller revolving on the inner side of the cylinder. Roller and cylinder turn in the same direction, but the motion is slow, and the upper rollers have a transverse action, caused by the oscillating sockets on which they are slung. The revolutions of the rollers draw the canvas web and the wool forward on to the next cylinder. The wool is not only held firmly and pressed by the cylinder, but the oscillating movement rubs the fibres together, causing them to combine in the closest unity. The warm water, by softening and slackening the fibres, causes them to cling together, and aids in the felting process. Through from three to six pairs of felting rollers the wool passes, growing firmer and more consistent, and what was once a soft web issues a fine, solid piece of felt. Few manufacturing processes are so quickly effective as this. No matter what has yet to be done to it, this is a veritable fabric, and might well be worn as a blanket by an Indian, or used as a bed-mat by any civilised person. It is cloth. Wound on to a beam through squeezing rollers, which press out the water, the felt is now ready for further treatment.

Though a very simple machine, some care is required in the working of it. For one thing, felts are not all of one thickness, and the setting of the cylinders and rollers determine what thickness the felt is to be. Another fact to be noted is that wools have a limit to their capacity for refinement in felting just as in yarn. Indian wool cannot be spun to a higher count than 10's and produce sound thread; neither is it wise to attempt producing a very fine felt with that wool. The felt-worker may be led to fancy he does not need to study the yarn capacities of wool, but this is a mistake. The same principle governs all fabrics, whether woven or felted. The wool which spins to a high count of yarn will also felt into a fine cloth—that is, if it be a felting wool.

Roller Felting Machine. Fig 74 shows the side elevation of a roller felting machine of the most modern construction. In this machine there are bottom rollers of iron, AA, as well as steam-heated copper cylinders, BB, to support the wooden rollers, CC, pressing down upon the wool, which is borne on the endless sheet, D, passing through the water trough, E, and between the two sets of rollers. One of the eccentric shafts is denoted by FF, and the eccentrics at the end of each roller are shown by GG. Controlled by two rollers, the sheet H descends into the machine beside the driving pulley, J, along the endless web, D, through the felting rollers, emerging as felt at K.

Table Felting Machine. Roller felting produces a disturbing effect upon the wool. To obviate this, a flat table felting machine, known as the Bywater & Beanlands patent has been brought into use. The principal feature of the machine is the flat felting apparatus. It is composed of two plates, which are wrought upon the felt in an effective manner. Over the trough of a long machine is placed a flat, steam-heated table, and above it, set so as to work on whatever may be on the surface of the table, is an iron plate, to which lateral and transverse motion is given. From 75 a good general notion of the working of this machine may be gathered. As many as six batt sheets can be felted on the flat table felting machine, though only one is shown at H. Between each layer of wool a canvas sheet, A, would be put to keep them separate. But here we have the felt being formed into one thick fabric. Over and under the tables, an endless web, D, is run through the trough of water, E. The first table, B, first receives the wool on to its steam-heated and moist surface, and then, moistened and heated, the sheet passes on to the hardening table, C. Above the table is the hardening plate, F. By means of the pulley, L, the plate is raised or lowered, and the transverse and lateral motions are given to the top hardening plate by the eccentrics, GG, and the connected levers, JJ. K is the driving shaft and pulley for the top plate, and M is the pulley which winds up the sheets. The action of this machine is alternate and automatic. When the felting has continued for the prearranged time, the top plate lifts; the felted portion moves onward, and a fresh portion of batt comes into place to be felted. As soon as the fresh piece is measured out, the top plate descends, and the felting begins again. In this way absolute uniformity of texture is secured.



75. TABLE FELTING MACHINE. (Wm. Bywater, Leeds)

Sulphuric Treatment. Low-class felts are sometimes mixed with flax or other vegetable fibres, but the higher grades are made absolutely free from all such matters. Even very good wools, as we know, are not always wholly free from burrs and other vegetable matters. In very fine felts, especially those which are dyed, the presence of even minute burrs would be highly inconvenient. To render that accident impossible, the felts are subjected to a bath in a weak solution of sulphuric acid. This process, while mechanically simple, calls for the utmost care, because one of the actions of sulphuric acid, if left unchecked, is the destruction of the felting property of wool. The solutions supplied to the trade, however, and the methods which have become traditional in practice, render that danger almost non-existent in the hands of the careful worker. Taken from the bath, the felt is thoroughly cleared of the acid by washing, and it is then in condition for further preparation.

Carpet felts, felts for linings, for builders, and many other industrial and domestic purposes, are allowed to retain their natural colour. Carpets, draperies, habit cloths, and all the higher classes of felts, are variously dyed and printed in colour and pattern. [See DYEING; also CALICO PRINTING.] Felt is finished in the same way as many other fabrics. The methods and machinery used in the finishing of textile fabrics are studied in a later stage of this course.

COOKERY RECIPES

Methods of Preparing, and Ingredients for, Various Puddings and Sweets, Savouries, Sauces, and Salads

COOKERY
continued from page 187.

PUDDINGS

Winchester Pudding

INGREDIENTS. Three ounces of rice, one pint of milk, a quarter of a pound of raisins, three ounces of candied peel, two eggs, two ounces of suet, a little lemon rind, a dust of nutmeg.

Method. Wash the rice well, put it in a pan with the milk, and let it cook very slowly (with the lid on the pan) till all the milk is absorbed. Stone and chop the raisins, also chop the peel and suet. Mix all these ingredients together, and add the sugar, rind, and nutmeg. Have ready a buttered basin, put in the mixture, cover it with a piece of greased paper, and steam it gently for two hours. Turn it on to a hot dish, and serve with it any nice sweet sauce.

Apricot Cream

INGREDIENTS. Half a pint of cream, half a pint of apricot purée, one ounce of leaf gelatine, one teaspoonful of lemon juice, a little jelly, two ounces of castor sugar.

Method. Rinse out a pretty mould with cold water, then coat it all over with clear wine or lemon jelly. Rub the contents of a small tin of apricots through a sieve. Melt the gelatine in a gill of water, then add to it the sugar and lemon juice. Whip the cream till it will just hang on the whisk. Strain the gelatine, etc., into the purée, and lastly add the cream, stirring it in very lightly; if liked, add a few drops of cochineal to it. Pour it into the mould, and leave it till set. Then dip the mould into tepid water, shake it gently, and turn the cream on to a pretty dish.

Peaches may be used instead of apricots.

Fruit Tart with Short Crust

INGREDIENTS. Two pounds of plums, four tablespoonfuls of sugar, three tablespoonfuls of water, half a pound of flour, six ounces of butter, lard, or dripping, half a teaspoonful of baking-powder, a pinch of salt.

Method. Wash and stalk the plums, half fill the pie-dish with the fruit, then put in the sugar, and lastly the rest of the fruit, piling it up as it will sink when cooked; pour in the water. Sieve together the flour, salt, and baking-powder; next shred and rub in the butter, then add enough cold water to make it into a paste. Roll it out on a floured board to the shape of the dish, but slightly larger. Cut off a strip the width of the lip of the dish; wet the pie-dish, put on the strip of pastry, brush that with water, then put on the lid, pressing the edges together. Crimp the edges neatly. Bake the tart in a quick oven for about three-quarters of an hour.

Any fruit may be used in the place of plums, but the amount of sugar must be varied according to the kind of fruit.

Plum Pudding

INGREDIENTS. One and a half pounds of chopped beef suet, one pound of breadcrumbs, one pound of currants, one pound of raisins, one pound of sultanas, one pound of mixed peel, one pound of brown sugar, half a pound of almonds, a quarter of a pound of cornflour, two nutmegs, four lemons, ten eggs, one gill of brandy, one gill of milk.

Method. Clean and prepare the fruit, and chop it finely. Mix all the dry ingredients together. Beat up the eggs, add the brandy and milk, and stir these into the dry ingredients, mixing them well. Put the mixture into well buttered moulds, and cover them with scalded and floured cloths; put them in a pan of fast boiling water, and let them boil steadily for ten hours. Keep them in a cool, dry place till they are required.

Orange Fritters

INGREDIENTS. Two or three oranges, castor sugar, four ounces of flour, one gill of tepid water, one tablespoonful of salad oil, the whites of two eggs, a pinch of salt.

Method. Sieve together the flour and salt. Make a hole in the middle of the flour, and stir into it smoothly the oil and water. Beat the whites of the eggs to a stiff froth, and add them lightly to the batter. Let the batter stand while the oranges are being prepared. Peel them, remove all the pith, and divide them into sippets. Have ready a deep pan of frying fat; when a bluish smoke rises from it dip the sippets of orange in the batter, and then drop them into the fat, and fry them a pretty golden brown. Drain them well on paper. Sprinkle over them castor sugar, and serve them piled up on a lace paper.

Any kind of fruit may be used, such as apples, apricots, or peaches.

Pineapple Soufflé

INGREDIENTS. Three ounces of flour, two ounces of butter, half a pint of milk, the yolks of three eggs and the whites of four, three ounces of tinned pineapple.

Method. Melt the butter in a pan, stir in the flour smoothly, add the milk, and stir the mixture over the fire till it forms a ball in the pan; then add to it a dessertspoonful of pineapple syrup, and stir it over the fire for a minute or two. Then separate the yolks and whites of the eggs, add the yolks one by one to the mixture, with the sugar, and the pineapple cut into neat dice. Whip the whites to a very stiff froth, then stir them very lightly into the mixture. Pour it into a buttered soufflé mould, which has a band of buttered paper tied round it coming four inches above the top. Lay a piece of buttered paper across the top of the band, and steam the soufflé gently for one and a half hours. Then turn it out, and pour round the pineapple syrup, which should first be made hot.

Ginger soufflé is made in the same way.

Wine Jelly

INGREDIENTS. One and a quarter pints of hot water, half a pint of sherry, half a pound of loaf sugar, two ounces of leaf gelatine, the shells and whites of two eggs, three lemons, one inch of cinnamon.

Method. Put all the water, wine, sugar, and cinnamon into a clean, bright steel or enamel pan. Pare the lemons thinly, add the rinds and the strained juice to the other ingredients. There should be a quarter of a pint of juice. Next put in the gelatine, and lastly wash the egg shells, crush them small, and add them; whisk the whites of the eggs stiffly, and add them also. Put the pan over the fire, and whisk with an egg whisk till the contents begin to boil. Take out the whisk and let the mixture boil up to the top of the pan. Draw the pan to one side, put on the lid, and let it settle for ten minutes. While it is settling, turn a chair upside down on the kitchen table, tie a clean glass-cloth to the legs, place a basin under the cloth. Pour some boiling water through the cloth to heat it; empty it out of the basin, then gently pour the jelly into the cloth. When a little has run through, slip another basin in the place of the first, and put the jelly back into the cloth to re-strain it. Continue re-straining it until it is quite clear, then pour it into a mould which has first been rinsed out with boiling water then with cold. If liked, the mould can be set with any kind of fruit.

Apple Amber

INGREDIENTS. Two pounds of apples, three ounces of Demerara sugar, the rind of one lemon, three eggs, an ounce of castor sugar, a quarter of a pound of any kind of pastry, and some glacé cherries.

Method. Peel, core, and slice the apples, put them in a saucepan with the sugar and the grated rind of the lemon. Let them stew gently till they are tender, then rub them through a sieve. Roll out the pastry and lay a strip of it round the top of the pie-dish, having first brushed the dish with a little water. Separate the yolks and whites of the eggs, beat up the yolks, then add them to the apple pulp; pour this mixture into the dish; ornament the border with little stars of pastry, which should be brushed with water before being laid on. Bake it in a moderate oven for about fifteen minutes. Meanwhile, beat the whites of the eggs to a very stiff froth, heap it up roughly over the top of the pudding, sprinkling it as you do so with castor sugar. Decorate it with a few glacé cherries. Put it in a cool oven till the meringue is set and just slightly tinted.

Banana Trifle

INGREDIENTS. Eight bananas, eight sponge cakes, one lemon, half a pint of cream, half a pint of milk, two eggs, castor sugar, raspberry jam, angelica, and a few glacé cherries.

Method. Peel the bananas and cut each in four. Cut each cake in four, and make the pieces up into little sandwiches with the jam. Put the milk in a pan on the fire and bring it to the boil; beat the eggs, pour the milk on to them, sweeten the custard to taste. Pour it in a jug, put the jug in a saucepan with boiling water to come halfway up it. Stir it over the fire till the custard thickens; it must not boil or it will curdle. Let it get cold. Put a layer of the cake in a glass or silver dish, pour over some custard, next put a layer of bananas, then a little grated lemon rind; then more cake and custard, and so on till all the ingredients are used. The trifle should be as dome-shaped as possible. Lastly, pour on the rest of the custard. Whip the cream, flavour and sweeten it to taste, then heap it roughly all over the trifle. Decorate it prettily with glacé cherries and shreds of angelica.

Peaches, apricots, pineapples, or oranges may be used in the same way.

Meringues

INGREDIENTS. The white of four eggs, half a pound of castor sugar, cream, and a little salad oil.

Method. First, prepare the board—if you have no special one, use an ordinary pastry one—brush it over slightly with salad oil, then cover it with a piece of foolscap paper; brush this also over with oil. Separate the yolks and whites of the eggs, putting the whites into a large basin. Sieve half a pound of fine castor sugar. Whisk the whites of the eggs to a very stiff froth, then stir in the sugar as quickly and lightly as possible with a wooden spoon. The mixture is now ready for shaping. Choose two dessert spoons the same size, fill one with the mixture, then with the other scoop it neatly out on to the prepared board. They should have an egg-like appearance. As they are shaped put them on the board an inch from each other Put the board in a very cool oven for them to dry slowly; they must be only tinted the palest straw colour. They will probably take about an hour. Lift them carefully off the board with a knife, turn them over, press the soft part inside the shells very gently with the finger. Put a clean piece of paper on the board, put the meringues on it with the underside uppermost and dry that also. They are then ready. They will keep any length of time in a tin box. Do not put in the cream till just before they are wanted. Whip the cream stiffly, flavour and sweeten it to taste, fill each half, then press them together. Pile them up on a glass dish and serve.

Pancakes

INGREDIENTS. Four ounces of flour, half a pint of milk, one egg, a quarter of a teaspoonful of salt, one lemon, lard for frying.

Method. Put the flour and salt in a basin and mix them well; make a hole in the centre of the flour, pour in two tablespoonfuls of milk and the egg, and stir them with a wooden spoon round and round. Add more milk, until all the flour is mixed in and half the milk is used, then beat it well with a wooden spoon till the surface is covered with bubbles; next add the rest of the milk, and, if possible, let the batter stand for an hour. Melt about two ounces of lard in a small pan; have ready a small frying-pan, pour about a teaspoonful of the melted lard into it, and when a faint smoke rises, pour in enough batter to thinly cover the bottom of the pan. Fry till it is a golden brown underneath, shaking it gently now and then to make sure it is not sticking, then toss it over and fry the other side. Slip the cake on to a piece of sugared paper, taking care to lay the side that was first fried on the paper. Shake over a little castor sugar and a squeeze of lemon juice, roll up the pancake neatly, and keep it hot while the others are being fried. Serve them as quickly as possible garnished with slices of lemon.

A Salad of Fruits

Ingredients. A small tin of apricots or peaches, a small tin of pineapple chunks, three bananas, two oranges, half a pound of black grapes, one ounce of pistachio nuts, the juice of a lemon, castor sugar to taste, one small bottle of white wine.

Method. Peel and slice the bananas, peel the oranges, and scrape off all the pith ; then divide them into sippets and cut each sippet in two or three pieces. Cut the pineapple and apricot into dice. Blanch, shell, and shred the pistachio nuts. Put all the fruits in a salad bowl, strain in the lemon juice, add the wine and sugar to taste. Cover the bowl, and let the salad stand an hour. Serve it as cold as possible.

In summer leave out the pineapple and add instead a quarter of a pound each of raspberries, red currants, strawberries, and cherries.

SAVOURIES

Croûtes à la Parisienne

Ingredients. A small jar of German caviare, green butter, anchovy butter, two or three slices of bread an eighth of an inch thick.

Method. Stamp the bread into small rounds with a plain cutter, and fry them a pretty golden brown in butter. Let them get cold. Next, arrange a small heap of caviare in the centre of each round. Pipe round it a border of anchovy butter, and lastly, round the edge of the croûton, pipe a border of green butter. Arrange the croûtons on a lace paper.

The anchovy butter is made by mixing together two boned anchovies, two ounces of butter, and a dust of cayenne. These are rubbed through a sieve and coloured prettily with a few drops of anchovy essence.

Green butter is made by boiling three handfuls of spinach, draining it well, and pressing it through a sieve ; the fluid is then mixed with two ounces of butter, a teaspoonful of chopped parsley, and salt, pepper, and lemon juice to taste. It should be a pretty shade of green.

Stuffed Olives

Ingredients. Slices of white bread, a small bottle of stoned olives, anchovy paste, anchovy butter.

Method. [For anchovy butter see Croûtes à la Parisienne.] Stamp out small rounds of bread with a plain cutter, and fry them a pretty brown. Let them cool, then spread a thin layer of anchovy paste on each croûton. Place a stoned olive in the centre ; fill the centre of each olive with some anchovy butter, and put a neat border of it round the edge of each croûton. Put a tiny sprig of parsley on each olive. Arrange the croûtons on a lace paper.

The croûtons should be about an inch and a quarter, or less, across.

Hatelets de Fromage

Ingredients. One ounce of semolina, half a pint of milk, salt and pepper, two yolks of raw eggs, one ounce of Parmesan cheese.

Method. Boil the semolina in the milk till it is thick enough to stand alone, season it with pepper and salt. Then add to it the yolks of two eggs and the Parmesan cheese ; stir the mixture over the fire for a minute or two to cook the yolks. Spread the mixture on a plate ; it should be half an inch thick. When it is cold, stamp it into rounds, with a cutter the size of a shilling. Cut half a pound of Gruyère cheese into rounds the same size, place these rounds alternately on a short skewer, beginning and ending with the cheese ; there should be three rounds of cheese and two of semolina on each. Brush these over with beaten egg, and cover them with white crumbs, then fry them a pretty golden colour in hot fat. While they are hot, draw the skewers out carefully Pile the hâtelets upon a hot dish, and serve them at once.

Cheese Custard

Ingredients. Two ounces of grated Parmesan cheese, one ounce of grated Gruyère cheese, two whites and three yolks of eggs, salt and cayenne to taste, one and a half gills of cream.

Method. Beat the eggs together without frothing them, then whip the cream and add it, also the cheese, salt, and cayenne to taste. Be sparing with the salt, as some cheese contains so much Well butter a soufflé case, and put in the mixture—it should come about half way up. Place the case in a baking tin with water in it, and bake it in a quick oven till it is just set and a delicate brown. Serve it at once or it will sink.

Devilled Prawns

Ingredients. Two or three dozen prawns (according to size), a little flour, cayenne, two teaspoonfuls of chopped parsley.

Method. Shell the prawns. Toss them lightly in the flour. Put them in a frying basket and shake off all the loose flour. Have ready a pan of deep frying fat ; when a bluish smoke rises from it, plunge the frying basket into the fat and fry them a nice brown. Drain them on kitchen paper. Dust them over with cayenne, sprinkle the parsley over them, and serve them on a lace paper garnished with cut lemon and parsley. Shrimps and whitebait can be treated in the same way.

Cheese Aigrettes

Ingredients. A quarter of a pound of flour, one ounce of butter, half a pint of cold water, two eggs, three ounces of any stale cheese, cayenne.

Method. Put the flour on a tin in the oven for a few minutes, to dry it, then pass it through a sieve. Put the water and butter in a pan and bring them to the boil ; then throw in the flour, and stir this mixture over the fire until it will leave the sides of the pan clean. Let it cool slightly, then add the eggs, one by one, beating them well in. Grate the cheese finely, and add it with some cayenne, and, if necessary, a little salt as well. Spread the mixture on a plate to cool. *Have ready on the fire a pan of deep* frying fat—it is best to wait till a faint bluish smoke rises from it—then take it off the fire to cool slightly. Now take a teaspoonful of the mixture, drop it into the fat and let it fry a golden brown. Drain it on paper. When all are fried, serve them very hot, sprinkled with cheese. They may be re-heated in the oven, and will keep a long time in a tin box.

SAUCES

Bread Sauce

Ingredients. Half a pint of milk, two cloves, half an ounce of butter, two tablespoonfuls of bread-crumbs, one small onion, salt and pepper.

Method. Peel the onion, then stick the cloves into it. Put the milk, onion, and cloves into a saucepan on the fire. While it is boiling, rub some stale bread through a sieve till you have two tablespoonfuls. When the milk boils, sprinkle in the crumbs; add half an ounce of butter, and let it all simmer gently for about ten minutes. Season it nicely to taste. Take out the onion and cloves, and serve the sauce in a hot tureen.

Bearnaise Sauce

Ingredients. Four shallots, one gill of white sauce, three ounces of butter, half a gill of tarragon vinegar, half a gill of malt vinegar, three eggs, one teaspoonful of chopped chervil and tarragon, salt and pepper.

Method. Chop the shallots finely, put them in a saucepan with the vinegars. Boil these with the lid off the pan till they are reduced to half, then add the white sauce [see Melted Butter Sauce], whisking it all the time till it is very hot; add one by one the yolks of the eggs, whisking them in briskly. On no account let it reach boiling point Next draw the pan to the side of the stove and whisk in the butter a little at a time till all is used. Strain the sauce through a fine strainer, add the tarragon and chervil, reheat it very gently, then serve it in a hot tureen.

German Sauce

Ingredients. Two yolks of eggs, a glass of sherry, castor sugar to taste.

Method. Put all the ingredients into a small saucepan and whisk them quickly over a slow fire till the mixture is all froth. On no account must it be allowed to boil, or it will curdle. Serve it at once.

Melted Butter Sauce

Ingredients. One and a half ounces of butter, one ounce of flour, three quarters of a pint of either milk, milk and water, or milk and stock.

Method. Melt the butter in a saucepan, stir in the flour smoothly, then add the liquid a little at a time; stir it over the fire till the sauce boils well and thickens.

Having once made the foundation, a great variety of sauces may be made with slight additions.

For plain melted butter, add salt and pepper.

For sweet melted butter, add sugar.

For parsley sauce, add two teaspoonfuls of chopped parsley.

For caper sauce, add two teaspoonfuls of capers.

For anchovy sauce, add two teaspoonfuls of anchovy essence.

For shrimp sauce, add a gill of picked shrimps.

For onion sauce, add two large onions (chopped).

For egg sauce, add one or two hard-boiled eggs.

Tomato Sauce

Ingredients. Half a pound of tomatoes, one onion, one carrot, a small bouquet of parsley and herbs, a few bacon trimmings, half a teaspoonful of cornflour, salt, pepper, and castor sugar, one gill of stock or water.

Method. Peel and slice the carrot and onion, put these in a saucepan with the bacon, and fry them gently; slice and add the tomatoes, also the herbs. Stir these over the fire for a few minutes, then pour in the stock, bring it to the boil, and let it boil for twenty minutes, or till the vegetables are tender. Next rub all through a sieve, put the sauce back in the saucepan, make it quite hot, add the cornflour mixed with a little cold water and salt, pepper, and sugar to taste. This is a delicious accompaniment to chops, steaks, and grills of all kinds.

Brown Sauce

Ingredients. One small carrot, one small turnip, one small onion, two ounces of butter or beef dripping, one and a half ounces of flour, one pint of stock, salt and pepper.

Method. Wash and prepare the vegetables and cut them into thin slices. Melt the butter in a saucepan; when it is quite hot, put in the vegetables and fry them a good brown. Next, shake in the flour and fry it a pale brown. Now add the stock, or water with a little meat extract will do. Stir all together till the sauce boils, then draw the pan to the side of the fire and let it simmer gently for half an hour. Skim it well. Strain out the vegetables, and season the sauce carefully. Half a glass of Marsala would be a great improvement, but it is not necessary.

SALADS

French Salad

Ingredients. Three lettuces, one endive, a handful of young dandelion leaves, one teaspoonful each of chopped thyme, mint, and parsley, two hard-boiled eggs, one small beetroot, salad dressing.

Method. Wash the lettuces, endive, dandelion leaves, and parsley. Pull them into convenient-sized pieces. Mix them all together in a salad bowl. Garnish with the eggs and beetroot, cut in slices, and hand with it some good salad dressing.

Beef Salad

Ingredients. Half a pound of cold beef, a small beetroot, a quarter of a pound of tomatoes, two lettuces, two hard-boiled eggs, a clove of garlic, one gill of salad dressing.

Method. Cut the meat into long thin shreds. Wash and prepare the lettuces. Skin the beetroot, and boil the eggs for fifteen minutes. Next cut the eggs, beetroot, and tomatoes into dice, and the lettuces into small pieces. Mix half of the lettuce with all the other ingredients. Press the mixture into a pudding basin which has been rubbed over with the garlic, leave it for a few minutes, then turn the basin downwards on a glass or silver dish. Give it a gentle shake and lift the basin carefully up, leaving the salad behind. Arrange the rest of the lettuce leaves in a border round, and, if liked, decorate with a few slices of tomatoes.

PRACTICAL SOLID GEOMETRY

Solids in More Difficult Positions. Sections made by Vertical, Horizontal, and Inclined Planes. True Shapes of Sections

Group 8

DRAWING

14

Continued from page 1796

By WILLIAM R. COPE

Solids with Sides Inclined to Both Horizontal and Vertical Planes

453. A Cube, Standing on One Edge, with its Vertical Faces Inclined to the V.P. at 35°, and its Sloping Faces Inclined to the H.P. at 45°. First draw the plan and elevation when the vertical faces are parallel to the V.P., as in **421**. Turn the plan thus found so that hf makes 35° with XY, and project to meet the parallels from $a'b'c'd'$ for the elevation.

454. A Cube, when the Plane of One of its Faces is Inclined to the H.P. at 35°, and at Right Angles to the V.P. Draw the plan $aBCD$ when the cube stands with its face in the H.P., and project the points of this face to XY. Draw $a'c'$ at 35° with the H.P. (*i.e.*, with XY), and rotate B' and C' into it, thus obtaining b' and c'. Draw perpendiculars to $a'c'$ at a', b', and c', making them each equal to BC (an edge of the cube). Join e' and g', which completes the required elevation. Draw projectors from a', b', c', e', f', g', to meet horizontals from a, B, C, and D, for the required plan.

Additional Projections from the Same Plan. Very often different views of an object from other standpoints are necessary to explain its true form. These views may be easily obtained by *changing the position of the intersection line* XY instead of drawing a fresh plan; and much time and labour is thereby saved. Problem **453** might be solved in a similar manner as explained in **455**.

455. A Rectangular Prism with a Square End in the H.P., and One Face Parallel to the V.P. Also Draw a Second Elevation when One of its Vertical Faces makes an Angle of 30° with the V.P. First draw the square $abcd$ for the plan as shown, and project from it for the elevation $a'b'f'e'$. Then draw $X'Y'$ at 30° with XY (as if XY were turned until it made 30° with its original position—*i.e.*, at 30° with the original V.P.). Projectors from $abcd$ perpendicular to $X'Y'$ will give the required second elevation as shown. The heights $a''e''$, etc., are the same as $a'e'$, etc.

456. An Equilateral Triangular Prism with its Ends Parallel to the V.P. and One Rectangular Face in the H.P. Also, a Second Elevation when the Axis is Inclined at 60° with the V.P. First draw the triangle $a'b'c'$ for the elevation, and project from it for the plan. From this plan draw projectors (for the second elevation) perpendicular to $X'Y'$, which is at 60° with XY, or with the V.P. The line $f''c''$ is the same height from $X'Y'$ as the point c' is above XY.

457. A Hexagonal Prism with One of its Sides in the H.P., and its Ends Parallel to the V.P. Also, a Second Elevation when the Axis is Inclined at 45° with the V.P. Proceed as in **455** and **456**. Begin with the regular hexagon $a'b'c'd'e'f'$.

The Circle, Cone, Cylinder, and Sphere

458. A Circle in a Plane which is Vertical and Parallel to the V.P. The elevation is the circle $a'b'$, and its plan the line ab, projected as shown.

459. A Circle in a Vertical Plane which is Inclined to the V.P. at 50°. For the plan draw ab at 50° with XY, upon it describe a semicircle, and divide it into any convenient number of equal parts (say four) at C, D, and E. Draw perpendiculars from C, D, and E, to meet ab in c, d, and e, from which draw projectors perpendicular to XY. Make $c'c'$ equal to ab, and bisect it by a horizontal line for the points a' and b'. Set off a distance equal to eE or dD on each side of $a'b'$ to obtain the points e', e', d', and d'. Draw the ellipse through the points thus obtained, which completes the elevation.

460. A Cone, Lying with its Side in the H.P., and its Axis Parallel to the V.P. First draw the plan and elevation when standing upright with the base in the H.P. Then $ABbC$ is the plan, and $A'F'b'$ the elevation. Rotate the latter, so that $b'F'$ is on XY and the point A' at a', then $a'b'f'$ is the required elevation. Project from a', b', c', f', to meet horizontals from A, B, C, and F, for the plan.

461. A Cylinder, with its Axis Inclined at 20° with the H.P. and Parallel to the V.P. Also, Another Elevation when viewed from the Left at Right Angles to its Original Position. The elevation is an oblong $a'b'c'd'$ with $a'b'$ inclined at 20° with XY. For the plan, describe a semicircle on $a'c'$, divide it into, say, four equal parts, and draw parallels to $a'b'$ through each division, to meet $a'c'$ and $b'd'$ in e', f', and g'. From each of these points project perpendiculars to XY to intersect bc and the other lines drawn parallel to XY, and thus obtain the ellipses as in **459**.

For the *side elevation* draw $V'P'$ perpendicular to XY, for the side elevation of the V.P. Place $a''d''$ (the centre line) as far from $V'P'$ as bc of the plan is from XY. Also place $e''g''$, etc., similarly. This is best done by taking P' as centre and rotating the points as shown by curved dotted lines to meet XY. Draw perpendiculars from these points in XY to meet the horizontals from first elevation. Complete as shown.

462. A Cone, with its Base Inclined at 60° with the H.P., and its Axis Parallel to the V.P. Also, a Second Elevation when the Axis is Inclined at 45° with the V.P.

and its Base, as before, 60° with the H.P. Draw $a'b'$ at 60° with XY and equal to the diameter of the base. Bisect it in c', draw $c'f'$ perpendicular to $a'b'$, and equal to the axis or height of the cone. Join $a'f'$ and $b'f'$. Then $a'b'f'$ is the elevation. For the plan, describe a semicircle on $a'b'$, and divide it as before. Draw a centre line af at a convenient distance parallel to XY. Draw projectors from a', b', c', d', e', f', set off the ordinates on both sides of af, and draw the ellipse and sides of the cone.

For the second elevation, draw $X'Y'$ at 45° with XY, and project perpendiculars to $X'Y'$ from each point in the plan. Draw $c''c''$ parallel to $X'Y'$, and the same distance from it as c' is above XY. Each of the points a'', d'', etc., is respectively the same distance from $X'Y'$ as a', d', etc., is above XY. Complete as shown.

463. Two Spheres, whose Radii are as 3 : 1, Lying in Contact with Each Other on the H.P., and the Line Joining their Centres being Parallel to the V.P. Draw one circle (say, the smaller) on XY for the elevation of one sphere. Draw its vertical diameter, and produce it so that Ab' is equal to the sum of the radii of the two spheres. With b' as centre and $b'A$ as radius, describe an arc Aa' to cut a horizontal line drawn at a distance from XY equal to the radius of the other (larger) sphere, in the point a'. With a' as centre describe another circle for the elevation of the other sphere. For the plan draw projectors, and complete as shown. The line ab must be parallel to XY in this case.

Sections

An architect often wishes to show the internal construction of a building; or an engineer the inner works of a machine. To represent this we must imagine the building or machine to be cut through by a vertical or horizontal plane, and a drawing made of the cut or *section*. This drawing would indicate the position, arrangement, and thickness of the walls, floors, etc.; or similarly the parts of the machine.

It is usual to represent the section or cut part of the object by a series of parallel lines making an angle of 45° with the intersecting line XY.

Care should be taken to distinguish between the *sectional plan and elevation* and the *true shape* of the section. The *sectional plan* is the appearance of the object when viewed vertically from above, and the upper portion removed; the *sectional elevation* is the appearance when viewed horizontally forwards, and the front part removed; the *true shape of the section* is seen when the section is looked at perpendicularly to the plane of section. Sometimes a part of the portion removed is indicated by dotted lines for clearer explanation.

Sections made by Vertical Planes Parallel to the V.P., or by Horizontal Planes Parallel to the H.P

464. Given the Plan $cfde$ of a Cube Cut by a Vertical Plane ab, Draw the Sectional Elevation. Project from c, f, d, e, for the elevation, making $c'c'$, etc., equal to the edge of the cube, and join. From a and b draw projectors to the elevation for the section, and $a'a'b'b'$ is the section or cut part. In this case, as also in Problems **465** to **468**, the *true shape* of the section is shown, because we are supposed to be looking perpendicularly at the section.

465. The Elevation of a Sphere Cut by a Horizontal Plane $d'e'$ is Given. Draw the Sectional Plan. Project from c' the centre, and from a' and b' the ends of the horizontal diameter through c', to c, a, and b, and describe the outer circle for the plan. From d' and e' draw projectors to meet ab in d and e. With c as centre and cd as radius describe the inner circle for the section.

466. The Plan of a Hexagonal Pyramid is Given, and is Cut by a Vertical Plane hk. Draw the Sectional Elevation. Draw projectors from each point, fix g' at a height above XY equal to the height of the pyramid, and join the points. For the section draw projectors from h and k to meet XY in h' and k'. Join $h'g'$ and $k'g'$, then $g'h'k'$ is the sectional elevation.

467. The Plan $abcd$ of a Cylinder is Given, and is Cut by a Vertical Plane ef. Draw the Sectional Elevation. Draw projectors and obtain the elevation of the solid. To obtain the width $e'e'$ or $f'f'$ of the section, draw a semicircle on ad, then eg is half the width of the section. Set off $a'e'$ equal to eg on either side of $a'b'$ to obtain the points e', e', f', f'.

468. The Elevation $a'b'c'$ of a Square Pyramid is Given, with one of its Triangular Faces in the H.P. and its Axis Parallel to the V.P. It is Cut by a Horizontal Plane $d'e'$. Draw the Sectional Plan. Draw af at any convenient distance parallel to XY, and project from a', b', and c', for the plan, making cg and bh each equal to $b'c'$, an edge of the square base. For the section draw projectors from d' and e', then $ddee$ is the sectional plan.

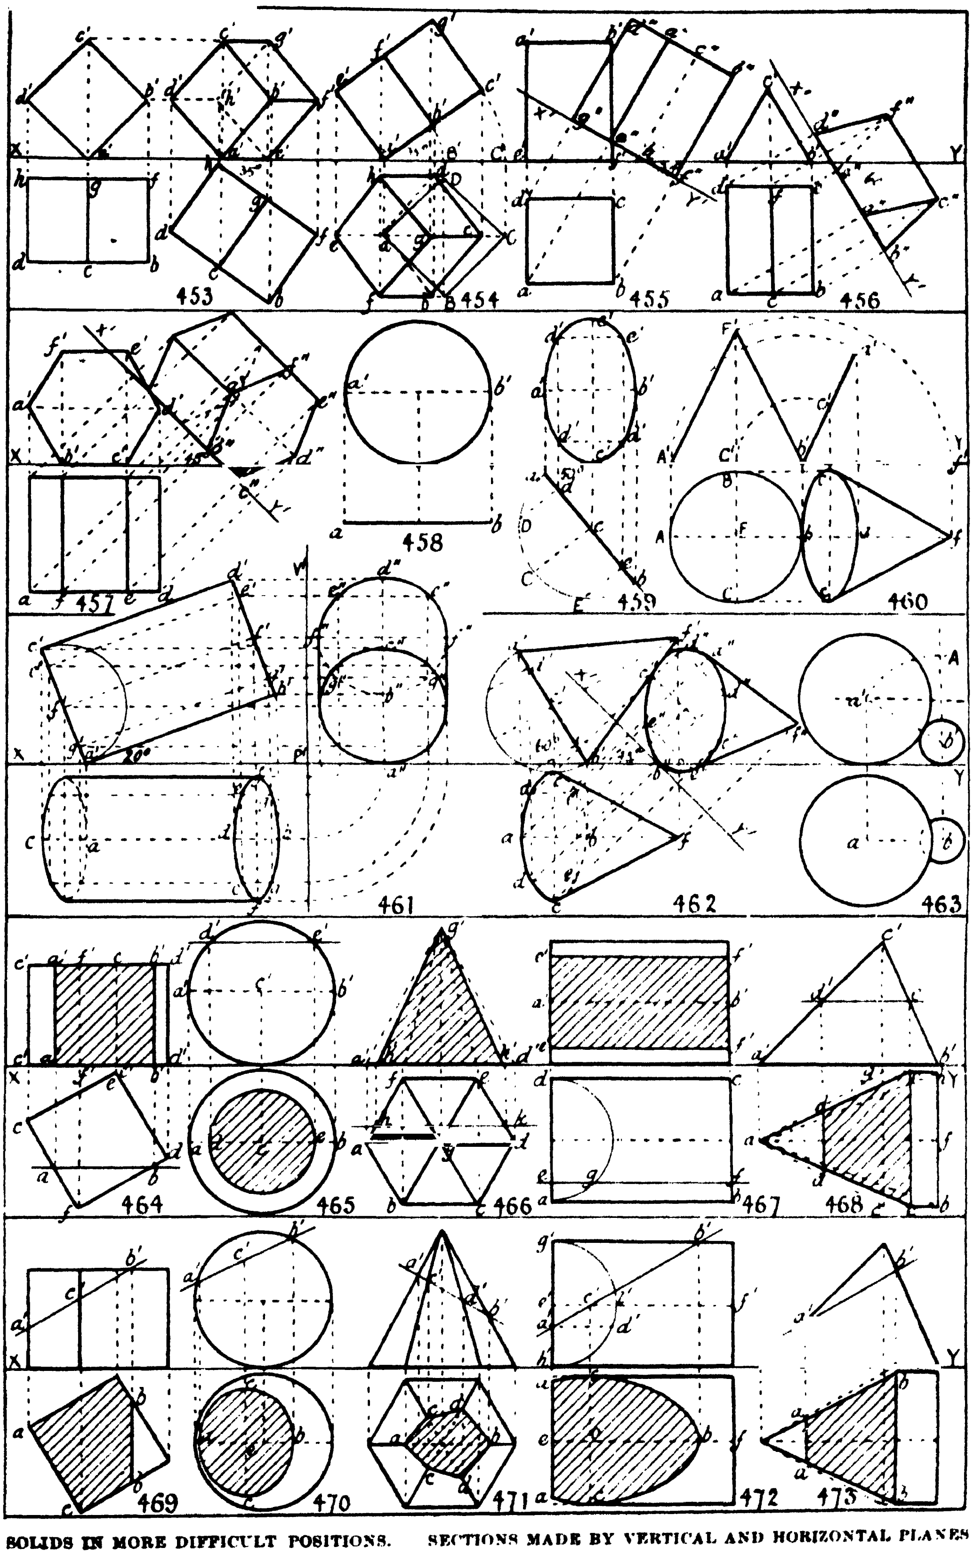
Sections made by Planes Inclined to the H.P., but Perpendicular to the V.P.

469. The Elevation of a Cube is Given, and is Cut by a Plane $a'b'$ Inclined to the H.P., but Perpendicular to the V.P. Draw the Sectional Plan. Draw projectors and obtain the plan of the cube. The section is easily obtained as shown.

Note. In **469** to **473** the sections are not their true shape, because we are not looking perpendicularly to the section plane.

470. The Elevation of a Sphere is Given, which is Cut by a Plane $a'b'$ Inclined to the H.P. Draw the Sectional Plan. Obtain the plan of the sphere as in **465**. Bisect $a'b'$ in c'. Draw the projectors from a', b', and c'. Make ec equal to $a'c'$ or $b'c'$. Draw the ellipse through $acbc$ for the section.

471. The Elevation of a Hexagonal Pyramid is Given, and is Cut by a Plane $a'b'$ Inclined at 30° to the H.P. Draw the Sectional Plan. Obtain the plan, and draw



SOLIDS IN MORE DIFFICULT POSITIONS. SECTIONS MADE BY VERTICAL AND HORIZONTAL PLANES projectors from *a′*, *b′*, *c′*, *d′*, for the plan of the section as shown.

472. GIVEN THE ELEVATION OF A CYLINDER, WHICH IS CUT BY A PLANE *a′b′* INCLINED AT 30° TO THE H.P. DRAW THE SECTIONAL PLAN. Obtain the plan, in which draw the centre line *ef* for the plan of the axis. To obtain the width *ea* of the section, upon *g′h′* describe a semicircle, and through *e′* draw *e′f′* parallel to *XY* for the elevation of the axis, which is cut by the section plane in *c′*. Through *a′* draw *a′d′* parallel to *e′f′*, then *a′d′* is the width of half the section at the left-hand end of the cylinder. Draw projectors from *b′* and *c′*. Make *ea* (on both sides of *ef*) equal to *a′d′*, also *ec*, *ec*, each equal to *e′l′*, which is half the width of the section at *c′*. Draw the curve through *a*, *c*, *b*, *c*, *a*, and join *aa*, which completes the sectional plan.

473. THE ELEVATION OF A SQUARE PYRAMID IS GIVEN, LYING AS IN **468**, AND IS CUT BY A PLANE *a′b′* INCLINED TO THE H.P. AT 30°. DRAW THE SECTIONAL PLAN. Obtain the plan as in **468**. Draw projectors from *a′* and *b′*, and complete the sectional plan as shown. The dotted lines in plan indicate the upper portion removed.

How to Find the True Shape of a Section

474. A CUBE STANDS WITH ONE OF ITS FACES IN THE H.P. AND A VERTICAL FACE INCLINED AT 30° TO THE V.P. THE CUBE IS CUT BY A PLANE *a′b′* INCLINED AT 75° WITH THE H.P. AND PERPENDICULAR TO THE V.P. DRAW THE PLAN, ELEVATION, AND TRUE SHAPE OF THE SECTION. Draw the plan of the cube, so that the edge *ef* is inclined at 30° with *XY*, and project the elevation. Then draw the section plane *a′b′* so that it cuts the cube at an inclination of 75° with *XY*. (As no definite position of the cutting plane is indicated in the data, *a′b′* may be drawn anywhere through the elevation, as long as it is inclined at 75° with *XY*.) Draw projectors from *a′* and *b′* to the plan, then if the left hand portion be removed, *aagbb* is the sectional plan.

To obtain the *true shape* of the section, project at right angles from each point *a′*, *g′*, and *b′*, where the section plane cuts the elevation, and transfer the widths of the section from the plan; thus, make *b″b″* equal to *bb*, *a″a″* equal to *aa*, etc., then *a″a″g″b″b″* is the true shape of the section. Or project from the plan and transfer the distances from the elevation, so that *h‴g‴* is equal to *b′g′*, and *g‴l‴* equal to *g′a′*, then *a‴a‴g‴b‴b‴* is the true shape of the section. In the first method it should be noticed that *m″n″* is equal to *mn*, and *a″m″* equal to *am*. It is not necessary to use both methods, only the one which is most convenient.

475. A SQUARE PRISM, WITH ITS AXIS HORIZONTAL, BUT PERPENDICULAR TO THE V.P., AND A FACE INCLINED AT 25° TO THE H.P. IS CUT BY A VERTICAL PLANE *ab* INCLINED AT 45° TO THE V.P. DRAW THE SECTIONAL ELEVATION AND THE TRUE SHAPE OF THE SECTION. Draw *b′c′* at 25° to *XY*, and construct the square for the elevation of the object. Project from each corner for the plan of the same. Draw *ab* (anywhere in this case, so long as it makes 45° with *XY*), and project from *a*, *c*, *d*, *b*, to the elevation, so as to obtain the sectional elevation *a′a′c′b′d′*. For the true shape of the section, draw horizontals from *a′*, *a′*, *c′*, *b′*, *d′*, and at any convenient distance, in order to avoid confusion, draw *a‴e‴* parallel to *a′a′*. Make *e‴c‴* equal to *ac*, *c‴f‴* equal to *cd*, *f‴g‴* equal to *db*, and through *f‴* and *g‴* draw parallels to *a‴e‴* to intersect the horizontals. Join *a‴a‴c‴b‴d‴* for the true shape of the section.

Another Method to Obtain the True Shape of the Section. Draw *X′Y′* at any convenient distance from, and parallel to, *ab*. Project from *a*, *c*, *d*, *b*, perpendicular to *X′Y′*. Make the points *a″*, *a″*, *c″*, *b″*, *d″* respectively the same height above *X′Y′* as *a′*, *a′*, *c′*, *b′*, *d′* are above *XY*. Join the points thus obtained, and *a″a″c″b″d″* is the true shape of the section.

As students often find the projecting of these sectional views somewhat troublesome, it would be a good help to draw the complete elevation of the object on *X′Y′*, and either rub out the removed part, or represent it by dotted lines as shown in **475**.

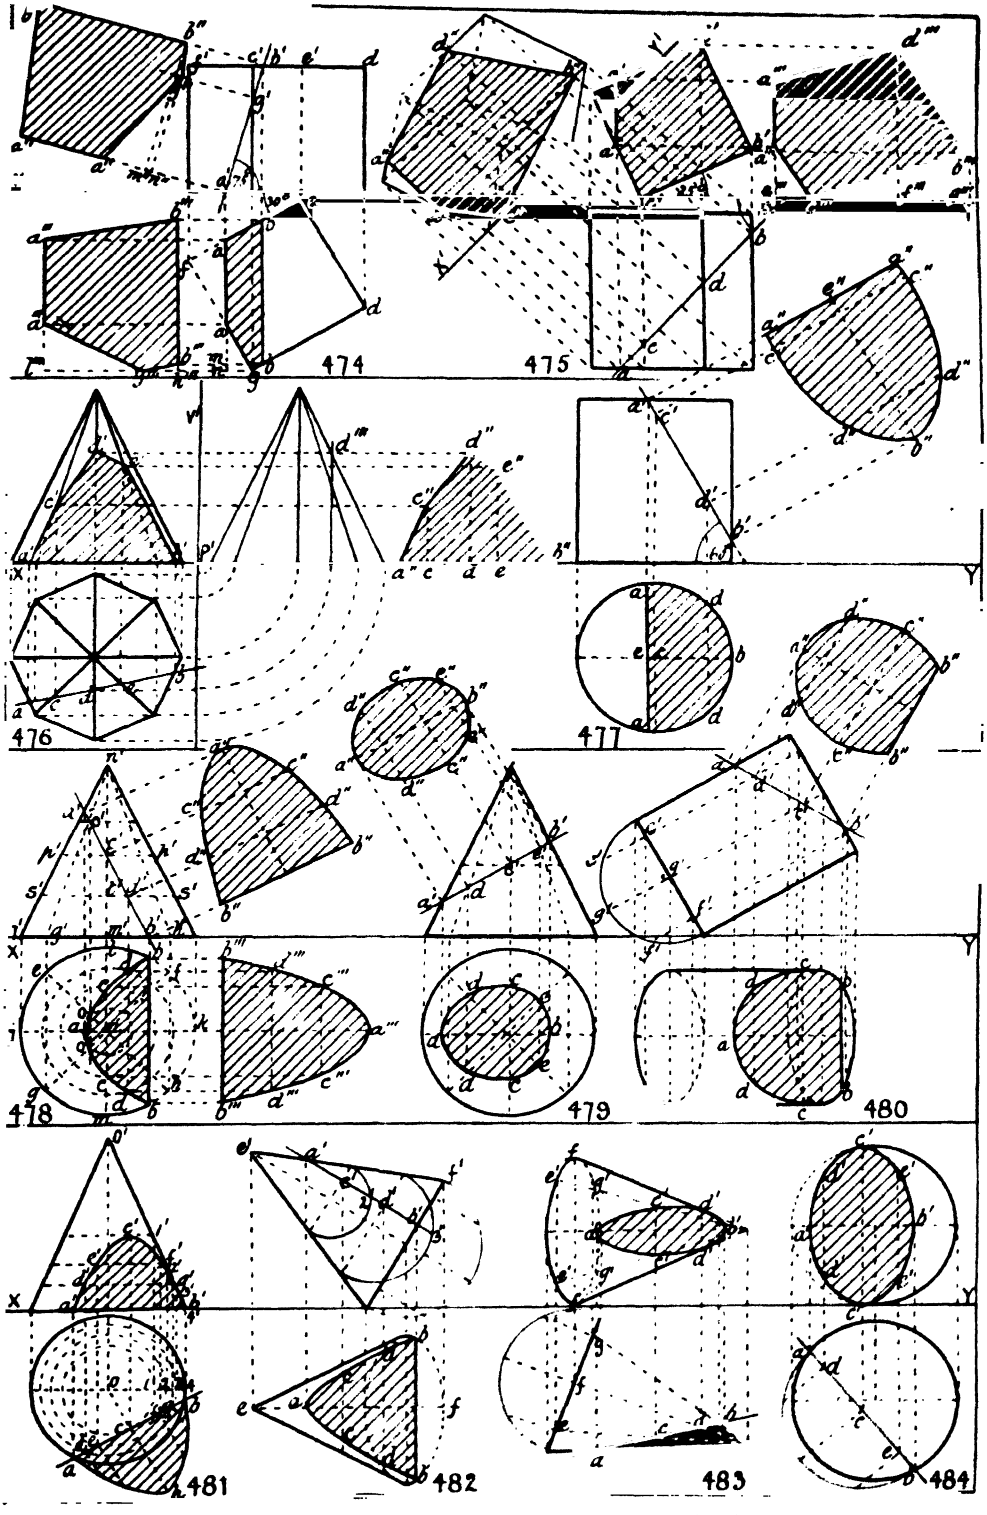
476. GIVEN THE PLAN OF AN OCTAGONAL PYRAMID CUT BY A VERTICAL PLANE *ab*. DRAW THE SECTIONAL ELEVATION, AND TRUE SHAPE OF THE SECTION. Draw the elevation, and project from the points *a*, *c*, *d*, *e*, *b* to determine *a′*, *c′*, *d′*, *e′*, *b′* in the elevation. Join the latter points, and the sectional elevation is complete. The elevation of the point *d′* is obtained by drawing a side elevation of the pyramid, projecting from *d* to *V′P′*, turning *d* into *XY*, and erecting a perpendicular to meet the outside edge of the pyramid at *d‴*. Through *d‴* draw *d′d‴* parallel to *XY* to fix the point *d′* in the sectional elevation.

To obtain the true shape of the section, set off on *XY*, *a″c* equal to *ac*, *cd* equal to *cd*, etc., erect perpendiculars from *c*, *d*, *e*, to meet horizontals from *c′*, *d′*, *e′*. Join the points *a″*, *c″*, *d″*, *e″*, *b″*, which give the true shape required.

477. THE ELEVATION OF A CYLINDER STANDING ON ONE END IS GIVEN, WHICH IS CUT BY A PLANE *a′b′* INCLINED AT 60° WITH THE H.P. DRAW THE SECTIONAL PLAN, AND THE TRUE SHAPE OF THE SECTION. The plan of the cylinder is a circle. Project from *a′*, and complete the sectional plan as shown.

To obtain the true shape of the section, find the centre *c* of the circle, and take any convenient points *d*, *d*, in the circumference. Project from *c*, *d*, and *d*, to *a′b′*, the elevation of the cutting plane. Draw a centre line *b″c″* at any convenient distance from and parallel to *a′b′*. Project from *a′*, *c′*, *d′*, *b′*, make *a″a″* equal to *aa*, *c″c″* equal to the diameter through *c*, and *d″d″* equal to *dd*. Draw the curve through the points thus obtained, and *a″b″a″* is the true shape required.

478. GIVEN THE ELEVATION OF A CONE STANDING ON ITS BASE, AND CUT BY A PLANE



SECTIONS MADE BY VERTICAL AND INCLINED PLANES

$a'b'$ Parallel to its Side. Draw the Sectional Plan and True Shape of the Section. The plan of the cone is a circle, in which draw the diameter jk parallel to XY, and the other diameters eh, fg, lm, so as to divide the plan into (say, eight) equal parts. Obtain these lines on the elevation, then the section plane cuts them in the points a', o', and c'. Point a' is on line $j'n'$, therefore its plan is on jn at a, as projected; point o' is on line $g'n'$, and its plan is therefore on gn at o; and the corresponding point on the further side of the cone is on en at o. As point c' cannot be projected vertically, as regards the distance of its plan on either side of jk, through c' draw $p'p'$ parallel to XY, to represent the elevation of a horizontal section through c', then $c'p'$ is the distance of c from jk on either side. Also, we do not know how far the plan of d' is both sides of jk. Therefore, imagine a horizontal section through d', then $s's'$ is its elevation, and $t's'$ is the distance of d from jk in the plan. Point b' is on the circumference of the base, and therefore its plan is on the circle at b. Draw the curve through b, d, c, o, a, o, c, d, b, and join bb, which completes the sectional plan.

The plan of the points o', c', and d' might be found by drawing circles for the plan of each horizontal section through those points, then projectors from each point to meet the circles respectively will give the plan of each point as shown.

For the true shape of the section two methods are shown, which are constructed similarly to the method used in **475** and **477**. The diagrams will now be easily understood.

479. The Same as **478**, but Cut by a Plane $a'b'$ not Parallel to the Side, but Inclined to the H.P. at 30°. Draw the plan and divide it into any number of (say, eight) equal parts as before, and proceed as in the previous problem **478**.

The true shape is easily obtained as shown. Notice that $c''c''$ is equal to cc, $d''d''$ to dd, etc.

480. The Elevation of a Cylinder is Given, and is Cut by a Plane $a'b'$ Inclined to the H.P. at 30°. Draw the Sectional Plan and True Shape of the Section. Obtain the plan as in **461**. On the elevation describe a semicircle (which is half the true shape of the end), and divide it into (say, four) equal parts. Draw parallels to the elevation of the axis from each point in the semicircle. From a', d', c', b', draw projectors to the plan. Make dd equal to twice $e'e'$, cc twice $g'g'$, etc. Draw the curve and complete the sectional plan as shown.

The method of finding the true shape is similar to that in the preceding problems.

481. The Plan of a Cone Cut by a Vertical Plane ab is Given. Find the Sectional Elevation and the True Shape of the Section. Draw the elevation and project the points a and b to XY. Then obtain the height of the section. Draw oc at right angles to the section line ab, and describe a circle with centre o and radius oc. From 1 the point where the circle cuts $o4$, project to the elevation for $1'$. Through $1'$ draw a horizontal line to represent the elevation of the circle, and project from c to meet this line at c', the highest point in the section. Obtain other points in the curve by taking points d and e, and describe circles through them from o as centre. Project from 2 and 3, where these circles cut $o4$, and draw their elevations at $2'$ and $3'$. Projectors from d, e, f, g, to meet these elevations of circles give the points d', e', f', g'. Draw the curve and complete.

For the true shape of the section make the perpendicular ch from c equal to the height of c' above XY, and the perpendiculars at d, e, f, g, equal to the heights of the respective points d', e', f', g', above XY.

482. The Elevation of a Cone Cut by a Plane Parallel to the Axis is Given. Draw the Sectional Plan. Obtain the plan as in **462**. Project points a' and b' for a and bb. For other points take c' and d', and draw sections parallel to the base. The semicircles on these lines give half the true shape of the sections at these points c' and d'. Project from c' and d', and set off on each side of the centre line ef of the plan a distance equal to $c'2'$, and $d'3'$ for the points cc and dd. Draw the curve and complete as shown.

483. The Plan of a Cone with its Axis Horizontal is Given, and is Cut by a Vertical Plane ab.

484. The Plan of a Sphere Cut by a Vertical Plane ab is Given. Draw the Sectional Elevation in Each Case.

The diagrams explain themselves for these two problems.

WHAT PSYCHOLOGY IS

The Science of the Mind. Its great Names and its great Questions.
The Origin of Ideas. Growth of the Mind and the Brain

Group 3
PSYCHOLOGY
1

By Dr. C. W. SALEEBY

THE title of our new course has a somewhat formidable appearance. It suggests physiology, but sounds even more obscure, and the very fact that it is spelt with a silent "p" is an annoyance. There is little doubt that a better word for the description of the science of mind would have been phrenology, *phren* being the Greek word for mind. But, as everyone knows, that term has been taken for the pseudo-science which attempted to discover the mental and moral characters of a man by observation of his skull. That curious delusion is abandoned, but we shall have to spend some time upon what may be called the new phrenology, which enables us to allot to certain well-marked areas of the brain the performance of certain mental functions.

What Psychology is not. Psychology is literally the science of the soul; but we cannot here employ a term to which many meanings have been applied, and we may content ourselves by defining our subject as the science of mind. Most emphatically we must reject a now popular modification of this definition, wherein we are asked to believe that psychology is the science of consciousness.' If there is anything of which the unbiassed, open-eyed psychologist of to-day is convinced beyond all question, it is that there are realms of mind, of mental activity, of psychical processes—use what term you please—that lie beyond the sphere of consciousness. We do not like to say "below the level of consciousness," because that figure suggests inferiority, and these processes must be regarded as in many ways of far profounder significance than consciousness itself. Consciousness and mind are not synonymous; their realms are not coterminous. The latter has an immeasurably wider meaning than the former; so far, indeed, is consciousness from being the whole of mind, that it should rather be regarded, important though it be, as a mere aspect or function of the immeasurable reality which it is our business to study in this course.

Is It Worth While? Here and there, a sober and business-like reader may ask whether it is worth his while to pursue this subject. He fully understands the importance of matter and energy, of chemistry and physics, of engineering and electricity. To study these is to make some acquaintance with modern science, which is none other than organised knowledge, and which is, therefore, assuredly destined to rule the world. But is it worth while, he may ask, to study mind? Even supposing that men can discover anything about it, is the knowledge worth having? If such a reader will give us a fair hearing, we may convince him that it was worth his while. If we fail to do so, the fault will certainly be in our own incapacity, and not in the subject.

Or, there may be another reader with an exact and sceptical mind, loving accuracy and precision of statement, impatient of anything that cannot be closely measured, and still more impatient of speculation, or of anything that claims to be science, whereas it is no more than a mere word-spinning. Such a reader, rather exaggerating the facts, may ask whether the history of thought is not strewn with the wrecks of false psychological systems, and whether there is any certainty in the matter. But we hope to convince such a reader that modern psychology is a real science, employing the same methods and principles as any other science, and worthy of no less respect.

The Key to the Facts of Life. But we cannot yet proceed to our subject without insisting upon the transcendent importance which the advance of science has lately conferred upon it. The student of the course on PHYSICS will remember the references to the materialism of thirty years ago. He will remember that that doctrine is now no longer held, save by two or three unfortunates here and there, who have added nothing to their knowledge since 1870. In a subsequent course we shall have to discuss materialism and its modern equivalent. For the present, we must merely observe that since it is no longer possible to explain man and the universe in terms of matter and force, the study of mind, which is neither matter nor force, has assumed new importance, or, rather, has been restored in the eyes of all to the supreme place which it has held in the eyes of the wise since the dawn of thought. If we are convinced that matter does not hold within itself the key to the riddle of existence, and if we hold that there is any key to the riddle, it is to mind and to mind alone that we must turn. The study of philosophy thus necessarily demands a prior study of psychology, and since philosophy is no less than the quest for reality, this ground is plainly the highest upon which we can place the claims of our study.

But from other than the philosophical points of view, psychology is equally important. For instance, we have to recognise that the behaviour of men, that human nature, accounts for an enormous proportion of the evils of life, and also that it is the key to an overwhelming proportion of the facts of life. The key to all human institutions is human nature. The study of man as a social animal, the study of his history, his laws, the rise and fall of nations, of civilisation, of the types of societies, of marriage, of progress and decadence wherever found—the due study of all these, nowadays subsumed under the science of Sociology—demands an acquaintance with the science of man's mind.

But these are not practical matters, it may be said; yet the effects of legislation and the due construction of laws are practical matters, and so is education, which, indeed, properly regarded, is of higher practical importance than any other matter. Yet there can be no due education, no real comprehension of the problems involved, no adequate solution of them, without an understanding of the manner in which the human mind is developed from infancy to adult life. If psychology could justify itself to the utilitarian on no other score than its importance in education, it would have a justification surpassable by that of no other science.

The Methods of Psychology. The mind, of course, is the instrument of all the sciences, psychology included, and thus the science of mind is in the extraordinary and unique case that its instrument and its subject are one. Thus there are two distinct ways of studying our subject—ways to which there is no parallel in the case of any other science. We may look within ourselves and study our own minds—the method of *introspection*; or we may look out at other minds than our own, just as we look at a mineral or a meteor, but with this profound difference—that we make the acquaintance of other minds than our own by the intervention of matter. The only mind which each of us knows at first hand is his own; the fact that there are any other minds than his own is really no more than an inference from the physical actions of other persons. He might, if he chose to be so foolish, regard other persons as merely automatic, which was the preposterous verdict of the philosopher Des Cartes upon the lower animals. Thus it is open to each of us either to study his own mind immediately, or to study the minds of others mediately—the medium always being matter of one kind or another. The contrast between these two methods may be made at this very early stage of our study, because it helps us to understand its history; and having defined our subject, it is, of course, most desirable that we should proceed to a brief account of its history, which is one of the most remarkable and instructive of its kind.

"Know Thyself." From the remote ages of the earliest Greek philosophy, the Ionian speculation of more than five centuries before Christ, comes the ancient maxim, "Know thyself," the wisdom of which has remained to this day as the shortest and final verdict on the value of psychology. If we roughly review the whole of Greek philosophy, we find the study of mind to have occupied far more time and attention than, perhaps, all other subjects taken together. The results, however, are utterly disproportionate. This is said without bias, no one having a more profound respect for the incomparable Greek genius than the present writer. But it is the fact that scarcely any psychological truths whatever are yielded us by the sum total of Greek thinking on this subject. On the other hand, there is an enormous mass of error, the greater part of which is not merely erroneous, but ludicrous and ridiculous.

Now, how are we to explain this fact, remembering how great and sincere were the thinkers who accomplished so little? Probably the chief explanation is that these thinkers were absolutely without any appreciation of the scientific method. They made no experiments, they made no systematic observations. Both experiment and observation they despised as partaking of the mechanical or as diverting the mind from the contemplation of the "pure idea." They confined themselves to the introspective method alone; and the whole history of psychology through more than twenty-five centuries teaches with uniform monotony that the introspective method alone invariably and signally fails.

The Slow Progress of Psychology. The second most conspicuous reason for the failure of the Greeks and for the amazingly slow progress of psychology until the nineteenth century is to be found in the fact that the science was not clearly distinguished from the other studies with which it is allied, or, rather, upon which it has a bearing. When we consider the subject of heat in the study of physics [see PHYSICS] we see how absolutely essential it is to distinguish between the physical and psychological aspects of our inquiry. We see, for instance, that we should err most grievously if we were to estimate heat by our sensations. In the first place, there is no trick that our sensations may not play us; and in the second place, the character of our sensations does not depend alone upon the character of the external objects which arouse them, but upon the character of those objects *and* upon the character of our senses; the second factor being, indeed, of incalculably more importance than the first. For centuries and centuries the progress of physics, and, indeed, of all the sciences, was hampered, if not almost entirely arrested, by the backwardness of psychology, and there was thus established a vicious circle. For psychology itself could not advance until the value of the scientific method had been demonstrated in the other sciences.

But, on the other hand, psychology was injured far more seriously by its confusion with metaphysics and countless false philosophies and religions. At last psychology has freed itself, in almost every civilised country except Great Britain, from all its encumbrances, and is pursued as a free and independent science—that is to say, free and independent as the other sciences are, free from external dictation. But, as in all history at all times, there has been reaction and falling into extremes; and this we shall illustrate in a moment, after we have briefly alluded to the great names in psychology between the decadence of Greece and the middle of the nineteenth century.

Great Names in Psychology. Greece was succeeded by Rome, the greatest military power the world has ever seen; but Rome added scarcely anything of moment to art, certainly nothing original, and even less to science and philosophy. Then came the dark ages, during which the scanty seeds of knowledge were tended by an Arabian thinker here and there. In the thirteenth century the greatest philosopher of the church, St. Thomas Aquinas, reinstated, by the force of his genius and skill, the philosophy of Aristotle, whom we may call the last and the greatest of the Greeks, and whose work, or such of it as had been preserved at all, had been flouted for more than forty generations. Aquinas went as far as the available science of his time—a pitiable quantity—could possibly take him. His psychological views are now merely of historical interest. Nor was psychology appreciably furthered by Des Cartes (1596–1650), or Spinoza (1632–1677). To the former, however, it appears that we must attribute, at any rate, the germ of a very great discovery, the discovery of what we call *reflex action*. Spinoza did little for psychology proper, but, as we shall see in a subsequent course, performed a lasting service for humanity by his study of the relations between psychology and the ultimate problem of philosophy.

Are We Born with Ideas? The next name that demands mention is that of the Englishman Thomas Hobbes (1588–1679), who was born before both Des Cartes and Spinoza, but outlived them both. In a review of our subject so brief that an immortal like Spinoza is dismissed in a phrase we can say no more of Hobbes than that to him must be credited the first clear recognition of the psychological law of the association of ideas.

Greater—as a psychologist, at any rate—than the author of the "Leviathan" is his successor John Locke, of Oxford (1632–1704), whose great "Essay concerning Human Understanding," one of the epoch-making books of all time, was published in 1690. The greatest accomplishment of Locke's great life-work was his destruction, once and for all, of the belief in *innate ideas*, with which psychology had handicapped itself until his time. All our knowledge whatsoever, he declared, is derived by "sensation," and by "reflection" upon the ideas derived by sensation. In other words, he declared that the whole of our knowledge is the product of experience. As an example of the more comical aspect of the notions which Locke refuted, we may quote the old belief that if a child were left to grow up without hearing any language he would revert to the supposed practice of his first parents, and speak Hebrew; on the contrary, we now know that the child would be an idiot.

Thus, the doctrine—not wholly true but very nearly so—which every one associates with the name of Locke, is a denial of the notion that the human mind is possessed of any innate ideas. He set himself to prove that "nothing is in the mind that was not first in the senses" (*Nihil est in intellectu quod non prius fuerit in sensu*). The child's mind, he declared, must be likened to a *tabula rasa*, a clean or blank tablet, on which nothing has been written. Aristotle had this idea, but did not avail himself of it. Thus, for Locke, all mental products whatever result from sensation, and from reflection upon past sensory experiences.

Immanuel Kant. Locke's great successor was the German-Scot Immanuel Kant (1724–1804). He is the dominant mind of the century which elapsed between Locke's death and his own. Now, Kant agreed that we cannot hold any ideas to be innate; he declared, however, that *time* and *space* are not ideas, but forms of the mind; not *thoughts*, but *apparatus for thinking*. As regards space, the doctrine of Kant is now definitely disproved. Modern psychology can describe with practical completeness the mechanism by which our ideas of space are built up; while it has gone far to explain the idea of time, for most certainly it regards both space and time as *ideas*, Kant notwithstanding. In a sense it is, of course, true that time furnishes one of the forms in which we think. Are we, then, to believe Locke, and try to conceive the idea of time as imprinted afresh upon each new mind—each such mind being as little predisposed to this or any other idea as is a blank sheet of paper? Or are we, with Kant, in some mystic manner, to conceive of time as an idea or form of thought which is native to mind and owes nothing to the external world—as a form, indeed, which mind, being somehow possessed of it, actually imposes, by its own arbitrary will, upon the outer world?

As in a thousand instances before, the truth has been found somewhere between the two opposing extremes: Locke and Kant are both right and wrong. The nineteenth century produced a thinker to whom occurred the novel method of studying mind not as existing but as evolving; and thus the work of the earlier thinkers was brought to fruition.

Mind and the Senses. The mind, of course, is not a *tabula rasa*; never was less accurate a phrase. It has, in each case, its own ineradicable predispositions and prejudices—products of "aeonian evolution." Amongst its predispositions may be reckoned a habit of looking at things under the form of time. So far the verdict goes with Kant and against Locke. But if we trace the history of mind, the almost incredibly base degrees by which it did ascend, and consider the amoeba, or, indeed, the single microscopic cell which may become a Newton or a Wagner, we shall be hard put to it to detect any innate ideas or forms of thought therein. Locke was unquestionably right in upholding the doctrine that nothing is in the mind that was not derived by the senses. If, however, we conceive of sensory experience as producing changes in the percipient organs, and of such changes as being inherited, then we can understand how age-long ancestral experience of a Cosmos which has certain characters has gradually developed a form of nervous structure which fits every new inheritor of it readily to appreciate the outer world under the forms which the characters of that outer world have imposed upon nervous structure in the past. "Time and space" are *not* forms imposed on the outer world by mind: they are forms imposed on mind by the outer world.

Herbert Spencer. The thinker who has helped to solve the problem is Herbert *Spencer*, who died almost exactly a century after Kant and two centuries after Locke. His great contribution to the subject, called the "Principles of Psychology," demonstrates the evolution of the mind, and was published in 1855, four years before Darwin demonstrated, in the "Origin of Species," the evolution of the body. Spencer is thus the founder of the evolutionary psychology by far the most philosophically important aspect of this science. The Scotsman, Alexander Bain, was a pioneer of the very important part of psychology which now has the uncouth name "physiological psychology." This is the branch of psychology which does not concern itself with origins, nor with philosophical questions, but attempts to associate as many mental processes as possible with physical or physiological processes. Very often this part of the subject, which has made the most astonishing progress within the last thirty years, is described as "experimental psychology"—the name given to it by its most distinguished exponent, Wilhelm Wundt, of Leipsic, who is, beyond all question, the greatest psychologist living when these words are written.

"Psycho-Physics." The astonishing progress of experimental psychology and of the physiology of the brain—very often called neurology, especially when it is contrasted with the almost stationary character of psychology through the ages which preceded it—has caused psychology to pass through a dogmatic period, closely corresponding to the dogmatic materialism from which physics has lately emerged. There was founded, for instance, the new "psycho-physics," which professed to be as accurate as physics itself and to calculate psychical processes in physical terms. It would be untrue to say that that science has accomplished nothing; but it was based on a false assumption, and has not accomplished, nor will it ever accomplish, any but an infinitesimal part of what its founders expected. The attempt to do without introspection altogether, and to treat mind as if it were a material fact of physics, has proved to be as inadequate as was the introspective method alone. Only by a due combination of the two methods, despising neither the material facts of the brain on the one hand nor the immaterial records of consciousness on the other, can we expect to make real progress. Herein is a lesson for dogmatists of all parties.

Kinds of Mind. But there are some points on which we can and must dogmatise: and one of them is this—the capital discovery, perhaps, of modern psychology—that it is no longer wise or defensible to conceive of mind as if it were possible to discover all its facts from the observation of one mind. From Plato to Kant, philosophers were content to look within themselves, and imagine that the facts they saw there were universally true. Psychology was purely introspective, and so it did not occur to its students to look out upon and contemplate minds other than their own.

It is true that one has direct knowledge of one's own mind, and only indirect knowledge of other minds. But that is no reason for proceeding on the ludicrously false assumption that it is possible to understand mind by the observation of single examples of it. Nowadays we have the psychology of crowds, the psychology of peoples, social psychology, child psychology, savage psychology, and comparative psychology, which studies the mental characters of the lower animals. It is an amazing thing that until the other day, so to speak, the very possibility of these subjects was scarcely conceived and was certainly not appreciated. At any rate, we shall no longer make such an error. We shall clearly recognise that psychology is at least—it may be more—an objective science, the student of which studies objects, things, existences outside him, which are none the less real because they cannot be seen or weighed like so many minerals, but yet which have to be studied in all their variety just as minerals are studied by the chemist and the geologist. Yet while we remember this necessary business of psychology, we shall not forget its unique character, in virtue of which the means of study—the mind—and the object of study are at bottom one and the same.

Is the Mind in the Brain? And this introduces us at once to the fundamental problem of psychology, a problem to which we must return in the course on Philosophy. What is the relation of mind and body? This question may be put in a rather striking form, offering a puzzle which, so long as it is put in that form, is utterly insoluble: Is the mind in the brain or the brain in the mind? It is to be feared that an overwhelming number of those who have some acquaintance with the physiology of the brain are nowadays inclined to answer that the mind is in the brain. They would go on to say, perhaps, that the mind is not a thing, but a function—a function of the brain. Some, at any rate, would say this; but many more would say that the mind must be regarded as a form of energy, the business of the brain being to convert other forms of energy—such as heat, chemical energy, and so on—into mind energy.

Is the Brain in the Mind? On the other hand, a very much smaller number of persons, whose training has been of a different kind, will answer most positively that the brain is in the mind; in other words, that all material things—the stars and the earth, the body and the brain itself—exist only in the mind, or in virtue of the mind which perceives them! We have no space to spare at present for this extremely important doctrine, which demands our profound respect, even though it may a hearty laugh when first we hear it. It is a problem of philosophy rather than of psychology. But we must, at all costs, spare space for considering the very popular doctrine that mind is a form of energy.

A SHORT DICTIONARY OF PHILOSOPHY & PSYCHOLOGY

See also A Short Dictionary of Biology, page 32

ABERRATION—A departure from normal soundness of mind.

Abnormal—Deviating from standard type.

Absolute—That which is not relative.

Abstract—That which is considered as having no application to any particular object, or to other ideas which naturally accompany it; opposed to concrete.

Accident—That which is not essential or substantial.

Acquired—That which is not inborn.

Actual—That which is in reality.

Adaptation—Adjustment or fitness.

Aesthesia—Sensibility; the general power or process of feeling.

Aesthetic—Relating to the feelings, especially those of beauty.

Affection—The elementary form of feeling; pertaining to feeling of all sorts.

Affirmation—The mental process of establishing a connection between ideas. Thus, the affirmation "Snow is white," establishes the connection of snow and whiteness.

Aggregate—A general idea of a group taken collectively.

Agnostic—One who maintains a neutral attitude regarding all subjects which are incapable of scientific proof.

Agnosticism—The doctrines of the agnostics.

Alter—The individual's thought of another self as such.

Altruism—Dispositions having as their conscious end the advantage of an Alter or other self.

Amnesia—Loss of memory.

Analysis—That investigation which proceeds by a resolution of the complex phenomena of mind into simple ingredients or constituent factors. The analysis of a mental product is the viewing of it by separate acts of attention in its several component elements or aspects. This must be carefully distinguished from that actual separation of parts as seen in a chemical analysis.

Animism—The belief in the existence of a human spirit surviving the death of the body.

Annihilation—The reduction of the object into absolute nothingness.

Anoia—Want of understanding.

Antithesis—Logical or verbal opposition.

Apathy—Lack of normal emotional sensibility.

Apodictic—Capable of clear demonstration.

Apparition—An unusual or preternatural appearance or phenomenon.

Apperception—The fixing of a new sensation through the revival of kindred ideational elements.

Apprehension—The conceiving of a particular idea, object, or event, alone and apart from others.

Arcana—Things hidden or unknown.

Aristotle—A celebrated Greek philosopher, a disciple of Plato, born about 384 B.C.

Atheism—The disbelief of the existence of a God or supreme intelligent Being.

Attention—The special direction of the energy of the mind towards something present to it.

Attribute—An essential characteristic of a being or thing.

Auditory perception—Perception by hearing.

Aura—A supposed emanation of a psychic nature. Also the sensations that precede an attack of epilepsy.

Automatic actions—Actions effected by the living organism independently of any stimulus from without, or of volition.

Axioms—Necessary and self-evident truths.

BEAUTY—That which arouses a pleasing sensation, which pleases. Beauty is chiefly appreciated by sight and hearing.

Belief—A mental state in which judgment yields assent.

Bilocation—The alleged perfect and simultaneous existence of one and the same individual in two distinct places at one time.

Biogenesis—That view of the origin of life which teaches that living organisms can spring only from living parents.

Biogenetic—Pertaining to biogenesis

Blind spot—That portion of the eye which does not transmit rays for perception.

Brain—The organ of the mind.

CAPACITY—The power of receiving or acting upon impressions.

Casual—Accidental, fortuitous.

Categorical judgment—A statement made as holding good without reference to any other condition.

Cause—That which results in existence.

Certainty—The degree of assurance felt with reference to something presented to the mind.

Characteristic—A distinct trait or quality.

Chiromancy—The art and science of attempting to interpret by the lines of the hand, palmistry.

Choice—The selection from competing means to an end.

Clairaudience—The alleged ability to hear sounds not normally audible.

Clairvoyance—The alleged faculty of seeing objects not normally visible to an ordinary observer under the same circumstances.

Co-adaptation—Complex, as opposed to simple adaptation.

Cognition—The being aware of an object.

Colligation—The union of quantitatively like elements in consciousness.

Complex—Not simple.

Comprehension—Knowledge of the relational type.

Conceptualism—The assertion that the mind has the power of forming general ideas, or ideas of classes of things, over and above the power of picturing individual objects.

Concrete—*Objective, not merely abstract.*

Condition—An essential thing.

Confucius—A Chinese philosopher (551–478 B.C.).

Congruity—*The quality of agreement* among the parts of an essential whole.

Conscience—Moral reason, moral sense.

Consciousness—In its widest sense, all modes of mental life, the sum total of psychical existence, the mind's knowledge of its own operations or of something acting upon it, the distinctive character of mental life.

Consent—The volition to allow something to take place.

Content—That which is mentally perceived.

Control—Voluntary command of mind or body. Used by Spiritualists to denote the influence believed by them to be exerted upon a medium by incarnate beings.

Co-ordination—The relation between constituent members of the same group.

Correlation—The act of apperception considered as resulting in explicit relationships of a mental whole.

Cosmology—A part of metaphysics; or a theory of the Cosmos.

Criterion—A standard of judgment.

Crystal vision—The awakening of visual sensations or perceptions by looking intently upon a crystal or polished surface.

DEDUCTIVE—The method of drawing inferences from the general to the particular.

Delusion—A false belief.

Design—A conscious and deliberate plan of action.

Desire—A craving, a yearning, a feeling of want; the mental state of uneasiness awakened by the representation of an absent good.

Determinism—The doctrine that denies the freedom of the will.

Discrimination—A judgment of differences between objects.

Docetian—Pertaining to the Docetæ, a sect which taught that Christ during his earthly life possessed a phantom, not a real body; that He acted and suffered only in appearance.

Dream—A mental and conscious though disordered process taking place during sleep.

EGO—The whole person, self. The personal identity.

Emotion—The faculty of feeling passion, affection, sentiment.

Empiricism—The theory that accentuates the assumption that all our mental possessions are a product of purely sensuous experience.

Eudaemonism—The theory that happiness is the chief good for man.

FACULTY—That which renders a mental process possible.

Fatalism—The doctrine which teaches that all our acts are determined by fate or external circumstances, independently of volition. Never to be confused with determinism.

Free-will—The doctrine that we have freedom of choice in action.

GENERALISATION—The process of recognising likenesses, and asserting many particular facts in one general statement.

HABIT—A mental process whose repeated performance results in progressively easier accommodation.

Hallucination—The perceptual construction of an object having no elements of external reality. (Contrast Illusion, in which there are real data.)

Hypnosis—An artificially-produced sleep-like condition.

IDEA—A mental conception.

Idealism—The belief that matter has no existence other than as a sum of sensations. Its *being* is *being perceived.*

Idealists—Those who deny the existence of a material world, independent of the mind of man or the Deity. The doctrine has many variants. (See *realism.*)

Identity—The recognition of a thing as different from all others.

Illusion—The construction from the basis of real data of a mental object incorrectly accepted as real. A deceptive act of apprehension.

Image—The mental scheme in which sensations are revived.

Imagination—The power of having mental images.

Immortality—That attribute in virtue of which a being is free from death.

Individual—A single being.

Inference—That operation by which we derive a new judgment from some other judgment previously known.

Instinct—A natural aptitude which guides animals in the unreflecting performance of complex acts useful for the preservation of the individual or the species; compound reflex action.

Introspection—Attention on the part of an individual to his own mental state.

Irrelevant—Not pertinent to the question.

JUDGMENT—The full, explicit carrying out of a process of synthesis.

KANT—A German philosopher, born 1724, died 1804. The central point of his system is found in the proposition that before anything can be determined concerning the objects of cognition the faculty of cognition itself, and the sources of knowledge lying therein, must be subjected to a critical examination.

MATERIALISM—The doctrine which denies the existence of any spiritual substance, and holds that mind is mere matter, or a product of the material organisation; opposed to Idealism and Spiritualism.

Medium—A person supposed to be sensitive to control by incarnate spirits.

Memory—An ideational process of reproduction and recollection of prior experiences.

Metaphysical—Pertaining to metaphysics. Abstract.

Metaphysics—That science which seeks to trace all branches of human knowledge to their first principles in the constitution of human nature. The science of mind or intelligence. The word is applied to the science which studies things as they are, as well as things as they appear. Sometimes used as synonymous with psychology [q.v.]. Sometimes as synonymous with ontology [q.v.].

Metempsychosis—The transmigration of the soul or ego from one bodily form into another.

Mind, or Soul—The thinking principle; that by which we feel, know, and will, and by which the body is animated. [See *soul.*]

Motive—Whatever attracts the will; the apprehension of a desirable end.

NEGATION—The opposite of affirmation. The denial of a connection between ideas. Thus, "The snow is not perfectly white."

Nominalism—The assertion that the universal, or general, has no existence, or objective reality, other than as a name which is applicable indifferently to various objects which resemble one another in certain respects.

Noumena—Things in themselves, objects of pure thought apart from all elements of the senses. The reality underlying phenomena or appearances.

OBJECT—Whatever consciousness recognises.

Obsession—The supposed efforts of an evil spirit to influence a human being. Also a "fixed idea" in the insane.

Occult—That which is hidden or secret.

Ontology—The doctrine of being. That part of the science of metaphysics which seeks to investigate and explain the nature and essence of all things—their *ultimate reality.*

Orientation—Normal ability to recognise one's surroundings.

PERCEPTION—Objective knowledge, the apprehension of external reality.

Phantasm—An apparition of a person still living.

Phenomenon—Something seen or perceived. Literally an appearance.

Philomathic—Pertaining to the love of learning.

Philosophist—A lover of sophistry, a would-be philosopher.

Philosophy—Literally the love of wisdom (*philos*, love; *sophia*, wisdom). The search for wisdom. In modern usage *philosophy* may be defined as the universal science which aims at an explanation of all the phenomena of the universe by ultimate causes. It seeks to explain phenomena by inquiring into causes, reasons, powers, and laws. Applied to a particular sphere of knowledge, it denotes all the general principles relating to that sphere—*e.g.*, moral philosophy means the science which treats of duty.

Phrenology—Literally the science of the mind (*phren*, the mind; *logos*, discourse). The term now means a doctrine founded on an assumed knowledge of the functions of various parts of the brain obtained by comparing their forms and magnitudes in different individuals with the traits which these individuals are found to possess. The theory was first propounded by Gall, a Viennese physician. The faculties in this system are divided into two groups—feelings and intellect. A phrenological chart is a map of the head drawn on the skull which purports to indicate on the exterior the particular areas of feeling or intellect which lie in the brain underneath.

Planchette—An apparatus for recording delicate movements of the hand, and by which so-called automatic or spirit writing is obtained.

Platonic—Pertaining to Plato, or his philosophy.

Platonism—The ethics, physics and dialectics of Plato. It is maintained that there is no one system in these writings to which the author uniformly adheres.

Poltergeist—A supposititious incarnate being which, while remaining invisible, demonstrates by mischievous acts and noises, usually in or about houses.

Preternatural—Transcending ordinary natural agencies.

Psychiatry—The medical treatment of mental diseases.

Psychic, Psychical—Pertaining to the human soul or spirit or mind. Especially now applied to that force by means of which spiritualists aver they can communicate with the spirit world, also by which they can move material things without physical agencies. The force by means of which so-called spiritualistic phenomena are produced.

Psychology—That branch of philosophy which studies the human mind or soul, and consciousness wherever found, as in the lower animals.

Psychometry—The power supposed to be possessed by some persons of ascertaining from an article some characteristics of its possessor. A method of determining the interval between the reception of a sensory stimulus, and the execution of a responsive movement.

Psychoses—The manifestations of phenomena of mind.

Psycho-therapeutics—The treatment of morbid conditions by "suggestion" or hypnotism.

Purpose—A deliberately-formed intention with regard to a series of acts, or a remote end.

RAPPORT—The peculiar relationship which exists between a hypnotised person and the hypnotiser.

Rational Psychology—The investigation into the nature of the mind itself.

Realism—The doctrine that matter exists per se and apart from the subjective sensations of the percipient mind. Opposed to idealism [q.v.].

Reason—(1) The intellectual power of understanding; (2) the particular exercise of the understanding involved in the process of reasoning; (3) the total aggregate of spiritual power possessed by man.

Reflex Action—Movement in response to sensory stimuli without the intervention of any mental effort.

Resolution—The mental determination of a purpose.

SCEPTICISM—Absolute scepticism is the theory that positive truth is unattainable by human intellect; partial scepticism discredits some convictions of mankind, generally deemed to be of vital importance.

Self—The subject of individual consciousness.

Self-consciousness—The process of reflection on the self.

Sense—The capacity of the living being for a particular species of sensation.

Sensibility—The power of experiencing sensation.

Sentiment—An emotion of an abstract character.

Socratic—Pertaining to Socrates, the Greek sage, or to his method of teaching and philosophy. That method was by means of interrogatories. The proposition was not laid down authoritatively, and the pupil was led to acknowledge it by a series of questions put to him. The inductive method and the definition of ideas are two principles of science ascribed to Socrates.

Soul—The mental principle believed by Animists to be separate from the body, and having personal individuality.

Spectre—A ghostly apparition.

Spinozism—The system of philosophy of Spinoza, born 1632, died 1677.

Spiritualism, or Spiritism—A form of animism which holds that the human identity persists after physical death, and that incarnate spirits can by means of a peculiar psychic force communicate in various ways with living human beings.

Sub-consciousness, sub-liminal consciousness—The conscious process given in a state of inattention; consciousness apart from the waking state.

Subjective—Denoting mental in opposition to material phenomena.

Syllogism—A type of deductive reasoning.

Synthesis—The process of integrating, or combining, thought.

TELEPATHY—Communication between mind and mind otherwise than through known channels of the senses.

ULTIMATE—The last of a series.

VOLITION—The act of determining choice, or forming a purpose.

Voluntary—Pertaining to the will; subject to, or controlled by, the will. Intentional. [See *reflex action.*]

WEREWOLF—A conception belonging to the superstition that human beings took the form of wolves, while retaining human intelligence.

Will—The capability of self-determination. Synonymous with volition.

ZOOTHEISM—The worship of Deity under the form of an animal.

Zoroaster—A teacher of Eastern Iran. Date unknown (probably about 1000 B.C.).

GOVERNORS AND FLYWHEELS

Types of Governors. Centrifugal Force in Machine Construction and its Requirements. Different Kinds of Flywheels. Hammers

Group 12
MECHANICAL ENGINEERING

APPLIED MECHANICS
concluded from page 1908

By JOSEPH G. HORNER

IT seems a far cry from the devout Galileo watching the swinging of a lamp in the dim religious light of a church at Pisa to the mathematical theory of a governor!

Yet the factors that enter into calculations concerning governors are related to those with which the swinging of a pendulum are concerned. A few simple tests with a leaden ball attached to a fine thread suspended from a hook or nail will reveal one or two important relations between the length of thread and number and time of oscillations. If the arc through which the leaden ball swings be not very great, it will be noticed that with the same length of string the same time is occupied by each oscillation, although the angle through which the pendulum swings may vary. In other words, the oscillations through small arcs are isochronous (Greek *isos* = equal, *chronos* = time).

The Pendulum and the Governor. Careful observation would also show that as the thread is increased in length the time occupied by each swing increases, and that the number of oscillations in a given time decreases. With one thread 9 or 25 times as long as another, the time of each oscillation will be three or five times as long, and the number of oscillations reduced to ⅓ or ⅕. That is, in different pendulums, the duration of the oscillations varies as the square root of the length of the pendulum, and the number of oscillations in a given time varies inversely as the square root of the length. Several important relations are shown by the formula $t^2 : \pi^2 :: l : g$, where t is the time in seconds of one oscillation; π, the ratio between the circumference and diameter of a circle $= 3{\cdot}1416$; l, the length of pendulum; g, the acceleration due to gravity, 32·2 feet per second. Thus,

$$t^2 g = \pi^2 l,$$

and therefore time,

$$t = \pi \sqrt{\frac{l}{g}};$$

and acceleration of gravity,

$$g = \frac{\pi^2 l}{t^2}.$$

(This latter formula has been used for determining the value of the acceleration of gravity at different points in the earth's surface.)

The connection between the theory of the pendulum and that of the governor is more clearly seen in considering the action of a simple conical pendulum [216]. The ball G, suspended by the string GH, from the point H, describes a circle as shown by the dotted lines, outlining in its revolution the figure of a cone. Now, the forces which act on G are identical with those acting on the balls of an unloaded Watt governor, if we neglect the weight of the arms and sleeve.

The Operating Forces. These forces are three in number: A, the tension or pull of the string, as shown by the arrow, along GH, this being equivalent to the pull of the arm of a governor [217]; W, the weight of the ball acting downwards; F, the centrifugal force tending to move the mass outwards from the centre (see below). Here, then, we have a system of forces in equilibrium to which the triangle of forces may be applied [217]. Then, $F : W :: r : h$, r being the radius from the centre of the mass to the axis, and h the height of revolution. Therefore, $F \times h = W \times r$, and since, as stated below, centrifugal force

$$\frac{W\pi^2 rn^2}{900g},$$

this value of F may be substituted in the equation:

$$\frac{W\pi^2 rn^2}{900g} \times h = W \times r$$

and

$$W\pi^2 rn^2 \times h = W \times r \times 900g.$$

Therefore,

$$h = \frac{W \times r \times 900g}{W\pi^2 rn^2} = \frac{900g}{\pi^2 n^2};$$

and since $900g \div \pi^2$ is a constant, it is clear that the height of revolution, h, does not depend on the weight of the ball or the length of the arm, but on the rate of revolution. As this increases, h must diminish, just as the shortening or lengthening of the rod of an ordinary pendulum affects the number of oscillations in a given time. As h diminishes, owing to the increased speed of the engine and consequent flying outwards of the balls, the sleeve is raised, and this, acting on the links and levers, partially closes the throttle valve, and so reduces the volume of the steam and speed of the engine, as described later.

If the number of revolutions per minute are known, the value of h may be found for this class of governor by the above equation ($\pi^2 = 9{\cdot}8696$; $900g = 28{,}980$). And since $n^2 = \frac{900g}{\pi^2 \times h}$, then the number of revolutions per minute

$$n = \frac{1}{\pi},$$

The Loaded Governor. In order to enable the governor to work at a higher speed and operate the throttle valve with greater delicacy and precision, the governor is loaded by a central weight, and the relations shown by the equations for an unloaded governor then become:

$$h = \frac{900g}{\pi^2 n^2}\left(\frac{W + w}{w}\right),$$

$$n = \frac{1}{\pi}\sqrt{\frac{900g}{h}\left(\frac{W + w}{w}\right)},$$

in which W is the weight in pounds of the central weight, and w that of each ball. On comparing these equations it is clear that for any particular height of revolution, the speed of revolution is greater in the loaded than in the unloaded type; and that for any particular rate of revolution, the height, h, is less in the loaded form than in the other type. Also, the advantage in speed is represented by the ratio $\sqrt{W + w} : \sqrt{w}$. Friction has also to be considered, but both theoretical and practical demonstration show this to be a negligible quantity as $W + w$ is increased. Loading a governor either by a central weight or a spring thus provides a means of overcoming great frictional resistance.

Centrifugal Force. In considering the forces acting on the balls of a governor, allusion was made to centrifugal force, and, before proceeding further, it will be advisable to consider this force. Really the term centrifugal (Latin *centrum* = the centre, *fugio* = I fly from) is a misnomer bequeathed to us by early philosophers, who concluded that a force existed tending to drive bodies revolving in a circle away from the centre. Otherwise, they argued plausibly, how shall we explain the counterbalancing force necessary to compel a body to revolve in a circle as seen, for example, in the whirling round of a weight attached to a string. Hence, the term *centrifugal* force was used to indicate the tendency of the body to fly from the centre, and *centripetal* force to indicate the pull towards the centre, these forces being necessarily equal and, of course, opposite.

Actually, however, the tendency of such a body is to continue its motion in a straight line—*i.e.*, to obey Newton's first law, "Every body continues in a state of rest or of uniform motion in a straight line, except in so far as it is compelled to change that state by force acting on it." Therefore, at any point in the circle the body W [**218**] is forced to move in an unnatural path, and tends to move as a tangent to that circle, as at *a–b*, *c–d*, *e–f*. Remembering that the term acceleration may mean a change in *direction* as well as in velocity, the body W thus has an acceleration towards the centre of the circle, its amount being represented by $v^2 + r$; v = velocity in feet per second, and r = the radius of the circle in feet. The centrifugal force is the product of this acceleration and the mass of the body, and since the latter

$$= \frac{\text{weight of body}}{g},$$

then

$$F = \frac{Wv^2}{gr},$$

in which F represents the magnitude of the centrifugal force and W the weight of the body in pounds. As velocity

$$= \frac{2\pi r \times n}{60}$$

($2\pi r$ being the circumference of the circle, and n the number of revolutions per minute), this quantity may be squared and substituted for v^2 in the formula, thereby giving another statement for centrifugal force when the number of revolutions per minute are known.

$$F = \frac{W\pi^2 rn^2}{900g}.$$

Wherever, in engineering, revolving masses are concerned, these centre forces have to be considered, and if there exist any lack of balance in the revolving parts, the wear on the bearings, and the vibration set up, will cause considerable damage.

Bursting of Flywheels. In the governor (which *regulates* the speed of an engine), centrifugal force is utilised in the opening out of the balls, but in the flywheel (which *steadies* the speed of an engine), and other revolving wheels, centrifugal force produces a tension in the rim sufficient at times to burst the wheel, sometimes causing loss of life. Consider the rim to be divided into a great number of small sections, as in **219**. The centrifugal force for each separate section is then equal to: weight of section × $v^2 + rg$. For the whole, the aggregate of all the sections, F = weight of the rim × $v^2 \div rg$. The tensile stress, however, in the rim acting tangentially as in **218** amounts to

$$\frac{\text{weight of rim} \times v^2}{2\pi rg}.$$

The Purpose of Flywheels. The main purpose of the flywheel is to provide a reservoir of energy. In the steam engine, and also in gas and oil engines, the energy is supplied in jerks, as it were, at brief intervals, while the work to be done—the resistance to be overcome—is a constant quantity. This intermittent supply of energy is sometimes noticeable in steamers propelled by paddle-wheels as a monotonously regular forward jerk. But the enormous mass of a steamer, a locomotive, or a train is sufficient to store up the excess of energy during the period when the supply is greater than the demand, and to part with it when the resistance exceeds the power supplied. Hence, it is hardly necessary to say that a flywheel is not required in marine or locomotive engines. There is another case where a flywheel is needed —when the energy imparted is used periodically instead of regularly. Punching and shearing machines are an example of this intermittent utilisation of energy. The accumulated energy of the flywheel is sufficient to produce the operation of punching, shearing, slotting, etc., when without its aid the engine would possess insufficient power to perform these operations.

The Stored Energy of Flywheels. The energy acquired by the flywheel is called "kinetic energy." Work is performed by the flywheel in virtue of its *motion* just as the

GOVERNORS, EMERY-WHEELS AND HAMMERS

potential energy of a pile-driver enables it to perform work in virtue of its *position*. Work is done until the body possessing kinetic energy is brought to rest. The kinetic energy of a moving body of mass m

$$= \frac{m \times v^2}{2g},$$

and in the case of a wheel the velocity in feet per second

$$= \frac{2\pi r \times n}{60},$$

where n is the number of revolutions per minute. Therefore kinetic energy of flywheel

$$= \frac{m \times \left(\frac{2\pi r \times n}{60}\right)^2}{2g} = \frac{m \times 4\pi^2 r^2 \times n^2}{2g \times 3600} = \frac{m \times \pi^2 r^2 \times n^2}{2g \times 900}.$$

Inspection will show that for one particular flywheel all the quantities in this equation are constant except n. Hence the kinetic energy depends directly on the square of the number of revolutions in a minute, while for different wheels the energy is proportional to the mass and the square of the velocity.

Practical Issues. It must not be imagined that the design of an engine governor is so simple a matter as to be embodied in the formulæ just given. If such were the case, there would not be so large a number of variations in design. Many of these are veritable puzzles to the uninitiated. But if we consider for a moment or two what a governor is expected to do in the modern factory or generating station, we shall at least understand that the problems presented are not so easy of solution as they appear on first thoughts.

Conditions of Governing. The most exacting conditions are those that exist in cotton-spinning mills and in electric generating stations. A variation of about 2 per cent. in the number of revolutions per minute of a high-speed engine is as much as is consistent with steady, satisfactory working. Two per cent. is a very small margin when we remember that the governor cannot begin to act until the speed of the engine changes. Hence the necessity for responsiveness, a need which increases with speed. So that the difficulties of fitting governors instantly responsive are much more difficult of solution than they were in the old days of slow-running engines, for which the Watt governor answered well enough. A very brief account of some of the principal devices is all that can be given here, bearing in mind that however diverse the forms, the principle remains unaffected—that is, the centrifugal force and gravity must be in equilibrium. It is necessary also to mention that improvements are not wholly to be credited to the governors alone, but also to better forms of throttle-valves, as those of double-beat type, which are more delicate and precise in action than the old elliptical throttle-valve.

Crossed-arm Governors. The early type of Watt governor is shown in **217**, where h is the height of the cone, measured from the radius line r to the apex. This governor is too sensitive, because the height h varies greatly and rapidly with changes of speed. As the number of revolutions per second varies inversely as the square root of h, it is not possible for the engine to run regularly. A better form is that in which two points of suspension are provided at some distance below the apex, because as the balls rise, the apex drops, and therefore there is less effect on the height of h than in the previous case, and the balls have to move a less distance to effect a change in speed. The best form possible in this design is the crossed-arm governor [**220**], where h remains nearly constant for all variations in load. This is approximately isochronous, or astatic, a condition which is best fulfilled when the balls move in a parabolic path, and these do so nearly. But it is not a perfect governor, because it is liable to *hunt*, due to its sensitiveness. That is to say, it is too quickly responsive to minute changes, with the result that it will sometimes produce, instead of check, changes. Hence, pseudo-astatic governors, or those in which the too rapid action is checked by springs or weights, are preferred. Moreover, one essential condition to responsiveness is that the governor shall run more rapidly than the engines, so that with the high-speed engines of to-day the speeds of governors have to be very high. Some contrasts are shown by the figures.

Fig. **220** is a good pattern of crossed-arm governor, approximately astatic. It is driven by the small belt pulley A through bevel wheels B to the spindle C, carrying the crosshead D, from which the arms are suspended. The sliding sleeve E receives the connecting rods by which the vertical movements of the arms are transmitted to the lever F, the spindle G of which actuates the throttle valve in any convenient way.

Centre-weighted Governors. A much better type is the centre-weighted, or Porter, governor [**221**], made also with many variations in the details of fitting. Here—the example being by Tangyes, Ltd.—the balls are connected to rods above and below, forked to embrace the top of the vertical spindle, and the lower portion of the central weight A. As they fly outwards, therefore, they raise the weight, but their movement is also checked by its resistance. The throttle lever B is actuated as before, through a forked end, and the governor is belt driven also by the pulley and bevel gears seen below.

Spring Governors. In another large group of governors the resistance of a spring is utilised to check the opening of the balls. In these the resemblance to the Watt is not obvious. There are many, as the Hartnell [**222**], Burrell, Robey [**223**], and others. The power of the spring is adjustable. In **223** the governor controls the action of two sets of valves, as shown, with dashpots.

Slip is fatal to the accurate working of governors, hence the belt driving is often abandoned; chain driving by a Renold chain sometimes takes its place, but more often the governor is put on the crank-shaft.

Many governors exercise direct control over the slide valves through the slot links, an illustration of which occurs in **222**.

Flywheels. These are dangerous objects unless the results of centrifugal force are safeguarded in some way. Many flywheels have fractured, with results disastrous to property and fatal to life. The following are the methods adopted in modern practice.

Cast - iron Flywheels. In casting these, the first difficulty lies in the shrinkage of the metal in unequal sections. Thus, the rim alone is considered in apportioning the mass of revolving metal, the arms being neglected, as far as their mass is concerned. Their only function is the due connection of the rim with the boss, and this is a point of cardinal importance—the embodiment of sufficient strength to resist the pulling or tensile action of the rim, and to resist the effect of stresses set up by the shrinkage of the cooling metal. The latter alone has been the primary cause of many fractures of wheels, although the strength of the arms, as obtained by calculation, was ample.

Causes of Ruptured Flywheels. When a flywheel cools after casting, the rim and central boss remain hot much longer than the arms, and so continue to shrink after the arms have set rigidly. This is where the mischief occurs. The shrinking rim and boss subject the arms to mixed stresses, and the arms resist the shrinkage of the rim and boss. The net result is that though the wheel does not fracture at the time of cooling, yet it is in such a condition of internal stress or tension, that a slight excess of speed of revolution above the normal is liable to fracture it. It is a fact that the majority of flywheel fractures arise from this cause alone. Much can be done by care on the part of the designer and founder to proportion the rim, arms, and boss; or by hastening the cooling of the rim and boss, and delaying that of the arms, so that the cooling shall take place in about equal times. This is properly done in cast-iron flywheels; but as there is always an element of risk, the practice has grown of abandoning such wheels in favour of those built up in separate pieces, bolted together, and in another direction of using arms of wrought iron in rims and bosses cast around the ends of the arms.

Though, therefore, cast iron is used for wheels of small and moderate dimensions, the composite wheels are almost invariably used for those of large dimensions.

Wheels with Wrought - iron Arms. In these the arms are cut off from the bar, jagged at the ends, and inserted in the mould with the jagged ends projecting into the spaces prepared for rim and boss, and the metal is poured round the ends, so enclosing them. There are two objections to this, one being the flimsy, skeleton-like, unsightly appearance of the arms; and secondly, the real risk of the arms becoming bent by the centrifugal efforts of the rim, an accident which has frequently happened. Hence the reason why the built-up wheels have preference.

Built-up Composite Wheels. Of these there are several designs, the best of which are found in mill engines, often combined with toothed wheels. Various means of union are adopted. The rim is cast in segments, and united with cottared dowels. The arms are cast individually, and bolted to the rim across the joints of the latter, and also bolted to a central boss. Or sometimes the boss segments are cast with the arms, and bonded with wrought-iron rings to maintain them truly.

Grinding Wheels. Revolving masses are continually exercising the ingenuity of the mechanic. The modern practice of grinding as a rival to purely cutting operations has given an immense impetus to the development of the use of rapidly rotating wheels of emery, corundum, carborundum, etc. Comparisons with the old-fashioned grindstone crawling slowly round at about 100 revolutions per minute gives no manner of idea of the emery wheels of to-day. The latter run at a peripheral speed of about 5,000 ft. per minute, and this subjects them to a tensile stress tending to burst them of about 75 lb. per square inch. Of course, such wheels do sometimes fracture, but evil results rarely follow, because provision is made with a view to prevent the fragments from flying asunder. This takes two forms. In one [**224**, **225**, and **226**] the body of the wheel is so gripped by bosses that, even though it breaks, the pieces are still retained. In the other [**227**] a hood (A) encircles the wheel, excepting just at the locality where the actual grinding is being done, and so confines fractured portions.

Centrifugal force has to be carefully considered in connection with the armature windings of dynamos and motors. If these are not secured efficiently with bonds, the wires will fly outwards, and so work loose.

High-speed Shafts. A dynamical effect of much practical importance arises out of the rotation of unbalanced shafts, particularly that of crank shafts. The counterbalance weights put in the driving wheels of locomotives are carefully calculated and located to neutralise the dynamical effect of the two cranks, which are situated at right angles to each other, and by which the driving wheels are rotated through pistons and connecting-rods. They do for the crankshaft what the flywheel does for the ordinary steam engine. But for these cranks the motion of the engine would produce a succession of hammer-like blows on the rails, destructive alike to the rails and the mechanism of the engines.

The cranks of compound marine engines are balanced, but in a different way. Extensions are forged on the cranks at the side opposite to the crank.

When there are three cranks situated at angles of 120°, no counterbalancing is necessary, because the cranks balance each other round the axis.

Precautions with High-speed Pulleys. Plain shafts and pulleys, having no sensible lopsidedness, often develop wobbling or vibratory movement at high speeds. In the case of pulleys this is obviated, at the speeds at which they generally run, by balancing them in the course of manufacture on knife edges, and carefully removing metal from those portions which come to rest in the lowermost positions. This is necessary in all high-speed pulleys. But shafts, though turned truly, do at a very high speed—the *critical speed*—develop vibration which often subsides at a higher or lower speed. In such cases extra bearing support must be afforded, or the shafts must be stiffened without increasing their weight. This explains, too, why stiffness in a shaft is of greater importance than mere torsional strength. The latter alone would yield impracticable results. It also explains why steel has superseded iron for shafting in present-day design.

Pulleys and drums of great weight on light shafts inevitably set up vibrations, in spite of good balancing; hence it is necessary to lighten them where possible. In present practice, pulleys of rolled steel have largely superseded the heavier ones of cast iron; and those built of timber, lighter than steel, enjoy a rapidly growing popularity.

Hammers. Of the gravity mechanisms pure and simple, perhaps the most obvious are the pile-driving monkeys, and the steam and drop hammers. Here foot-pounds = lb. weight multiplied into the height fallen in feet, represents the dynamical effort. In either case the monkey, or the tup, is the weight usually taken as the falling weight, though in steam-hammers [**228**] the weight of the piston and piston-rod should be included. An advantage of all these mechanisms is that one of the factors is capable of variation, that of the height of fall. In the pile-driver, the winch by which the monkey is raised regulates it; in the steam-hammer it is the volume of steam admitted; in the drop-hammer the height is regulated by the belt or board.

Although we have spoken of the falling weight of a hammer only, few steam-hammers are made like this now, but the pressure of steam is introduced to accelerate the descent of the tup. This increases the speed of working, enabling many more blows to be struck in a given time, in addition to the greater dynamic effect. Hammers are made generally to operate by working a hand-lever for each blow, or self-acting, as in the type shown in **228**. Note should be made of the great relative mass of the anvil-block A, of cast iron, which is absolutely necessary to enable it to absorb the blows without excessive vibration.

The Hammer Blow. The energy of the blow of a hammer is expressed in foot-pounds, and may be ascertained by the following formula:

a = Area of piston in square inches.
p = Average pressure of steam on piston during downward stroke in pounds per square inch.
S = Stroke of piston in feet.
W = Falling weight in pounds.
E = Energy of blow after full stroke, and before striking, in foot-pounds.

$$E = (ap + W)S.$$

The velocity of the tup the instant before striking may be calculated by the following formula:

P = Total pressure on piston = pa.
F = Total force causing downward acceleration = $P + W = pa + W$.
g = Acceleration due to gravity = 32·2.
V = Velocity after full stroke and before striking, in feet per second.

$$V^2 = \frac{2FgS}{W}.$$

The force of a blow cannot be stated in terms of weight at all, because the pressure of a weight is continuous, whereas the force of a blow is expended in a moment. Messrs. B. & S. Massey, the steam-hammer makers, have, however, ascertained by careful experiments that the maximum blow of a 5-cwt. double-acting steam-hammer, with moderate steam pressure, produces a crushing effect upon a piece of hot iron as great as that produced by a load of about 30 tons, and a ½-cwt., double-acting steam-hammer, a crushing effect equal to that produced by a load of about 2½ tons.

PIANOFORTE PRACTICE

Influence of the Different Schools. Sight Reading. Pianoforte Study in England. Examinations. Memorising, Teaching, and Performing

By M. KENNEDY-FRASER

ALTHOUGH the pianoforte is a comparatively modern instrument, and had not yet ousted the harpsichord by the end of the eighteenth century, still, the keyboard music of the Elizabethan period (1600), when English harpsichord players and composers were the first in Europe, is adaptable to the modern instrument. The music of the French Couperin of a century later (1700) is a rich storehouse of dainty keyboard pieces, while his contemporaries, the Italian Scarlatti and the German Bach, are used at this day as pianoforte classics.

Grading our Teaching Material. In grading music, moreover, for *teaching* purposes we do not take it chronologically. On the contrary, we should start with the music that is easily understood at the present day, and gradually learn to appreciate the idiom of the more difficult, because more remote, classics. And here, again, it is wise to begin with the music of Clementi, who lived a century later (1800) than Couperin. Clementi's music helps to form good keyboard habits, lying easily as it does to the hand, and affording a rich supply of pleasant material for the practice of scale passages and broken chords and the like, and containing nothing eccentric. It is not, however, very exhilarating musically, and the young student must have this sort of fare interlarded with bits from the modern romantic school—Schumann's "Jugend Album," Tschaikowsky's "Jugend Album," Grieg's "Lyric Pieces," Jensen's "Wanderbilder," and the like. Easy duet playing should be begun as soon as possible, and if Mrs. Curwen's method be used for beginners—which can be highly recommended—the elementary duets in it will be found to open an easy door to the delightful world of "ensemble" playing. The study of the really great masters of pianoforte literature—Bach, Chopin, and Beethoven—must not be entered on too soon; Schumann's bigger works, his "Papillons," "Novelettes," "Fantasie-stücke," etc., should also be left to a fairly advanced stage. His music, on the whole—like that of Brahms—is not so well calculated to lead the player into good tone production as Chopin's, although there are some works that prove the exception—for special purposes.

Influence of Chopin. Chopin's influence on the player's technique is like that of Bellini's on the singer's. These both insensibly lead the student into the "bel canto" with its exquisite beauty of tone and phrasing. One may say that, as a rule, the student should study the beautiful before the characteristic.

Mendelssohn's "Songs without Words" are dainty little tone pictures suitable to lead up to more solid fare, and a useful graded edition of them is Germer's, where you will find them in the order of difficulty. Easy and graceful salon music, such as Durand's waltzes and Godard's, Schuloff's, and Chaminade's pieces, should not be neglected, especially in the pianist's early stages, as they are suggestive as to colouring, rhythm, etc. Neither should waltzes be tabooed, as they teach much in a simple way in the matter of good phrasing and good melody work, and, again, rhythmical feeling. An excellent introduction to Chopin's Nocturnes will be found in some of Field's; and the knowledge of the fact that the French Pole began his nocturne writing in imitation of the Irish pianist composer makes the comparative study of the two interesting.

Introduction to Study of Bach. The best introduction to Bach is Bach. Use his little preludes and his two-part and three-part "Inventions" sandwiched with the easy gavottes, etc., from the suites; but the study of Bach should be preceded by a good course of Scarlatti. As we have said, in the earlier stages use the lighter works of the classical school—some of Kuhlau's sonatinas can be recommended—but do not omit to couple these with short romantic pieces.

Beethoven stands as the dividing line between the purely classical and the ultra-romantic schools. The great classicists before him were Haydn and Mozart; the great romanticists after him were Schumann, Chopin, and Liszt. The latter almost completely changed the style of pianoforte playing, but they themselves were grounded in the older classical school. Liszt, the greatest pianist of the nineteenth century, was a direct pupil of Czerny, whose pupils we all are, in an indirect way, through the practice of his famous studies.

It is reported, by the way, that the master wrote these studies standing at a desk in his teaching-room, while his pupils played through what they had prepared for their lessons.

Guides to Teaching Material. As a guide to the choice of teaching material of all kinds, one should possess such a book as Eschmann-Dumur's "Guide du Jeune Pianiste," which is a catalogue of the entire repertoire of pianoforte pieces and studies graded from the earliest stages up to the virtuoso summit.

For the application of educational principles to the elementary teaching of music there is Mrs. Curwen's Teacher's Guide, in two grades, and for helps in teaching the elements of form and elucidating the emotional content one should consult such books as Carpé's "Phrasing" (Novello), Ridley Prentice's "The Musician" (a guide for pianoforte students in six grades), Knott's "Elements of Music," and Corder's "New Morley." If we buy our music (the standard works) as far as possible in volumes, we may thus form a library. The classics are cheap. Mendelssohn's *complete* pianoforte works, for instance, can be had in a beautiful edition for 7s. 6d. A complete copy of Chopin's mazurkas, the very best edition—Bote and Bock—can be had for 2s., and so with all his works. Beethoven, Schubert, Schumann, can be had on like terms. But it is a mistake to buy *miniature* editions for *study*, as they are bad for the eyes, and hinder ease in playing.

Sight Reading. As we advance we must patiently work at sight reading. In the elementary stages we may use Kunz's "Canons" (five-finger exercises in all keys), which can be used later as material for the practice of transpositions. With a fellow enthusiast let us play four-hand arrangements, beginning with easy gavottes by Rameau, Sully, etc., and persevere till we can play the symphonies of Haydn, Mozart, Schubert, Beethoven, and Schumann.

Nothing is so good for sharpening our rhythmical sense, and for acquiring and keeping up the art of sight reading, as ensemble playing of any kind. We should play accompaniments to violinists and singers whenever we have the chance. Begin with easy things. The good accompanist is rare. Schumann said that accompanying was a test of the musician. Transposition, which has already been treated in the SELF-EDUCATOR [see page 1057], should be studied, and for practising material we might get "Warriner's Transposition." In addition to the sight reading of song accompaniments we should *study* the best of the art songs, and ask the co-operation of singers. Such songs should not be approached merely from the singer's point of view—pianists will learn much from them.

The Modern Composers. There yet remains to be mentioned the pianoforte music of the latter half of the nineteenth century—that of the German Brahms, of the Scottish-Norwegian Grieg, of the Bohemian Dvorak (whose original four-hand music, "Legenden" and "Slavonic Dances," is of great value), of the Russians, Rubinstein, Tschaikowsky, Glazounow, Arensky, Rachmaninoff, Blumenfeld, Scriabine, Liadoff, and others; and that of the Parisian School—Saint-Saens, César Franck, Claude Dubussy, Mozkowski, Chaminade, etc., of the Scottish-American Edward Macdowell, whose "American Wood Idylls," "Sea Pieces," "Indian Idylls," and the like, are charming tone sketches of a light nature. The British composers since Sterndale Bennett, whose "Lake," "Millstream," and "Fountain" are alike poetic and pianistic, although they have occasionally written for the piano, have yet occupied themselves chiefly with cantatas, operas, and orchestral work, although mention must be made of Sir Alexander McKenzie's fine pianoforte concerto, the "Scottish," a work of really high rank. The younger British composers are, however, writing extensively for the piano, and among them there is not only great promise for the immediate future, but already brilliant achievement. Perhaps the new "*Edition Chas. Avison*" will do for these what "Belaieff" has done in the past for the Russian school.

Teaching. A few words now about teachers and teaching. Much is required from the pianoforte teacher. He is expected to teach alike literature and public speaking, as it were; he not only reads the classics with us, but trains us as dramatic reciters. Some teachers are strong on one side, some on the other, and some few are famed for both. Some try to make of the pupil a sound musician, some specialise in training for brilliance, some try to give technique, some interpretation. The art of tone production, or touch, till recent times, was left largely to chance. The most far-famed teacher in Europe for the last twenty years has been the Pole Leschitizky, in Vienna. He is an old man and much in request; it is not easy to get lessons from him; but he has a great number of "preparers" who work with him, giving two or three lessons a week, the master himself giving one lesson a month or so. Great artists—performers such as D'Albert, Paderewski, and others—sometimes give occasional lessons to artist pupils, but one goes to them for hints on style and interpretation, not for technical and systematic instruction. The Continental conservatoires are inexpensive—some of them, indeed, free—but although the small towns in which they are located offer advantages in the form of a musical atmosphere for the young student, the pianoforte teaching in some of them is based on out-of-date "Methods," and the lessons given are of little more than merely nominal duration; so that the student finds it necessary in many cases to pay for additional private lessons outside the institution.

Pianoforte Study in England. But, except for a perhaps cheaper and brighter life, there is no need for the ambitious pianoforte student to leave our own country; and, indeed, except for the sake of gaining a wider and more varied experience at the end of his student days, before settling down to a teaching or performing career, it is foolish of him to leave our shores, since our own schools and private teachers are really far stronger than the Continental piano teachers at present. The student must *hear* a great deal of good music; it is one of the most important factors in his education. Much good music can be heard in London and the provinces, orchestral, solo, instrumental, and vocal; and all the great performers visit us periodically. The pianoforte student must not neglect opera either, since much pianoforte music, many of Beethoven's sonatas and Chopin's compositions, for example, pre-suppose an acquaintance with dramatic diction, so to speak. The Royal Academy and the Royal College of Music can offer an all-round musical education second to none in Europe. For pianoforte playing we can nowhere get more satisfaction, more fruitful teaching, than at the Royal Academy, of which one of the professors has sent out the most complete and scientific monograph on pianoforte touch and technique (in its widest sense) that Europe or America has yet seen. We mean the author of "The Act of Touch," etc., so often quoted in these pages, Tobias Matthay, a London-born German, whose interpretative teaching is as striking as his technical in its results. Students may enter the Royal Academy for one year, but three years is understood to be a course. They may enter at any time, although the academic year begins in September. Fees are thirty-three guineas per annum. Alike at the Royal Academy and at the Royal College, there are a great number of scholarships which can be obtained by those sufficiently talented at competitions, the dates of which are duly announced. And, of course, private lessons may be obtained of all the teachers of these institutions, if the student does not wish to join one of these.

Examinations. The "Associated Board," being a joint institution of the R.A.M. and R.C.M., is consequently the most esteemed examining body. Examinations in pianoforte playing are held by it all over the country and in the Colonies at local centres. The *professional* certificates obtainable are those of the R.A.M., the Metropolitan Examinations (Licentiate), held in September and at Christmas, and those of the R.C.M. (Associateship), held at Easter. It is now quite expected that young professional musicians should pass one of these examinations, and it is difficult to obtain positions at schools without them. Students of the R.A.M. and R.C.M. can, on leaving, obtain a teaching diploma, if proved deserving of such, and R.A.M. students who greatly distinguish themselves are awarded the A.R.A.M. (Associateship).

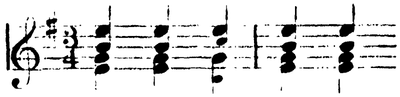
As to the preparation for examinations, even if one feels oneself fit for the work, it is safer not to hurry. We should take two years, preparing the prescribed work for both. When the stuff comes out *study* it carefully, make it our own, then lay it aside a little and take it up again to polish. Von Bülow said "there never was a piece composed yet that had no difficulties" Select difficult passages and work at them quietly and steadily; know them intimately on the keyboard and go over them always with concentrated attention. Then gradually work them in with the preceding and following bars until they are securely built into the edifice. Then beware, for although practice means that we are getting our fingers to find their keys semi-automatically, yet *we must never* let our playing get entirely automatic; it then gets dead and goes from bad to worse. We must keep the rhythm *alive*, *will* it every time we play, and quick movements will not then run away with us; we shall have them in rein.

Necessity for Regular Practice. Many students who succeed in playing a toccato-like movement fairly well at first, practise it into everything that is bad just because they do not attend to what they are playing, neither musically nor technically, and so the rhythmical grip is lost, and nothing then avails but to put the piece aside until such time as the mind can take it up afresh and give the needful vivid attention.

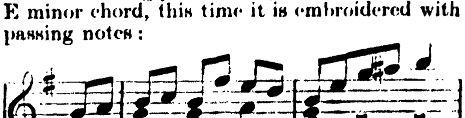
To gain endurance we must practise regularly, but with breaks; it is not wise to play more than two hours consecutively, and not even as long as this until we are well in training. Frequent quarters of an hour of tiring technical work suffice; rest brain and nerve and muscle, then return to work. Begin as early in the day as possible, and take frequent intervals for healthy outdoor exercise. The amount of practice will count for nothing unless it is *every day* begun well and kept on the right lines. We should begin with, and have frequent recourse to, the Daily Tests, quoted from Matthay's "Act of Touch" and "Relaxation Study."

The Student's Piano. Secure as good a piano as possible; it is one of our best teachers, because of the wonderful variety of tone obtainable from it. It tempts one to paint with tone. Have a grand if possible. If we can afford only an upright (a cottage), we must get the best maker we can afford; and if we cannot buy outright, all the good makers offer the three years' system, which is better than hiring. The best makers are Bechstein, Steinway, Broadwood, Erard, and Blüthner, and some of the younger English firms are also rising in public estimation.

Performing and Memorising. Lastly, about performance. If we are amateurs we should try to play simple things to perfection, and should not attempt to perform to others things that present real difficulties to ourselves. Needless to say, we must memorise one or two short lyrics and keep them polished up ready for use. It will help greatly to memorise if we first *analyse*. Let us try it, say, for Grieg's "Elfin Dance" from his first book of "Lyric Pieces." The simplicity of the material and frequent repetitions make it comparatively easy. It is in the key of E minor, and the first five chords—all of them the chord of E minor save one—give the rhythmical germ of the whole. Note the deviation at the third chord from B and E by contrary motion to C, printed in small type.

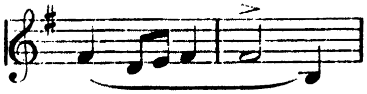


The following passage is again made out of the E minor chord, this time it is embroidered with passing notes:

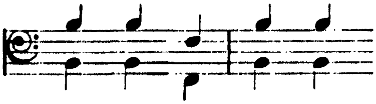


Learn each of these little bits carefully and join them together. We shall not proceed further till we have absolutely mastered these two and their connection one with another. Next follows a repetition of the opening chord motive, this time on B minor; add this to the other two.

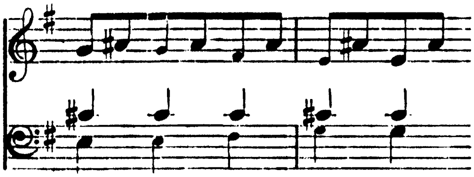
Then note specially, in what follows, the little fairy horn motive for the left hand.



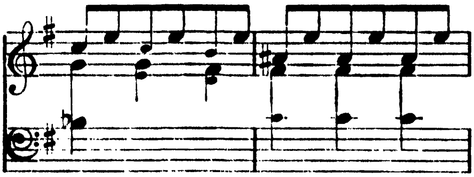
This requires very careful study and practice, and we must always *attend* to it, hearing the horns mentally before playing the passage, and listening to make sure that the horn passage really tells through the upper accompaniment. And now the whole thing is repeated. Then comes again the five-beat motive, very easy to remember this time, for it is in single notes, forming octaves between the two hands.



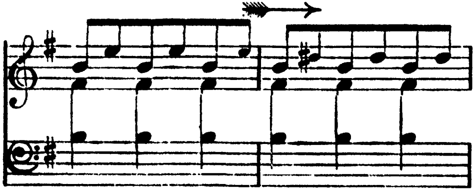
In the next passage observe that there are two persistently recurring notes, A♯ in the right hand and C♯ in the left, while the *moving* notes E, F, G, and G, F, E, are just the reverse each of the other.



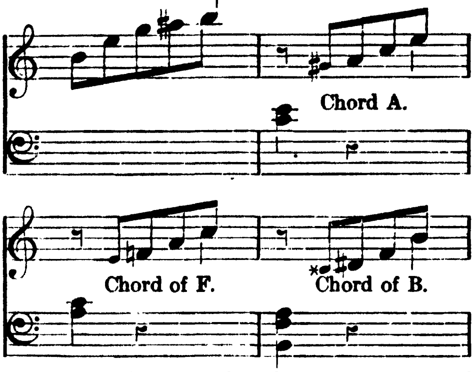
This fairy-tripping measure, after a repetition of the five elephantine footsteps, is again heard, although in the notation picture the A♯ appears now as B♭. Then follows an exact *imitation* of this a minor third higher, and still another and a higher, but this time not an *exact* imitation, for the bass here moves in *similar*, not contrary, motion to the other moving part.



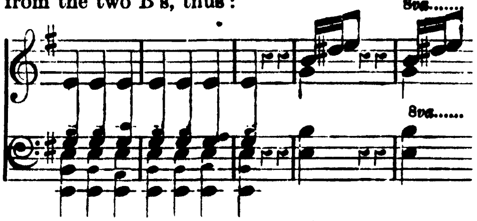
The second of this pair of bars is re-echoed in the two bars that follow, the only fresh idea being the suspension of the E over the D♯, thus:



And now all is repetition *da capo*, till we reach the last line, the coda, the tail-piece, which enters suddenly after the latter part of our second motive, imitating and re-echoing it thus "with a dying fall":



This re-echoing is based upon a series of chords, each introduced by a passing note half a tone below a note of the chord—these passing notes are printed in smaller type. Now we close with the opening chord motive, lengthened by two additional throbs, and note here again how simply variety in unity has been obtained—unity and variety have been said to be the keys to beauty—by simple deviations in contrary motion from the two B's, thus:



It concludes with these two dainty little elfin screeches on the chord of E minor with expressive interloping half-tone-below passing notes—D♯.

If we have never memorised before, we should try this, taking it quietly, perseveringly, intelligently, imaginatively, and—provided we do not let the mind wander—success is sure.

Nervousness. Most artists suffer from nervousness. If we could think more of composer and composition and less of ourselves we might get rid of it. As Matthay has pointed out, if only you succeed in really listening while you play, and realise that your audience is listening also to the *music*, and therefore not to you personally, that moment all nervousness disappears as if by magic. Practising clubs are useful. As members we may learn to play before others, which we should take every opportunity of doing. The key resistance varies on different instruments. It is well to be able to prelude that we may test this resistance sufficiently on a strange piano before beginning serious performance. We should practise preluding on series of chords and dare to improvise. If we persevere in this as in all else, what is exceedingly difficult to do at first becomes automatically easy in course of time, till we forget that we ever had to learn.

Pianoforte concluded

RADIUM AND THE WORLD

The Light Thrown by Radium upon the Origin and End of our Earth. The Rays and Energy of Radium. Radium and Life

Group 5

CHEMISTRY

14

Continued from page 1917

By Dr. C. W. SALEEBY

THE revelation of radium has led us to believe that the human race may now expect many more million years of sunlight than we had hoped for ere the discovery of radium upset the accepted cosmical time-table. The accepted view as to the sun's heat was, as we have already seen, that it is produced by a continuous gravitational shrinking of his substance. Helmholtz, Lord Kelvin, and many other physicists have addressed themselves to this problem, and the verdict passed upon humanity was that it cannot expect more than 5,000,000 years to live—probably 3,000,000 would be nearer the mark. After that, assuming that the sun received no help from anything but his own shrinkage, he would be too cold to support life upon the earth. Reasoning from similar evidence the physicists were able to assign his age to the sun; but while they declared that he may be perhaps 25,000,000 years old, the geologists declared that the crust of the earth was far older, dating from hundreds of millions of years ago. There the controversy long stood. The late Marquis of Salisbury, in his once-celebrated presidential address to the British Association, in 1894, made much of this enormous discrepancy between the two estimates. It served his purpose, which was to discredit the theory of evolution.

Is there Radium in the Sun? But if there be radium in the sun, then he has in it another and most potent source of his light and heat besides the shrinkage on which the physicists were calculating; and his age may well be as long as that which the geologists demand as necessary in the past for the formation of the earth's crust. Furthermore, if there be radium in the sun, there is no reason why he should not be vivifying a happy and fruitful earth ten or fifty or a hundred million years hence, instead of leaving posterity to die of frostbite after only three million years.

Let us glance for a moment at the reasons we have to believe that there is radium in the sun. In the first place, we have the fact, proved by Sir William Huggins and his followers, that suns and stars and comets contain just the elements that occur on the earth, the whole universe being thus made of the same material. Earth and sun were one in the nebula from which the solar system was formed, and therefore it would seem highly probable that any element occurring on the earth will also be present in the sun. A second reason for believing that there is radium in the sun is, as we have already seen, that its presence there would reconcile the disagreement between the cosmical time-tables of the geologists and the physicists, who are pluckily studying all time and all existence from the surface of this "luke-warm bullet," as Stevenson called the earth. A third reason is to be found in the fact that helium is known to be evolved from radium on the earth, and thus its presence in the sun suggests that there must be radium there also.

Electrons from the Sun. But the reader will ask whether there is not a very simple and definite manner of determining the answer to our question. If radium is truly an element, he will say, it must have a characteristic spectrum of its own. The lines characteristic of this spectrum should be recognisable in the spectrum of sunlight if radium be indeed present in the sun. Now, as a matter of fact, numerous observations have been made without obtaining any definite evidence from the spectroscope of the presence of radium in the sun. This fact, however, does not outweigh the positive arguments which we have already enumerated and others which are frequently being added to them—for it seems probable that the characteristic contributions which radium might be expected to make to the spectrum of sunlight may be absorbed by our atmosphere in such a fashion that they cannot be detected at its bottom where we live. There is, nowadays at any rate, no doubt that the sun gives out electrons just as radium does. One of the theories advanced for the formation of a comet's tail—a subject to which reference was made when discussing radiation pressure in the course on Physics—was that these electrons hit a comet and develop its tail by causing its lighter parts to stream behind it, for a comet does not develop a tail until it approaches the sun, and the tail is always turned away from the sun. The electrons given out by the sun are believed to strike our atmosphere, and thus, in certain conditions, to make the rare gas krypton that exists in the topmost layers of the atmosphere to become luminous; and that, it is believed, is the cause of the phenomenon known as the *Aurora Borealis*.

The Cooling of the Earth. But, as a matter of fact, we need not wait for a positive answer to our question—at any rate in so far as we ask it in the desire to explain the discrepancy between the two rival estimates of the age of the earth. Professor Ernest Rutherford, of the University of Montreal, the most distinguished student of Professor J. J. Thomson, of Cambridge, has gone far to solve this difficulty for us. One of the means by which Lord Kelvin estimated the age of the earth consisted in a calculation of its "secular cooling"—the rate at which the heat is radiated into space. But Lord Kelvin could not take into account, when he made that calculation, the remarkable fact lately discovered by Rutherford, which is that radium—or, at any rate, radio-active matter—is, so far as his observations have hitherto gone, a constant constituent of the materials that compose the earth's crust. Now Rutherford has calculated the proportion in which it occurs in the earth's crust, has estimated the amount of heat which such a quantity of radium must produce, and has actually shown that if his calculations be correct, the radium of the earth's crust suffices by its production of heat completely to replace and thus compensate for the heat which the earth constantly loses by radiation into space.

The Rays of Radium. Those immature atoms of helium, as we now believe them to be, which physicists call the *Alpha* rays, consist, of course, of material particles; they are not mere vibrations in the ether, like sunlight, the Röntgen rays, heat rays, electric waves, and most of the others with which readers of the course on Physics are more or less familiar. But the emission of these rays, and the production of the celebrated emanation to which they give rise, constitutes only one of the many activities of radium. There is a great deal more that goes on within the spinthariscope than the zinc sulphide paper reveals to us. The *Beta* rays, so-called, must later be discussed; but we may here dispose of the third variety of rays which are constantly being given off by radium, and which are known as the *Gamma* rays (Alpha, Beta, and Gamma are, of course, the first three letters of the Greek alphabet). Now the *Gamma* rays of radium are either identical with the Röntgen rays, which are now almost a commonplace, or are at any rate nearly identical with them. We may guess that it is the occurrence of these rays that explains the similarity, in the power of curing certain diseases, between radium and the Röntgen rays. Like these latter, the *Gamma* rays have the most extraordinary penetrating power. It is said that they can be detected after passing through five inches of armour plate. Not only does radium give out these rays, but it has the power of picking up, so to speak, any Röntgen rays that may be about. If you are looking at a piece of radium in the dark through a fluorescent screen, you may notice that it shines more brightly than before if Röntgen rays are being generated in the same room, showing that it has the power of picking them up and giving them forth again in an altered form.

What Half a Pound of Radium Would Do. But in addition to the three kinds of rays to which special names have been given, radium is ever giving out a large quantity of those rays which we call *heat*. Whatever the temperature of its surroundings, it is always a little hotter. So powerful is this action, and so nearly inexhaustible, that if you could obtain a sufficient supply of radium—probably half a pound would be quite enough—it would keep a room warm, not merely during your lifetime, but for hundreds of generations after you. We may note, however, that, as Professor Curie has remarked, one would not care to be in the same room as half a pound of radium.

Fastest Moving Matter Known. And now we turn to what are, in some respects, the most important products of radium. Like the *Alpha* rays, the *Beta* rays consist of particles. It is no easy matter to say, however, of what the particles consist. The particles that constitute the *Alpha* rays may freely be described, indeed, as particles of matter. As we have seen, they are really atomic particles. But the particles that constitute the *Beta* rays are of proportions almost infinitely smaller than those of the smallest atom. The name applied to them by their most distinguished student, Professor J. J. Thomson, is *corpuscles*: the most popular name, however, is *electrons*. These fly out from the radium at a most amazing speed. Sir Oliver Lodge has said of them, "Three hundred times faster than the fastest flying star, they are the fastest-moving matter known." Until the discovery of radium, it was thought that the greatest speed ever obtained by matter was that of certain of the "runaway stars." Arcturus, for instance—whom everyone should know who can recognise the Great Bear—moves at the rate of about one hundred miles a second, we used to be told, but that is a mere dawdle compared with the speed of these electrons.

Matter is Electricity. Now, each of these electrons or corpuscles carries with it a tiny charge of negative electricity. They are believed to be all of the same size; and the size is the same whether the electron be given out by radium or by thorium, or by uranium, or by any other radio-active substance. Hence it is that these substances are able to affect a delicate indicator of electricity; and it was by this means that Madame Curie, under the guidance of her husband, was enabled to discover radium. She began with two tons of pitch-blende, the mineral in which radium is principally found, and ended some months of hard work by obtaining one-tenth of a grain of radium. This property of affecting an electric indicator was the only guide and test that she had in tracing this minute quantity of the unknown substance for which she was seeking.

We have said that the electrons *carry* a charge of negative electricity, but now it seems probable that each of them *is* a charge of negative electricity, or, indeed, is *an atom of electricity*. And when we go on to inquire where these electrons come from, and what they are doing before they leave the radium, we reach the amazing conclusion that atoms of matter are made of atoms of electricity! As a result of the revelations of radium, not only do we know that one kind of matter may be changed into another, but we have found that matter itself consists of electricity.

The Marvels of an Atom. Readers of this and its companion course [PHYSICS] are already familiar with Lord Kelvin's estimate of the size of an atom. Roughly speaking, we may say that, if a drop of water were magnified to the size of the earth, the atoms within it would be somewhere between the size of small shot and cricket balls. This gives some faint idea of the size of an atom. But now imagine an atom of radium magnified to the size of St. Paul's Cathedral. Under such circumstances it would appear to consist of about one hundred and fifty thousand tiny particles, each of which is one of the electrons we have been speaking of, and the size of those electrons would be about the size of this dot, called a full stop, or period (.). Try and realise, if you can, from Lord Kelvin's illustration, what the size of an atom is, and then try to realise that the ratio of an atom to an electron—the ratio of an atom of matter to one of its constituent atoms of electricity—is the ratio of St. Paul's Cathedral to a full stop. Obviously one hundred and fifty thousand full stops would not fill St. Paul's Cathedral. And so far away from one another are the electrons in an atom that the distance is comparable to the distance between the planets of the solar system. Relatively to their size, the electrons are as far from one another in this inconceivably tiny atom as the earth is from Mars, which has an average distance from us of sixty millions of miles.

The Atom and the Solar System. This is by no means the only resemblance between an atom—or atomic system, as we should call it—and the solar system. Just as the planets are revolving round a centre, so the electrons in each of the atoms that go to make up those planets are also revolving round an atomic centre—revolving at a speed hundreds of times faster than the speed of the planets which they compose. And it is supposed that the electrons are constantly colliding with one another in their mad race within the atom, and the result of these collisions is to expel some of them from the atomic system. The electrons thus expelled constitute the *Beta* rays of radium. So small are the electrons, as compared with the atoms of ordinary matter, and so great is their velocity, that they pass through such a substance as the brass tube of the spinthariscope almost as if it were not there. The *Alpha* rays consist of bigger particles, and they are stopped with ease, but the *Beta* rays need a considerable thickness of matter to arrest them. But when they are arrested they can be shot forth again, just as they were from the radium itself. This explains the fact that ordinary substances, such as glass, which have been kept near radium, themselves become radio-active after a time. And this is what makes one think that there is an analogy between radium and genius. Both get their energy from within, and both can impart some degree of their powers to their neighbours.

A New Source of Energy. This property of evolving power within itself is one of the most extraordinary facts about radium. At first it was thought to get its power from sunlight, or from some sort of unknown waves in the ether. Then Sir William Crookes thought that the molecules in the air might constantly be striking the radium and so be imparting energy to it. But now we know that the energy of radium is derived from the motion of its electrons. And this is a new source of energy, greater than any which has hitherto been known.

The ingenious suggestion of Sir William Crookes that radium takes up the kinetic energy of the gases of the air is now known not to meet the requirements of the case. The view of Lord Kelvin that radium obtains its power by absorption of sunlight or of some other form of waves —known or unknown—in the ether has been abandoned even by its distinguished author, who has given his adherence to another view, now established beyond dispute and known as the *disintegration theory*. This is the theory the truth of which we have assumed all along. It is the view which asserts that the atom of radium itself is the seat of gigantic energies which are quite adequate to explain all the energy-producing properties of radium, without the need of any assumption that the radium really obtains its energy from without. This theory further maintains that the external energies of radium can be manifested only at the cost of its internal energies. If, indeed, this were not so there would be doubt thrown upon the doctrine of the conservation of energy. Thus, we believe it is only in virtue of the disintegration of its atoms that radium is enabled to exercise its remarkable properties. Hence the name of this theory.

Radio-activity is Universal. Radium is, of course, by far the most powerfully radio-active of all known bodies. It can be obtained with a radio-activity considerably more than a million times as great as that of uranium. Thorium also is very definitely radio-active. To these we may add the names of polonium and actinium, so-called, though there is now little doubt that these are merely names for the transient products of the disintegration of the radium atom.

But the truth is beginning to be recognised that radio-activity is not confined to the obviously radio-active elements. The wider our inquiry the more certain does it appear that radio-activity may be found wherever we look closely enough for it. Even ordinary air is radio-active, while the soil-air and that found in cellars and caves is still more so. Deep well-water at Cambridge was found to be radio-active, and then the waters at Bath and in many other places. There are, of course, two possible explanations of this fact. It may be, in the first place, that minute traces of radium or of one of the other markedly radio-active elements are distributed throughout all other forms of matter. Or, on the other hand, it may be that all matter is radio-active in itself. But if this be so, how are we to explain the very marked differences in the degree with which this property is manifested? The explanation is not far to seek. The three most markedly radio-active of all the elements are the heaviest three elements. Radio-activity must be regarded as an intrinsic property of large and complex atoms. Of course, these terms are relative, and there is no inherent reason why we should suppose that even the simplest and smallest atoms, such as those of hydrogen and helium, are destitute of this property. But if radio-activity be an indication and consequence of the disintegration of the atom, it is only reasonable that it should be manifested in greatest degree by those very heavy and complex atoms which have a very long range of consecutive change before they are resolved into simpler bodies.

Radium and Natural Selection. In a previous paragraph we hinted very briefly that the law which Darwin called *Natural Selection*, and Herbert Spencer called the *Survival of the Fittest*, may possibly have its realm of application in chemistry as well as in biology. We can readily understand how it might be applied to chemical compounds: innumerable compounds may be formed in the universe, but only the more stable ones will tend to persist.

Now that radium has revealed to us an entirely new conception of the origin and history of atoms, the question arises whether natural selection is not also applicable to them. The idea of natural selection is far older—ages older, indeed—than Darwin's application of it to organisms in 1859, or Spencer's application of it to societies eight years before. Indeed, the very first occurrence of this idea, so far as can be discovered, must be credited to the great Greek thinker, Empedocles, the most distinguished pupil of Democritus, whom we have already described as the veritable founder of the atomic theory. Reflecting upon the atoms conceived by his master, Empedocles is reported to have thought that innumerable species of atoms would be born, but that only those would survive which were best adapted to the conditions of the environment. Thus it was of atoms that the idea of the survival of the fittest was first conceived, and it is again to atoms that it has most lately been applied. The obvious reason why there is so little radium in the world is that its atom is unstable. Specimens of it are constantly being produced, but they cannot survive in the conditions in which they find themselves. We must thus regard the seventy-five or eighty different kinds of atoms with which we are acquainted as the more or less stable survivors from an absolutely indefinite number of possible atoms, most of which may have come into existence again and again, but which, like the dodo or the mammoth, have been exterminated by natural selection.

The Small Supply of Radium. The reader who realises that in radium we have discovered a source of almost inexhaustible power may be inclined to ask to what uses it has been turned. But in the first place it is necessary to note that the total amount of radium that has hitherto been isolated is extremely small. The use of the word *isolated* leads us to observe, in passing, that radium has not yet been obtained in its elemental form. It is known merely in the form of its simpler compounds, especially the chloride and bromide. But even of these the total amount yet obtained is almost ridiculously small. The difficulties of obtaining them are enormous, and though the process has been considerably improved since Madame Curie first performed it, it has been calculated that there is not much more than one gramme of pure radium salt in the world—that is to say, about 15 grains, worth about £3,000. Even this minute quantity exists only in the form of a few milligrammes here and a few there. Thus, whilst we may easily demonstrate that, let us say, half a pound of radium would drive an ocean liner for decades or centuries, the realisation of such speculations is not within the range of practice. Hitherto the direct utilisation of the energy of radium has been accomplished only for purposes of demonstration, as, for instance, in the radium clock. But, as we have already noted, radium has been turned to practical purposes in medicine and surgery.

Radium and Living Matter. Needless to say, the action of radium upon different forms of living matter has been the subject of close inquiry during the last few years. So far as the very lowest forms of life are concerned, it seems that under certain conditions radium acts as an antiseptic, though not a particularly potent one. Its powers in this direction have certainly been exaggerated. On the other hand, it is quite certain that, under particular conditions which we do not yet understand, the very radium which in other circumstances destroys malignant tumours, has a tendency to produce them, apparently having a stimulant action upon certain forms of living matter. The same paradoxical facts have been observed in the case of the Röntgen rays. It would certainly be an amazing thing if radium did not exert certain influences upon living matter. If we consider that everything in its neighbourhood is exposed to the constant evolution of heat, to a constant bombardment by particles of atomic size, and by the sub-atomic negatively electrified particles which we call electrons, and also to the constant reception of the *Gamma* rays, we can scarcely doubt that living matter may be very markedly and very variously affected by its influence.

How did Life Come to Earth? A sensational contribution to this subject has lately been made by Mr. Butler Burke, working at the Cavendish Laboratory of the University of Cambridge. Without venturing too far into biology, we may remind the reader that all forms of life are supposed to arise at the present day exclusively from pre-existing forms of life. Thus, it becomes a question how life first arose upon the planet: whether the primal origin of life was miraculous; whether, as Lord Kelvin suggested, the first germs of life were borne to the earth on a meteorite from the "moss-grown ruins of another world," or whether life first arose by natural processes from lifeless matter—if, indeed, it does not now so arise? But experiments undertaken to solve this last question—the question of spontaneous generation—seemed to show that life does not and cannot so arise in lifeless matter; and this was a most anomalous and inexplicable result for those who believed in the uniformity of Nature. Dr. Charlton Bastian, F.R.S., has persistently denied from the first the soundness of the logic with which these experiments were interpreted, but he was ignored.

Living and Dead Matter. Lately, however, Mr. Burke began to attack the subject, and the considerations which led him to it are of such interest to the philosophic student of chemistry that we may discuss them here. In 1875, Professor E. Pflüger, of Bonn, after many experiments and much thought, concluded that the difference between the living proteid molecule and the dead proteid molecule, such as a molecule of white of egg, lies in the manner of their oxidation. White of egg can be oxidised, or burned, if energy be granted it from outside. The living proteids of protoplasm undergo intra-molecular oxidation, in virtue, said Pflüger, of some unknown source of energy which imparts internal power to the molecule. Pflüger suggested that the chemical body called cyanogen (CN), the simplest possible compound of carbon and nitrogen, might be the source of the internal activity of the living molecule. Cyanogen occurs in all living matter, and it can be produced at incandescent heat. Hence, this was at least one theory which was compatible with the origin of life upon the heated earth of the remote past. Now Mr. Burke—who has been working in seclusion for 10 years—attempted to put Pflüger's theory to the proof. But he found that the intimate union of cyanogen with the most likely substances produced no results. Pflüger was wrong. But, nevertheless, Pflüger may have been right in his theory—wrong merely in seeking to apply it to cyanogen. Pflüger knew nothing of radium, which is a source of potential energy millions of times more abundant than even that of the active cyanogen radicle.

Cyanogen, we have already seen, is produced at incandescent heat, and was thus suggested as the prime source of the molecular energy which resulted in life a hundred million years ago, to quote an estimate of Lord Kelvin's. But radio-activity is manifested at equally high temperatures, and though it is now known that radium exists for but a few thousand years, yet it is being constantly evolved from uranium; and indeed, radio-activity is probably a property of all matter. Doubtless, then, radio-activity was in force on the earth a hundred million years ago.

An Extraordinary Discovery. But radium, the most radio-active of substances, only occurs to the extent of a few grains in a ton of pitch-blende, and so Mr. Burke's first proceeding was to obtain some radium in a much more concentrated form than—so far as we know—it ever occurs in Nature, and to see whether, under the most favourable conditions, such radium could impart to proteid molecules that internal energy which Pflüger declared to be the great characteristic of the living molecule.

For this purpose Mr. Burke prepared solutions of beef gelatin, usually known to the bacteriologist as bouillon, and sought to observe the action of radium upon them. So extraordinary and seemingly incredible was the result that he was compelled to devise a number of experiments in order to test it. He found that various radio-active bodies besides radium induced the same sequence of events; but we may continue to speak of radium alone, merely noting that the results may be assumed to be due to that property of radio-activity which radium possesses in pre-eminent degree, but which is displayed by the constituents of earth and sea and air alike—a fact of the first importance in this connection.

Mr. Burke found that when a few grains of radium chloride or radium bromide were sprinkled upon the surface of beef gelatin, the whole being subjected to the most efficient processes of sterilisation, such as no known form of living matter can survive, there appeared in the tubes thus treated (but not in the "control" tubes, which were similar in all respects save for the addition of the radium) a growth which any bacteriologist would have pronounced to be due to bacteria; this in tubes which had been subjected to a temperature of 130° C. under high pressure for half an hour! If anything was out of the question, it was that this growth was bacterial. However, crystals grow, and this might be a hitherto unknown kind of crystal, due to the action of radio-activity upon beef gelatin.

Growth Induced by Radium. The next step was plainly to examine a portion of the growth under the microscope. A magnification of about 1,200 or 1,500 diameters was used, and the growth was seen to consist of exceedingly small, rounded bodies, containing a somewhat darker structure in the centre. The only known crystal they resembled was a form in which calcium carbonate occasionally occurs; but these bodies were many times smaller than any such crystals, and the structure they contained looked exactly like the nucleus of a living cell, such as is not seen in these crystals of carbonate of lime; examination with the polariscope showed that these bodies had none of the characters which crystals display on such examination by special kinds of light. Thus there was abundant evidence to negative the view that they were crystals—evidence that would suffice even were there not positive evidence the most astounding in proof of the view that they were something else.

Organisms or Crystals? The results were submitted to one of the leading bacteriologists of the day, who, failing to find any defect of technique in the sterilisation of the tubes, examined the growths under the microscope, and pronounced the opinion that these objects were not bacteria. It was found that they had nuclei—unlike any known bacterium; it was found that they were soluble in warm water of a lower temperature than that in which bacteria dissolve; and it was found that they disappeared from the microscopic slides when these were exposed to diffused daylight, but returned after a few days in darkness. This is not the way with bacteria; when they dissolve there is an end of them—they are dead. But these things dissolve in daylight and reappear in the dark.

If, then, these things are not crystals and not bacteria, are they some new form of living matter produced by the action of sterilised radium on sterilised gelatin? It is found that when a portion of the growth is removed from the original tube, and placed—with aseptic precautions—on fresh sterilised gelatin, it continues to grow, though it would appear to have been removed from the action of the radium. Similarly, we saw that these objects reappeared on slides from which they had disappeared. Thus it would appear as if the radium had initiated a process which can continue without its assistance. But the most striking fact is yet to come.

Radiobes. Mr. Burke found that these objects, which he calls *radiobes* (from radium and Greek *bios*, life), never grew beyond a certain limited size, about one seventy-thousandth of an inch in diameter. When this limit is reached, they divide. This subdivision has been photographed, and is not open to dispute. Now, we believe that nothing but matter which is alive—in the strict biological sense—undergoes that "continuous adjustment of internal to external relations" which is implied in the act of subdivision when a certain size is reached. Herbert Spencer, who framed that profound definition of life which has just been quoted, was led to ask why living cells ever divide, why their size is always limited. He answered that the surface of a cell must always bear such a proportion to its mass that sufficient nutriment can pass through it. The larger the cell the smaller the ratio of its superficial extent to the mass—or, in metaphor, the bigger the body the smaller its mouth. Hence, the cell must divide its mass, thus greatly increasing its surface, and enabling growth to continue. It is a typical case of the adjustment of inner to outer relations; and, judged by this comprehensive but strict definition of life, the objects produced by the action of sterilised radium on sterilised bouillon are alive—they are *radiobes*.

A Theory of the Origin of Life. The beef gelatin of Mr. Burke's experiments was exposed, as we have observed, to much more potent radio-activity than is to be found in nature. But that which much radio-activity can do in twenty-four hours, a little radio-activity, such as that of the earth and sea-water, may do in, say, a hundred thousand years. Why not? May not life have originated, then, by the prolonged action of radio-activity upon those inorganic substances of earth or sea, which contain oxygen, carbon, and nitrogen? (In a previous section, we noted Dr. Bastian's demonstration that sulphur and phosphorus are not, as was formerly thought, essential to living matter.) Obviously, this question cannot be answered save by the lapse of time. There may be the highest probability, but not demonstration. Mr. Burke is contemplating, however, certain experiments which may be entrusted to the care of the authorities of the British Museum or some other responsible body, and which may ultimately enable the question to be answered.

The Limits of the Conclusion. Assuming for the present that Mr. Burke's experiments have the significance which he attaches to them, let us carefully delimit the measure of what they have demonstrated. Because certain radium salts, in the hands of living man, can produce life in lifeless media which have been derived from the living ox, we may not claim to have explained the origin of life on the lifeless earth, where neither man, nor beef gelatin, nor chemical laboratories were to be found. It is true that synthetic chemistry may very soon be able to build up the constituents of beef gelatin from their elements; but even if this were so, *intelligence* would still have to be reckoned with in Mr. Burke's experiments: and it is proposed to deny the action of intelligence in the first origin of life upon our planet. Only the very hasty and illogical, therefore, will jump to the conclusion that, even at their highest valuation, Mr. Burke's experiments have solved the age-long question. At the most, they have merely shown that life may arise under certain conditions in so-called lifeless matter.

The Old Definition of Life. The most striking fact of the controversy which still rages, and will probably long continue to rage, about this subject is the difficulty of framing an adequate definition of life. The truth is that the whole interest of the controversy, for nearly all of us, lies in the assumption that there *is* an essential difference between the living and the lifeless. It dates from the time when men talked of dead matter, and shared Plato's contempt for "brute" matter. But let us just consider the case of radium itself in this connection, quite apart from Mr. Burke's experiments. The old definition of life, which we owe to St. Thomas Aquinas, was that life is *self-movement;* and when we come to analyse the various definitions that have been framed since his time, we find that this is the essential idea of most of them. Yet, if life is self-movement, what are we to say of radium itself? It answers precisely to the definition. Its atoms are in a state of the most energetic and complicated movement, which owes absolutely nothing whatever to the incidence of external energies upon them, but which, on the contrary, causes them to radiate energy.

The New Definition of Life. We are very far here from maintaining that the atom of radium is alive in the sense that the living cell is alive. But we would insist upon this: that, in the light of the revelations of radium as to the structure of matter—and entirely without reference to the work of Mr. Burke—it is no longer possible to hold that there is an abysmal gap between living and lifeless matter. Radium has taught us that so-called dead or brute matter is, in a sense, very much alive; and we may very gravely doubt whether any definition of life can now be framed that includes all the known forms of admittedly living matter whilst excluding all those forms of matter which are generally regarded as lifeless.

So much for one of the many contributions of radium to the philosophy of science. The reader who is interested in the subject, and especially in the relations of recent discovery to the theory of universal evolution, may be referred to the present writer's book, "Evolution the Master-Key" (Harper & Bros., 1906), where a fuller treatment of the subject is possible.

EXAMINATION TEXTBOOKS

Examinations for the Institute of British Architects—continued. The "Final." List of Helpful Textbooks for Examination Candidates

By GASPARD TOURNIER

Final Examination. The preliminary work submitted for the final examination by the Royal Society of British Architects is to be on sheets half double-elephant size, 27 in. by 20 in. [See page 1912.]

1. A study of ornament from the round, shaded.
2. A set of working drawings of a design by the candidate of a building of moderate size, such as a country house, a school, or local institution; everything usual on finished working drawings to be shown, including drainage, also some leading details on a larger scale, and a perspective of the exterior.
3. Drawings of some historical building, or part of one, made from actual measurement, with details and figures denoted, accompanied by the original figured sketches plotted on the spot.
4. A sheet of diagrams of constructive masonry or brickwork, such as arches or groined vaults.
5. One sheet of diagrams of a roof truss of steel, 40 ft. span or over, with large scale details and calculations of the strength of each part worked out.
6. An adequate number of sketchbooks or other satisfactory evidences of having followed the carrying out of building works, with notes and sketches of the progress and conduct of such works, and of the study of buildings and travel.

Textbooks. The examination starts with the designing of a stated building of moderate size, which the candidate has to do, such as a golf club-house, parsonage, cottage hospital, or a part of a more important edifice, with constructive details and ornament, and a sketch of the exterior in perspective. The subject will be communicated in general terms to the candidate some days before the sitting. This item has allotted to it 350 possible marks out of a total of 1,000 for the entire examination, so that it is of primal importance.

For remaining subjects the student should consult the textbooks, to which matter we will now refer. At the end of the written examination there is an oral one on the same lines as that of the Intermediate.

"INTERMEDIATE" TEXTBOOKS.

In these modern days the number of textbooks for the Intermediate Examination is very great. Many excellent books cover the same ground in one way or another, but none can, from the nature of things, give all that is required in every direction, nor quite point out the distinction between essentials and non-essentials, or foresee and remove the stumbling-blocks of each student. No one can hope to be engineered through any course of study by books alone without individual help as he proceeds.

The following books can be recommended in the Intermediate Examination.

Classic Architecture and its Ornament. "The Orders of Architecture," by *R. Phené Spiers*; ditto by *C. Normand*; "Civil Architecture," by *Sir W. Chambers*; "Ornamental Sculpture," by *L. Vulliamy*; "Classic Ornament," by *H. D'Espony*; "The Architecture of Greece and Rome," by *W. J. Anderson* and *R. Phené Spiers*.

Gothic Architecture and its Ornament. The Works of *A. Pugin*; "The Analysis of Gothic Architecture," by *R.* and *J. A. Brandon*; "The Glossary of Terms used in Grecian, Roman, Italian, and Gothic Architecture," by *J. H. Parker*; the Works of *J. K. Colling*, "Architectural Parallels," by *Edmund Sharpe*, "The Styles of Architecture in England," by *T. Rickman*; "Historic Ornament," by *R. Glazier*.

History of Architecture. "The History of Architecture in all Countries," by *J. Fergusson*; "The Principles of Design," by *E. L. Garbett* (Weale's Series); "Lectures on Mediæval Architecture," by *Sir G. G. Scott*; "History of Architecture on the Comparative Method," by *Banister Fletcher*; "Histoire de la Vie et des Ouvrages des plus célèbres Architectes," by *A. C. Quatremère de Quincy*; "Histoire Générale de l'Architecture," by *D. Ramée*; "History of Architecture," by *A. D. F. Hamlin*; "Architecture of the Renaissance in Italy," by *W. J. Anderson*; "Early Renaissance in England," by *J. A. Gotch*.

Building Materials and Construction. "Builders' Work" and "The Building Trades," by *H. C. Seddon*; "Notes on Building Construction" (vols. i., ii., iii.), published by Rivington; "Tredgold's Elementary Principles of Carpentry," Ed. *J. T. Hurst*; "Foundations and Concrete Works," by *E. Dobson*; "The Construction of Roofs, Wood and Iron," by *E. W. Tarn*; "The Joints Made and Used by Builders," by *W. J. Christy* (the last three in Weale's Series); "The Strength of Materials and Structures," by *Sir John Anderson*; "Practical Masonry," by *W. R. Purchase*; "Practical Building Construction," by *J. A. Allen*; "Building Construction," by *C. F. Mitchell*; "Modern Practical Joinery," by *G. Ellis*; "Strains in Structures," by *Middleton*

Geometry and Projection. "The Rudiments of Masonry and Stone Cutting," by *E. Dobson*; "Descriptive Geometry," by *J. F. Heather* (both in Weale's Series); "Practical Geometry," by *E. W. Tarn*; "Geometry," by *Rawle*.

Books of general reference useful over the whole ground are: "The Encyclopædia of Architecture," by *Gwilt* (1888 edition); "The Dictionary of Architecture"; also reference pocketbooks, such as *Hurst's* and *William Young's*, published by Spon.

"FINAL" TEXTBOOKS.

Many of the books mentioned carry the reader further than the Intermediate Examination, and serve towards the Final one. In addition to these the following works are more specialised:

Classic Style and its Derivatives. "Temples at Ægina and Bassæ," by *C. R. Cockerell*; "Principles of Athenian Architecture," by *F. C. Penrose*; "Antiquities of Athens," by *Stuart* and *Revett*; "Antiquities of Ionia," published by the Dilettanti Society; "Magna Græcia," by *W. Wilkins*; "Erechtheum," by *H. W. Inwood*; "Palace of Diocletian at Spalatro"; "Palmyra and Baalbec," by *Wood* and *Dawkins*; "Constantinople," by *W. Salzenburg*; "Byzantine Architecture," by *Texier* and *Pullan*; "Architectural Antiquities of Rome," by *Taylor* and *Cresy*; "Edifices de Rome moderne," by *L. Letaroüilly*; "Renaissance in France," by *A. Berty*; "Motifs Historiques," by *C. Daly*; "Brick and Marble," by *G. E. Street*; "Later Renaissance Architecture in England," by *Belcher* and *Macartney*; "Historic Ornament," by *J. Ward*; "Italian Renaissance," by *G. J. Oakeshott*; "Renaissance Architecture in England," by *R. Blomfield*; "London Churches," by *G. H. Birch*; "English Interior Woodwork," by *H. Tanner*; "Architectural Works of Inigo Jones," by *Inigo Triggs* and *H. Tanner*.

Gothic Subjects. "Analysis of Ancient Domestic Architecture," by *Dollman* and *Jobbins*; "Churches of the Middle Ages," by *Bowman* and *Crowther*; "Dictionnaire Raisonné de l'Architecture Française," by *Viollet-le-Duc*; "Gothic Architecture," by *T. Rickman*; "Gothic Mouldings," by *F. A. Paley*; "Decorated Window Tracery," by *E. Sharp*; "Vaulting," by *R. Willis* (Transactions of R.I.B.A., 1842); "History of Gothic Architecture," by *E. S. Prior*; "The Open Timber Roofs of the Middle Ages," by *R.* and *J. A. Brandon*; "Architecture du V^e au XVII^e Siècle," by *J. Gailhabaud*; "Study Book of Mediæval Architecture," by *T. H. King*.

Materials in their Nature and Application. "Treatise on Building and Ornamental Stones," by *E. Hull*; "Timber and Timber Trees," by *T. Laslett*; "Timber and Some of its Diseases," by *H. Marshall Ward*; "Building Materials; their Nature, Properties, and Manufacture," by *G. A. T. Middleton*; "Decorative Plaster-work," by *Millar*.

Sanitary Science. "Annotated Model Bye-laws," by *Knight*; "Plumbing Practice," by *Clark*; "Sanitary Engineering," by *E. C. S. Moore*; "The Soil in Relation to Health," by *Miers* and *Crosskey*; "Healthy Dwellings," by *Sir Douglas Galton*; "Sanitary House Drainage," by *T. E. Coleman*; "Practical Hygiene," by *E. A. Parkes*.

Land and Site Surveying. "Mensuration," by *Baker* (Weale's Series); "Practical Trigonometry," by *Adams*; "Surveying and its Instruments," by *Middleton*; "Surveying and Levelling" and "Field Work and Instruments," by *Walmisley* (both in the technical series published at "The Builder" Office).

Strength of Materials and Construction. "Shoring and Underpinning," by *C. H. Stock*; "Carpenter's and Joiner's Assistant," by *J. Newlands*; "The Science of Building," by *E. W. Tarn*; "Practical Treatise on Strength of Materials," by *T. Box*; "Strains in Ironwork," by *Adams*; "Notes on Building Construction" (vol. iv.), published by Rivington; "The Principles of Graphic Statics," by *G. S. Clarke*; "Testing of Materials," by *W. C. Unwin*.

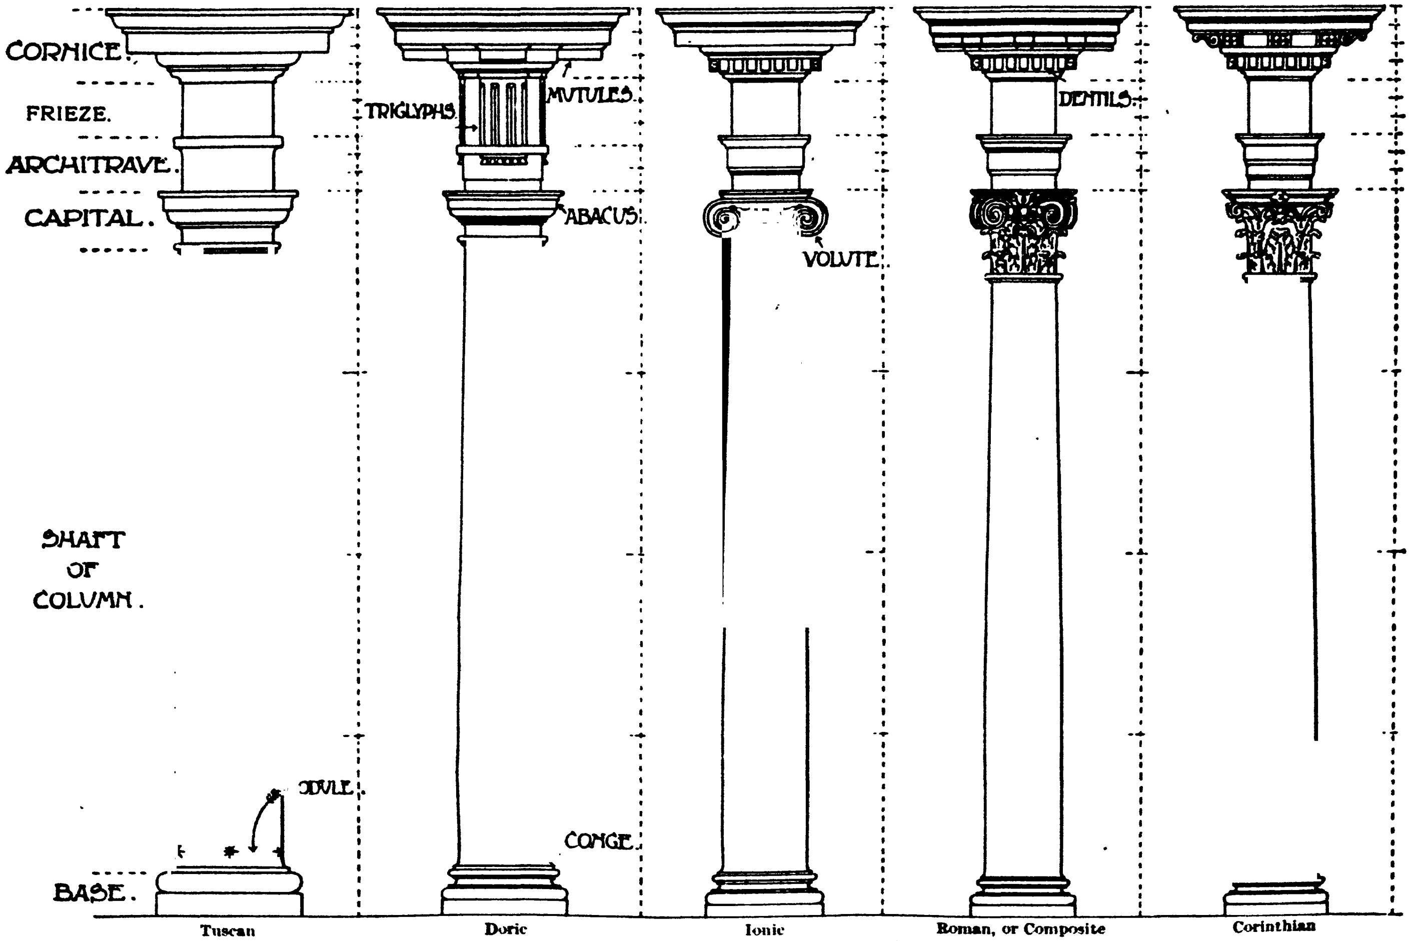
Specifications and Contracts. "The Architect's Legal Handbook," by *Jenkins* and *Raymond*; "The Schedule of Conditions for Building Contracts," issued by the Royal Institute of British Architects; "The London Building Acts," "Building Leases and Building Contracts," by *A. Emden*; "Architect's Liabilities," by the same writer; "Ancient Lights," by *Holden*; "Dilapidations," by *Banister Fletcher*, and "R.I.B.A. Handbook" on the same subject; "Student's Guide to Measuring and Valuing Artificer's Works," by *Dobson* and *Tarn*; Works by *J. Leaning* on Quantity Surveying and Specifications; "How to Estimate," by *J. T. Rea*; "Specifications in Detail," by *F. W. Macey*; "Approximate Estimates," by *Colman*.

For the study of Planning, the contemporary illustrated architectural periodicals give the best help, as types keep constantly advancing with the evolution of public wants and change of opinion on the best method of meeting them.

Many of the books in these lists are costly. Students who have passed the Royal Institute of British Architects' preliminary examination have the use of the Institute's library and its loan collection of books, and a large number of the books are available at the public libraries. There is also a loan library at the Architectural Association.

Course of Study. Having stated the branches of knowledge required by an architect, and their scope, we have now to indicate the course the student is advised to pursue for acquiring them.

The old-fashioned indentured pupilage is no longer recommended, for it is now frankly admitted by most architects that it is impossible for an architect in fair practice to give any time to teaching pupils; consequently what tuition the student ever gets in an office is scant and promiscuous. In the drawing department it is largely dependent on the individual good-nature of the assistant draughtsmen, who have work of their own to do needing much concentration and generally under pressure of time. The same objection occurs in the business branch, where the secretary or clerk is still less willing to add to his duties the functions of a teacher; so that the student is generally put to



THE ROMAN ORDERS OF ARCHITECTURE
Outlines from Sir William Chambers's Treatise on Architecture

tracing plans or going on sites to hold the measuring tape, etc.—excellent things for a start, but usually continued far beyond a reasonable time for learning such simple matters. The result is that many office pupils fritter and waste away the years of their indentures, and those who do not are obliged to have recourse to evening classes and night study, which, however buoyed up by enthusiasm a youth may be, often undermines his constitution.

Day Schools in London. There are now three architectural day schools in London for students wishing to follow architecture, and they are recommended to start with one of them.

The first is at University College, Gower Street; the second, at King's College, Strand; and the third, organised by the Architectural Association at 18, Tufton Street, Westminster. The fees per year total alike—namely, 45 guineas. The course in each institution varies as to detail, but all are planned on well-considered lines which are alike in essence and in efficient thoroughness. Broadly, it consists of lectures, and the remaining time is spent in the studio or workshop.

Take, for instance, the curriculum at the Architectural Association. In the studio during the first year are taught scale and freehand drawing, the elements of perspective, the orders of architecture, the elements of architectural styles, the elements of construction, and the drawing of portions of existing buildings by measurements. The lectures are on the following subjects: (1) The historical development of architecture, illustrated by visits to buildings and museums; (2) construction and materials, illustrated by visits to workshops and buildings in progress; (3) elements of ironwork. Their object is to link the lectures with the studio work and workshop demonstrations.

The Student's Course of Reading. The student is also given a course of reading for himself, directed by the master, to whom he can at all times refer for explanations and for that aid in distinguishing between essentials and non-essentials which the tyro can never do for himself. In the studio also no time is wasted by constant repetitions of facts already learnt; and there the student gets more real supervision than can ever be given him in an office.

Time spent under these conditions also enables a teacher to find out early whether the student's talents and tastes really fit him to become an architect; so that, in the event of his incapacity, the waste of a life may be averted.

The day-school course at the Architectural Association covers two years, at the end of which time the student is advised to move into the evening continuation classes. At University College and King's College the course lasts three years. It does not follow that the student need now be indentured to an office; many never are. Some are engaged as improvers.

Office Work. But an office, except for the higher-graded assistants, is necessarily a place where one has mainly to practise what one knows quite well already. The work turned out must be expert, not tentative, and therefore, for a young man, more recapitulatory than progressive. So, although a period of office work is desirable at this stage, further outside study is necessary, and later a course at the Royal Academy School, where the artistic branches of architecture are specially studied, is much to be recommended. Eventually the student enters an office as a responsible assistant, and a man should hold this position for several years before thinking of practising for himself. To do that before he is thirty years of age is not advisable. The pitfalls in the path of a practising architect are numberless, and those who undertake the risks too soon are courting failure for life.

Opportunities in Provincial Towns. Up to now we have had in mind students living in London, and, with more or less modifications, those in leading provincial towns, such as Liverpool, where the University College provides an architectural course. Most of the large towns have architectural societies, affiliated to the Royal Institute of British Architects, whose secretaries will be pleased to give reliable directions as to the educational resources available, and as to the choice of an office for pupilage—which must be the initial procedure in places lacking other advantages.

In smaller towns the student should avail himself of the local polytechnic and art classes as best he can. In a small town, with an architect of the right sort, and one who has a practice which, though small, is general in its scope, a student often gets a good start by being in a position of more intimacy, and with more chances for working his way forward in all the branches. But he must, of course, move later to where he can obtain wider opportunities for learning.

MAMMALS IN AIR AND WATER

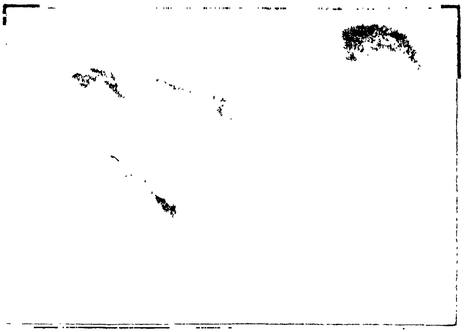
Parachuting Squirrels and Insect-eaters. Bats. Swimming Opossums. The Hippopotamus. Water Rats. The Walrus, Sea-lion, and Whales

continued from page 1871

By Professor J. R. AINSWORTH DAVIS

Parachuting Mammals. As elsewhere remarked, flying organs in their early stages of evolution were not used for the purposes of flight. In all probability they were, to begin with, "parachutes," by which climbing animals were enabled to descend from one branch or one tree to another with increasing facility. Such an endowment would be of obvious use in hunting for food, and also greatly help to baffle the attacks of climbing carnivorous enemies. Parachuting arrangements have been separately evolved in no less than three orders of mammals—*i.e.*, GNAWERS (*Rodentia*), INSECT-EATERS (*Insectivora*), and POUCHED MAMMALS (*Marsupialia*), the forms which possess them being climbers in all cases.

Flying Squirrels. Among parachuting GNAWERS the "flying" squirrels of South Asia, some of which range further north in the Old World, while others are also found in North America, are perhaps the best known types. Examination of such a squirrel [255] will show that the skin at the side of the body is drawn out into a well-marked fold, by which fore and hind limbs are united together. Smaller folds run from the fore limbs to the neck, and from the hind limbs to the base of the large bushy tail, though in some cases the latter are absent. The largest species are from 16 to 18 inches long, not reckoning the tail, which is of even greater length. When the folds are fully spread out, a very large surface is presented to the air, through which the animal is able to glide in a downward direction for nearly eighty yards. A certain amount of steering (partly by means of the tail) is said to be possible, and towards the end of a descent an upward direction may be taken if it seems desirable. In this particular group there have been at least two independent evolutions of parachuting mechanisms.



Rudland

255. FLYING SQUIRREL

The "flying" squirrels of Africa (which also possess climbing scales under the base of the tail) present similar arrangements, and there can be no question that these have been independently evolved. As in so many other cases, *e.g.*, diggers, similar conditions of life have resulted in similar adaptations answering similar purposes.

Flying "Lemurs." Among climbing INSECT-EATERS (*Insectivora*) we find one remarkable form in south-east Asia, the so-called "flying lemur" (*Galeopithecus*), which possesses well-developed parachuting membranes. Its organisation is so peculiar that it enjoys the distinction of being placed in a sub-order all by itself, while the remaining insect-eaters are grouped together in another. One noteworthy feature is the possession of a well-marked "web" between the fingers, which increases the parachuting surface.

McClellan

256. SEAL

Some of the climbing phalangers of Australia, belonging to the order of POUCHED MAMMALS (*Marsupialia*), have also evolved parachuting folds, which have earned for them the name of "flying" phalangers.

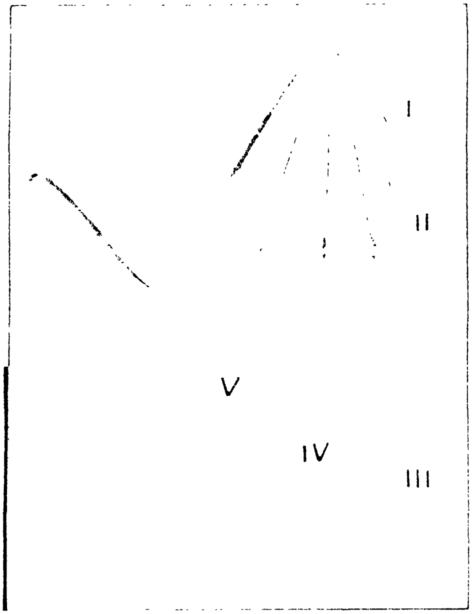
Flying Mammals. Under this heading there is but one order, that of the BATS (*Chiroptera*), and these may be looked upon as a special branch of the climbing insect-eaters, which began by parachuting, and then gradually converted their parachutes into wings. The mechanism is a very ancient one, and unfortunately geologists are not yet in a position to throw light upon the evolutionary stages. For owing to their habits bats are but rarely preserved in the fossil state.

The Wings of the Bat. The flying membranes of a bat are broadly similar in extent to those of a "flying" squirrel or "flying lemur," but special features of a remarkable kind are present. It is quite clear that a wing which is to be of any service must be firmly supported, so that appropriate muscles can bring it down with sufficient force upon the air, without undue "giving." And examination of the skeleton of a bat's wing [257] will show that this support consists of the very much elongated fingers (II. to V.), while the thumb (I.) still retains its independence, and possesses a strong hooked claw of service in climbing and scrambling.

If we imagine the fingers of the webbed hand of a "flying lemur" to gradually elongate, and the extended surface thus gained to encroach upon the ordinary parachuting fold at the side of the body, we shall get a very plausible explanation of the kind of way in which the wings of bats have gradually been brought into existence by the process of evolution.

The Muscles which Work the Wings. In bats, as in all other flying animals, the presence of wings is associated with the development of powerful muscles for moving them, and we accordingly find here that those in the chest region are very large. In order to give them a sufficiently large and firm surface for attachment, the under side of the breast-bone is provided with a prominent ridge or "keel."

As we shall see later on, the wings of Birds and of certain extinct Reptiles are constructed on two other plans, while those of Insects differ radically from all three. This well illustrates the general principle that the same biological end may be achieved by widely differing arrangements.



257. BONES OF A BAT'S WING
Photographed by Prof. B. H. Bentley

Swimming Mammals. The great majority of mammals are able to swim on occasion, for to do so it is only necessary for them to continue the movements which serve for progression on land. Man, unfortunately, is a notable exception to this. But there are members of several orders, and all those of two orders, which present special adaptations to an aquatic life. These are found in the general shape of the body, and extensions of surface for progressing in the water, as by flattening of the tail and webbing of the feet. At the same time the hairy covering is either short and dense, or it may be very greatly reduced, the eyes are small, as also are the external ears, and the nostrils are valvular.

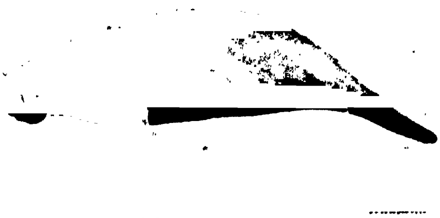
One of the two members of the order of EGG-LAYING MAMMALS (*Monotremata*), *i.e.*, the Duck-billed Platypus (*Ornithorhynchus*), is thoroughly aquatic in habit, as may be seen by its short thick-set fur, its webbed extremities (especially the front ones), its swimming tail (flattened from above downwards), its small eyes, valvular nostrils, and entire lack of external ears [241, page 1494].

A Huge Swimmer. Among the POUCHED MAMMALS (*Marsupialia*) we find a small opossum (*Chironectes*), native to Central and South America, which feeds upon fishes, and possesses webbed hind feet as well as a long, strong swimming tail. The most notable swimmer among the HOOFED MAMMALS (*Ungulata*) is the hippopotamus [234, page 1490], in which the hair is scanty, while the four-toed feet are of sufficiently spread nature to serve as paddles. The valvular nostrils are on the top of the snout.

Some of the INSECT-EATERS (*Insectivora*) are also expert swimmers, among these being our native water-shrew (*Crossopus fodiens*), in which the hands and feet are fringed with stiff hairs which give an extension of surface. Much more highly specialised is the insectivorous otter (*Potamogale*) of West Africa, with its dense fur, small eyes, and valvular nostrils. The feet are not webbed, and the swimming organ is the powerful tail, which is compressed from side to side. Not dissimilar in some ways are the Desmans (*Myogale*) of Spain and Russia, with webbed hind feet and strong tails. GNAWERS (*Rodentia*) also add their quota to the aquatic community. The capybara (*Hydrochœrus*) of South America, for instance, the largest living member of the order, possesses partially webbed feet, while our native water-rat, or rather water-vole (*Microtus amphibius*), is an expert swimmer, although its feet are not webbed. The hind limbs are the active agents of progression.

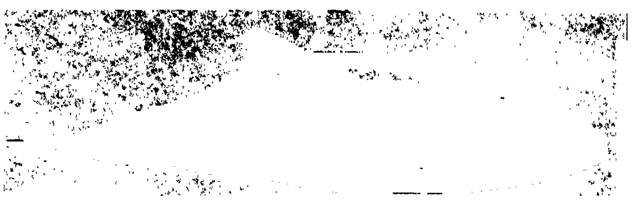
Aquatic Flesh-eaters. From the forms already mentioned we pass to others, a remarkable series of which belong to the FLESH-EATERS (*Carnivora*). The otter (*Lutra*), with its webbed feet, powerful swimming tail, and small ears, is a case in point. The rare sea-otter (*Enhydris*) of the North Pacific is constructed on somewhat similar lines. One entire subdivision of the order (*Pinnipedia*), contains aquatic animals only. All are distinguished by the possession of a thick coat of fat (blubber) beneath the skin, which is intelligible if we remember the cold regions in which they mostly live. The huge walrus (*Trichechus*) possesses paddle-like limbs, and its hair is very scanty. The sea-lions (*Otaria*) are somewhat more specialised on the same lines, except that, like ordinary seals, their fur is extremely close-set. These forms are also called "eared seals" because they still possess small external ears. In both walrus and sea-lion the hind flippers can be turned forwards to assist in a shuffling kind of progression on land or ice, while the former uses its tusks to some extent to help itself along in rough places. From these we pass on to the true seals (*Phoca*, etc.), in which the hind flippers are directed backwards, and bound up by folds of skin with the short tail [**256**], to constitute a very powerful paddle. This specialisation, though admirable for swimming purposes is, of course, a hindrance to progression on land, over which the true seals make their way by what may be described as a mixture of crawling and springing

Freshwater Seals. But little is known of the remote ancestry of Pinnipedes, but one of the ancient flesh-eaters (*Creodonta*), native to North America, possessed somewhat seal-like extremities. This creature (*Patriofelis*), was a lake-dweller, and appears to have lived upon freshwater tortoises. It is, therefore, not unlikely that seals and their allies were first evolved in fresh water, from which they ultimately made their way into the open ocean. Seals are now found in some inland seas—*e.g.*, the Caspian, Sea of Aral, and Lake Baikal; but this has a different significance, for we know that in comparatively recent geological times these bodies of water have been cut off from the main ocean of which they once formed a part.



258. MANATEE

An interesting parallel is afforded by Lake Tanganyika, which is inhabited not only by ordinary freshwater forms, but also by jellyfishes, certain molluscs, etc., which are characteristically marine. We may regard the lake, in fact, as a separated part of the Indian Ocean.



Rudland

259. PORPOISE

The Manatee. The order of SEA-COWS (*Sirenia*) includes only the manatee [**258**] and the dugong, both of which are purely aquatic. The fore limbs are flippers, and the absence of hind limbs is compensated for by the broadening out of the tail in a horizontal direction. The hair is very scanty, the valvular nostrils are on the top of the snout, and external ears are entirely absent. There is a thick layer of blubber. The tail of the manatee is rounded, while that of the dugong is produced into a pointed "fluke" on either side as in whales and their allies.

Mammals that Resemble Fishes. We come lastly to the WHALES AND PORPOISES (*Cetacea*), which are still more perfectly adapted to an aquatic life. We note in a porpoise [**259**], for example, the fish-like shape, well adapted for rapid progression through the water, and the smooth, practically hairless skin (beneath which is a thick layer of blubber). The fore limbs are flippers and the broad tail is horizontally flattened (only the edge can be seen in the figure), being shaped like that of a fish except that it is not vertical. Hind limbs and external ears are entirely absent, and the eyes are small. The nostrils of Cetaceans are represented by a single or double "blow-hole," of valvular nature, right on the top of the head, an obvious convenience for breathing air with most of the body submerged. The "spout" which issues from the blow-hole is not a column of water, as often erroneously supposed, but the chilled and condensed vapour of the expired air.

Origin of Marine Mammals. There can be no doubt that Cetaceans are the much modified descendants of land animals which have wrested the sovereignty of the sea from marine reptiles now long extinct. Unfortunately the geological record has not, so far, supplied us with the evolutionary stages of this ancient group, and all that can be definitely asserted is that the oldest types are in some anatomical features rather nearer land mammals than those existing at the present day. But it is a matter of opinion whether they are more closely allied to Hoofed Mammals or Flesh-eaters Most probably all three groups have descended from the same immensely ancient primeval stock, of which at present we have no certain knowledge.

Continued from page [illegible]

SPANISH—ITALIAN—FRENCH—GERMAN

Spanish by Mme. de Alberti; Italian by F. de Feo; French by Louis A. Barbé, B.A.; German by P. G. Konody and Dr. Osten

SPANISH

By Mme. de Alberti

THE Spanish alphabet is composed of twenty-eight letters pronounced as follows:

A	.. ah	I	.. ee	Q	.. coo
B	.. bay	J	.. hota	R	.. air-ay
C	.. thay	K	.. cah	S	.. essay
CH	.. tchay	L	.. el-lay	T	.. tay
D	.. day	LL	.. el-lyay	U	.. oo
E	.. a	M	.. em-ay	V	.. vay
F	.. ef-fay	N	.. en-ay	X	.. a-kis
G	.. hay	Ñ	.. en-nyay	Y	.. e-griega
H	.. ah-tchay	O	.. oh	Z	.. thay-tah
		P	.. pay		

These letters are of the feminine gender, and are divided into vowels and consonants, as in English.

Pronunciation. The Spanish vowel sounds do not vary, and must be pronounced fully and distinctly. The *u* is silent in the syllables *gue, gui; que, qui*, which are pronounced *gay, gee; kay, key*. When the *u* is to be sounded, it is marked thus, *ü*; as in *argüir*, to argue, which is pronounced *argooeer*.

Y is used both as a vowel and a consonant; alone, after a vowel and followed by a consonant; or, at the end of a word, it is a vowel and is sounded as *ee* in English. Before a vowel in the same syllable, or between two vowels in the same word, it is a consonant, and is sounded like the English *y* in *yours*.

C is pronounced hard before *a, o, u, l*, and *r*; ex., *cabra*, goat; *cola*, tail; *cuero*, hide; *claro*, clear; *crudo*, raw; which are pronounced *kabra, kola, kuero, klaro, krudo*. It is soft before *e* and *i*: ex., *cera*, wax; *cien*, a hundred; pronounced *thera, thien*.

CH, D, and F have the same sound as in English.

G, before *a, o*, and *u*, has the same sound as in English. Before *e* and *i* it is a guttural aspirate, like the English *h* very strongly aspirated: ex., *general* (general) pronounced *hénéral*.

H is never aspirated.

J has always the same guttural sound as *g* before *e* and *i*; it can only be rendered in English by the strongly aspirated *h*.

K is not used in modern Spanish; in the few words in which it used to appear its place is now supplied by c before *a, o*, and *u*, and by *qu* before *e* and *i*.

L has the same sound as in English.

LL, which is counted as a separate letter, can only be rendered in English by a combination of *l* and *y*, somewhat like *li* in vermilion: ex., *llorar* (to weep), pronounced *lyorar*.

M has the same sound as in English; it is never doubled in Spanish.

N has the same sound as in English. In words in which *gn* occur, both letters are distinctly sounded: ex., *dignidad* (dignity) is pronounced *dig-nidad*.

Ñ has a strong nasal sound, which is only approached in English by the *n* in poniard.

P has the same sound as in English.

Q is invariably followed by *u*; the two letters together, *qu*, are sounded like an English *k*.

R, at the beginning of a word, is pronounced like *rr*: ex., *rabia* (rage), *ruido* (noise); pronounced *rrabia, rrooido*. In the middle of a word it is sounded like the English *r*. When *rr* occurs it must be very strongly marked.

S is always pronounced *ss*: ex., *paseo* (a walk), pronounced *pas-say-o*. The final *s* is always very soft.

T has the same sound as in English; it is never doubled in Spanish.

V has the same sound as in English. Spaniards sometimes pronounce it *B*, but the practice is not encouraged by the Spanish Academy.

X has the sound of *gs*: ex., *exhalar* (to exhale), pronounced *egssalar*. In all words in which *x* was formerly a guttural aspirate it is now superseded by *j*. The most notable example is the name of *Don Quixote*, pronounced *Key-hot-ay*, which is now spelt *Quijote*.

Z is pronounced *th*, like the soft *c*: ex., *cruz* (cross), pronounced *kruth*.

The Accent. There is only one accent in Spanish, which is placed over the vowels *á, é, í, ó, ú*. It lengthens the syllable over which it is placed, so that the stress is laid upon it, and the rest are pronounced short: ex., *águila* (eagle), pronounced *á-guila*; *acá* (here), pronounced *a-cá*. It also distinguishes words which are spelt the same: ex. *el* (the), *él* (he).

Parts of Speech. There are ten parts of speech. The variable — *viz.*: article, noun, adjective, pronoun, verb, participle; and the invariable—*viz.*: adverb, preposition, conjunction, interjection.

Gender. There are three genders: masculine, feminine, and neuter. The neuter gender is never applied to persons or things, but only to adjectives, pronouns, etc., used to convey a substantive idea in a general or abstract manner: ex., *lo malo*, the evil, or all that is evil; *lo bueno*, the good, or all that is good); *lo mío*, mine, or all that is mine. The neuter gender has no plural.

Numbers. There are two numbers: the singular and the plural.

Punctuation. The use of punctuation marks differs from the English in two particulars. The mark of interrogation is placed at the beginning of a sentence, below the line (¿), and is repeated above the line at the end (?).

The mark of exclamation is also placed below the line (¡) at the beginning of the sentence, and is repeated above the line at the end (!).

Vocabulary	**Vocabulario**
God	Dios
The stars	Los astros
A comet	Un cometa
A star	Una estrella
The polar star	La estrella polar
The firmament	El firmamento
The moon	La luna
The moonlight	El resplendor de la luna
The new moon	La luna nueva
The full moon	La luna llena
The first quarter	El cuarto creciente
The last quarter	El cuarto menguante
The sun	El sol
Sunrise	La salida del sol

6. Old age is the procursor of death.
precursor de
7. (It) is a happiness that the future is
que nos
unknown to us.
sea desconocido.
8. Man is not of age until twenty-one.
no hasta (los) veinte y un (años).
9. Misery is cruel.
cruél.
10. The expense of education is great.
grande

Note. The article must be inserted before the nouns whenever these are given in the vocabulary. Practice will soon teach where the article is required in Spanish. Keys to Exercises are given in the succeeding lessons.

PROSE EXTRACT I.

[From the chronicle of the reign of Peter the Cruel. By Pedro Lopez de Ayala.]

Peter the Cruel and the Prince of Wales (the Black Prince) after the battle of Najera.	Don Pedro el Cruél y el Principe de Gales despues de la batalla de Nájara.
The Prince of Wales said to the king, Don Pedro, that, saving his Royal Majesty, neither his words nor his demands were in reason; for those knights and men-at-arms, who were there in his service, had striven for honour's sake; and if they had taken any prisoners they were their own; and the knights who held them were such, that not for any money in the world, though it were a thousand times the value of the prisoners they held, would they deliver them to him, for they would think that he redeemed them to put them to death: and that he should urge it no more, for it was not a thing which he could grant. However, if there were any among the prisoners upon whom he had passed sentence before this battle, he would cause them to be delivered to him.	El Principe de Gales dijo al Rey Don Pedro que salve su Real Majestad no decía, ni pedía razon; que aquellos Señores Caballeros y hombres de armas que alli eran en su servicio habian trabajado por la honra, y si algunos prisioneros habian eran suyos, y que tales eran los caballeros que los tenian que por dinero del mundo aunque fuesen mil tantos que valíese el prisionero que tuviesen que no le rendirian á él, por cuanto pensarian que los cobraba para los matar: que en esto no se trabajase, que no era cosa que él pudiese librar. Empero si tales caballeros fuesen presos, contra los cuales él pasára sentencia antes de esta batalla, que él se los haría entregar.
Then the king, Don Pedro, said to the Prince that if these things were to fall out so, he deemed his kingdom more lost than it was at first, for it was those very prisoners who had caused him to lose the kingdom, and since they were to escape thus, and not to be delivered up to him that he might come to an agreement with them and win them to his cause, he made but small account of the Prince's help, and deemed that he had spent his treasures in vain. Then the Prince was enraged at these words which the king, Don Pedro, had spoken to him, and he answered in this fashion: "Sir kinsman, it seems to me that you have now stronger means to recover your kingdom than you had when it was in your possession and you governed it in such a manner that you were like to lose it. And I would counsel you to cease this putting to death, and to seek some means of recovering the good-will of the lords and knights and noblemen, and of the cities and towns of this your kingdom; for if you do otherwise, and behave yourself as you did before, you stand in great peril of losing both your kingdom and yourself, and of being brought to such a pass that neither my lord and father the king of England, nor myself, shall be able to avail you aught, although we should be so minded." And these things thus passed between the king, Don Pedro, and the Prince upon that day, Sunday, after the battle as they lay there in camp.	Entonces dijo el Rey Don Pedro al Principe, que si estas cosas así habían de pasar que mas perdido tenía ahora el Reino que le tenía primeramente: que todos aquellos que eran presos eran los que le habían hecho perder el Reino, y que pues aquellos asi habían de escapar y no ser entregados á él para traer con ellos sus pleitesias para que quedasen suyos, que no hacía cuenta que le había ayudado el Principe; mas tenía que gastára sus tesoros de balde. Y entonces fué sañudo el Principe por estas razones que el Rey Don Pedro así le dijo, y respondiole de esta manera: "Señor pariente, á mí me parece que vos teneis maneras mas fuertes ahora para cobrar vuestro Reino que tuvistes cuando teniais vuestro Reino en posesion, y le registeis en tal guisa que le tuvisteis que perder. Y yó os aconsejaria de cesar de hacer estas muertes, y que buscáse manera de cobrar las voluntades de los señores y caballeros, y hidalgos, y ciudades, y pueblos de este vuestro Reino, y si de otra manera vos gobernais segun primero lo hicisteis, estais en gran peligro de perder vuestro Reyno, y vuestra persona, y llegarlo á tal estado, que mi señor y padre el Rey de Inglaterra, ni yo aunque quisiésemos no os podriamos valer." Y así pasaron estas razones entre el Rey Don Pedro, y el Principe aquel dia Domingo despues de la batalla que estuvieron allí en el campo.
Pedro Lopez de Ayala (1332-1407), poet, Court chronicler, and Chancellor of Spain.	Pedro Lopez de Ayala (1332-1407) poeta, cronista de la corte y canciller de España.

He was taken prisoner at the battle of Najera and brought to England, where he wrote some of his poems. He describes the events of the four reigns in which he lived with the knowledge of an eye-witness. His chronicles are the first attempt at serious history in Spanish. The spelling of the above extract has been modernised for the convenience of our students.	Fué hecho prisionero en la batalla de Nájara y llevado á Inglaterra donde escribió algunos de sus poemas. Describió los acontecimientos de los cuatro reinados durante los cuáles vivió, con el saber de un testigo ocular. Sus crónicas son el primer atento serio á una historia de España. La ortografía del extracto que antecede ha sido modernizada para la conveniencia de nuestros estudiantes.

PHONETIC RENDERING OF THE EXTRACT.

The following is a phonetic rendering of the pronunciation of the extract:

El Printheepay day Gah-les dee-ho al ray Don Paydro kay salvay soo rayal mah-hestah, no daythea nee paydeea rahthon; kay ah-kellyos say-nyores, cah-ballyerohs, ee ombrays day armahs, kay allyee airan en soo sairveetheo ah-beean trahbah-hado por lah onrah, ee see algoo-nohs preseonerohs ah-beean airan soo-yohs, ee kay tah-les airan loss cah-ballyerohs kay loss ten-eean kay por deenero dell moondo ahoonkay fooaysen mill tan-tohs kay vah-lee-essay el preseonero kay toovee-essen kay no lay rendeereean ah el por cooanto pensah-reean kay los kobrah-ba pahra loss mah-tar: kay en essto no say trahbah-ha-say, kay no airah kossa kay el poodee-essay lee-brar. Continued

ITALIAN

By Francesco de Feo

THE Italian alphabet (*alfabeto*, or, from the name of the first three letters of the Italian alphabet, *abbiccì*) consists of the following 21 letters pronounced as follows:

A	.. ah	H	.. àhckah	Q	.. koo
B	.. bee	I	.. ee	R	.. èhrreh
C	.. chee	L	.. ehlleh	S	.. èhsseh
D	.. dee	M	.. ehmmeh	T	.. tee
E	.. eh	N	.. ehnneh	U	.. oo
F	.. èhffeh	O	.. o	V	.. vee
G	.. dgee	P	.. pee	Z	.. dzèhtah

The letters *k*, *j*, *x*, *y*, *w* do not occur in Italian. *X* and *y* are used in mathematics to indicate an unknown quantity. *X* is also met with in the Latin *ex* (ehx) in compound words like *ex-deputato* (ex M.P.), *ex-direttore* (ex-director).

Vowels and their Pronunciation. A is always pronounced open and broad, like English ah! The student should pronounce the exclamation ah! the English bah, and then the Italian *la* (the, fem.), *ma* (but). After this he will find it easy to connect the same vowel sound with other consonants. In pronunciation this sound will be represented by *ah*, as *amare* (ahmàhreh), to love.

E is never mute in Italian. It has two sounds: closed, like *ai* in pain, as *venti* (véhntee), twenty; open, like *e* in let, as *vènti* (vèhntee), winds. These sounds will be represented by *eh*: *crèdere* (crèh-deh-reh), to believe.

I is not sounded as the English *i* in Italy, it, kiss. This sound will be represented by *ee*: *brindisi* (brèen-dee-see), toast.

O, like *e*, has two sounds: closed, like *o* in note, as *voce* (vòcheh), voice; open, like *o* in not, as *còrpo* (body).

U is always pronounced like *oo* in cool, as *punire* (poonèereh), to punish. This sound will be represented by *oo*.

The distinction between the open and closed sounds of *e* and *o* offers some difficulty to Italians themselves, so that foreigners need not be too particular about it. Those who have a knowledge of Latin will find assistance from the following hints:

1. **E** is closed when it replaces (*a*) a Latin long *ē:* mē, tē, fēci; (*b*) a Latin short *ĭ:* fĭdem, *fède;* nĭve (*m*), *néve.* The Latin long ī remains in Italian: infidu (m), *infido.*

2. **E** is generally open when it replaces a Latin short *ĕ:* pĕde (m), *piede.*

1. **O** is closed when it replaces (*a*) a Latin long *ō*: corōna, *corona;* (*b*) a Latin short *ŭ:* crŭce (m), *croce.*

2. **O** is generally open when it replaces a Latin short *ŏ:* hŏmo, *uòmo;* or a Latin *au:* *aurum*, *òro*. It has also the open sound when it is preceded by *i* or *u:* *piòve*, it rains; *cuòre*, heart; and before an *s* in substantives, as *ròsa*, *rose;* *spòsa*, spouse.

Diphthongs. In Italian, real diphthongs do not exist. Every vowel must be separately and distinctly pronounced. In words where the combinations *uo*, *ia*, *ie*, *io*, *iu* are found the *u* and *i* must be pronounced short: *buono* (boo-òno), good; *pieno* (pee-èhno), full; *più* (pee-oò), more.

Accent. In the Italian orthography, the accent is not shown, except when it falls on the last vowel of a word, when it is used either to mark a contraction, as in *virtù* (veer-toò) for *virtute*, or a verbal termination, as in *farò*, *dirò*. It is also used to distinguish the pronunciation of words spelt alike, but having a different accent and meaning. For example: *àncora*, anchor; *ancòra*, yet.

As a general rule, we may assume that the tonic accent or stress in Italian is laid on the last syllable but one. Whenever there is a deviation from this rule it will be here indicated by a grave accent, to show on which vowel the stress must be laid: *pàrlano* (pàhr-lah-no), they speak.

Apostrophe. The apostrophe is used to show the omission of a vowel, and, in some cases, of a syllable. For example: *l'uso* (loòso), the custom; *un po'* (oon po) a little, for *un poco.*

EXERCISE I.

ON READING THE VOWELS: *pane* (bread), *carne* (meat), *bene* (well), *cane* (dog), *capo* (head), *sera* (evening), *giorno* (day), *mattina* (morning), *libro* (book), *carta* (paper), *penna* (pen), *tàvola* (table), *amico* (friend), *fratello* (brother), *sorella* (sister), *zio* (uncle), *cappello* (hat), *capelli* (hair), *vino* (wine), *fiume* (river), *fumo* (smoke), *buono* (good), *cattivo* (bad), *piede* (foot), *dieci* (ten).

PRONUNCIATION OF THE ABOVE WORDS: Pàh-neh, càhr-neh, bèh-neh, càh-neh, càhpo, sèhrah, dgeeòrno, mahtteè-nah, leèbro, càhr-tah, pèhnnah, tàhvolah, ahmeèco, frah-tèhllo, sorèhllah, tseè-o, cahppèhllo, cahpèhllee, veèno, fee-òomeh, foomo, boo-òno, cahtteèvo, pee-èh-deh, dee-èh-chee.

Consonants and their Pronunciation. The consonants in Italian are sounded as in English, with the following exceptions:

C before *e* or *i* is sounded as the English ch in cherry, chin: *Cèsare* (chèh-sah-reh), Cæsar; *città* (cheettàh), town; *cibo* (cheèbo), food.

Ch is sounded as *k; chi?* (kee) who? *perchè* (pehrkèh), because.

G before *e* or *i* is sounded as the English *g* in geography, gin: *gente* (dgèhn-teh), people; *Tamigi* (tahmeè-dgee), Thames.

Gh is sounded as the English *g* in get, give: *botteghe* (bottèhgheh), shops; *ghinea* (gheenèh-ah), guinea.

Gli before a vowel, or at the end of a word, is pronounced like the *lli* in billiards, as: *bottiglia* (botteèleeah), bottle; *figlio*, (feèleeo), son.

Gn is sounded as *ni* in minion: *montagna* (montàh-neeah), mountain; *ogni* (*ònee-ee*), every.

H is not pronounced; *hanno* (ahnno), they have.

S, Z have two sounds: hard, *cosa, zampa;* soft, *uso, zolla.*

Sce, Sci are sounded as *sh* in shell, ship: *scena* (shèhnah), scene; *scienza* (shèhndzah), science.

Sch is sounded as *sk: schioppo* (skeeòppo), gun.

When two consonants (*mm*, *nn*, *tt*, etc.) come together, they must be both pronounced: *carro* (cart), *caro* (dear); *penna* (pen), *pena* (pain); *fatto* (fact), *fato* (fate).

EXERCISE II.

ON PRONUNCIATION. *Quel*, that; *questo*, this; *quasi*, almost; *mezzogiorno*, south: *òcchio*, eye; *ricomincia*, begins again; *ripigliar*, to retake; *lasciare*, to let; *cocùzzolo*, top (of a mountain); *esempio*, example; *mura*, walls; *guàrdano*, they look: *più*, more: *giogaia*, ridge; *oscuro*, dark: *due*, two; *a destra*, on the right.

PRONOUNCED: Koo-èhl, koo-èh-sto, koo-àhsee, meh-dzo-dgee-òrno, òckeeo, ree-comeén-chah, ree-peè-lee-ar, làh-shah-re, cokoòt-solo, ehsèmpeeo, moorah, guàhrdahno, dgeeo-gàh-eeah, oskoòro, doòeh, ah deh-strah.

EXERCISE III.

Quel ramo del lago di Como, che volge a mezzogiorno, tra due catene non interrotte di monti, tutto a seni e a golfi, a seconda dello spòrgere e del rientrare di quelli, vien, quasi a un tratto, a restrìngersi e a prender corso e figura di fiume, tra un promontòrio a destra e un' àmpia costiera dall' altra parte; e il ponte, che ivi congiunge le due rive, par che renda ancòr più sensìbile all' occhio questa trasformazione, e segni il punto in cui il lago cessa, e l'Adda ricomìncia, per ripigliar poi nome di lago dove le rive, allontanàndosi di nuovo, lascian l'acqua distèndersi e rallentarsi in nuovi golfi e in nuovi seni. La costiera, formata dal depòsito di tre grossi torrenti, scende appoggiata a due monti contigui, l'uno detto di San Martino, l'altro con voce lombarda il Resegone, dai molti suoi cocùzzoli in fila, che in vero lo fanno somigliare a una sega: talchè non è chi, al primo vederlo, purchè sia di fronte, come per esèmpio di su le mura di Milano che guàrdano a settentrione, non lo discerna tosto, a un tal contrassegno, in quella lunga e vasta giogaia, dagli altri monti di nome più oscuro e di forma più comune.

The Article. As in English, there are two articles in Italian—*definite* and *indefinite.*

DEFINITE ARTICLE (The) Masculine: *il*, *lo*, *l'*, for singular; *i*, *gli*, for the plural;

Feminine: *la*, *l'*, for the singular; *le*, for the plural.

INDEFINITE ARTICLE (A, An). Masculine: *un*, *uno*. Feminine: *una*.

Il is used before masculine nouns beginning with a consonant or consonants, except *z*, impure *s* (*s* followed by one or two consonants, as: *sp*, *spr*, *sc*, *scr*, *sch*, etc.), and *gn*, as: *il cane*, the dog; *il libro*, the book; *il braccio*, the arm.

Lo is used instead of *il* before *z*, impure *s*, *gn*, as: *lo zio*, the uncle; *lo scolaro*, the pupil; *lo gnomo*, the gnome.

L' is used before masculine and feminine nouns beginning with a vowel, as *l'onore*, the honour; *l'uomo*, the man; *l'oro*, the gold; *l'anima*, the soul; *l'arte*, the art. *Le* drops the *e*, and is written *l'* only before an *e*, as: *l'erbe*, the herbs; but *le opere*, and not *l'opere*.

I, Gli. When *il* is used in the singular, *i* is used in the plural, as: *i cani*, *i libri*. When *lo* is used in the singular, *gli* is used in the plural, as: *gli zii*, *gli onori*. The *i* in *gli* is dropped, and an apostrophe is put instead only before nouns beginning with an *i*, as *gl'inni*.

Un is used as the article *il*, and before a vowel, as: *un libro*, a book; *un ragazzo*, a boy; *un amico*, a friend.

Uno is used in the same cases as *lo*, as: *uno zio*, *uno scultore*, *uno gnocco* (oono nee-òcco), a little dumpling.

Una is written *un'* before a vowel, as *un' anima*; *un' abitudine*, a habit.

Masculine Nouns

scolaro (skolahro), pupil.
coltello (koltèhllo), knife.
temperino (tehmpehreèno), pen-knife.
ragazzo (rahgàh-tso), boy.
scultore (skool-tòreh), sculptor.
cavallo (cahvàhllo), horse.
zio (tseèo), uncle.

Feminine Nouns

penna (pèhnnah), pen.
rosa (ròsah), rose.
casa (càhsah), house.
busta (boòstah), envelope.
carrozza (kahrròtzah), carriage.
figlia (feè-leeah), daughter.
stàtua (stàhtooah), statue.
spàzzola (spàtzolah), brush.
sorella (sorèhllah), sister.

To form the plural of these nouns, change the terminations *o* into *i*, and *a* into *e*, as: libro, libri; cavallo, cavalli; rosa, rose; casa, case.

e (before e, *ed*) and; *o* (before o, *od*) or.

Io ho (eè-o òh), I have.
tu hai (too àhee), thou hast.
egli ha (èh-lee ah), he has.
noi abbiamo (nòee ahbbeeàhmo), we have.
voi avete (vòee ahvèhte), you have.
essi hanno (ehssee àhnno), they have.

EXERCISE IV.

1. L'amico. Io ho un amico. Tu hai una rosa. Egli ha una figlia. Noi abbiamo una casa. Il ragazzo ha una penna. Lo scultore ha una statua. Lo zio ha una spazzola. Lo scolaro ha un libro e una penna. Voi avete una sorella. Essi hanno un cavallo e una carrozza.

2. I ragazzi hanno un coltello e un temperino. Voi avete le buste e le penne. Gli scolari hanno le buste e i libri. Gli scultori hanno le statue. Gli zii hanno le case. Il ragazzo ha le rose. Gli amici hanno gli uccelli, i cavalli e le carrozze.

Some Prepositions

Di (before a vowel *d'*) of; *di Pietro*, of Peter; *d'onore*, of honour.

A (before a, *ad*) to; *a Londra*, to London; *ad Andrea*, to Andrew.

Da, from (after the passive verb, by); *da Roma* from Rome; *da me*, by me.

In, in. into; *in Germania*, in Germany.

Con, with; *con amore*, with love.

Su, on, upon; *su domanda*, on demand.

Per, for; *per voi*, for you.

These prepositions (especially *di*, *a*, *da*, *in*) when they occur with the article, are contracted into one word. For the contraction, change *di* into *de*, and *in* into *ne*.

Of the: *di il* (*de l*) *del*; *di la* (*de la*) *della*; *di lo* (*de lo*) *dello*; *di i* (*de i*) *dei*; *di gli* (*de gli*) *degli*, etc. (pronounced dehl, dehlla, dehllo, deh-ee, dèh-lee-ee).

To the: *a il* (*a l*) *al*; *a la*, *alla*; *a lo*, *allo*; *a i*, *al*, etc.; (pronounced, ahl, àhllah,

In the: *in il* (*ne l*) *nel*; *in la* (*ne la*) *nella*; *in lo* (*ne lo*) *nello*; *in i* (*ne i*) *nei*; *in gli* (*ne gli*) *negli*; (pronounced nehl, nèhllah, nèhllo, nèh-ee, nèh-lee-ee).

Some modern authors write also *de la*, *da le*, *de gli*, *da gli*, *ne la*, *a la*, etc., in two words. *Con*, *su*, and *per* are also contracted, but only with *il* and *i*, as *col*, *coi* (coèe), *sul* (sool), *sui* (soò-ee), *pel* (pehl), *pei* (pèh-ee).

NOTE. The compound articles follow the same rules as the corresponding uncontracted articles, *del padre*, *dello zio*, *dello scultore*, *dell'ora*, *delle parole*, *degli zii*, etc.

Masculine Nouns

danaro (dahnàhro), money.
giardino (dgeeàhr-deéno), garden.
regalo (rehgàhlo), present.
mèdico (mèhdeeco), physician.
signore (seeneeòreh), gentleman.
anello (ahnèhllo), ring.

Feminine Nouns

lèttera (lèhttehrah), letter.
seta (sèhtah), silk.
stanza (stàhndzah), room.
signora (seeneeòrah), lady.
Londra (Lòndrah), London.
Parigi (Pahreèdgee), Paris.

Sono, they are ; *avuto* (ahvoòto), had ; *ricevuto* (reechehvoòto), received ; *comprato*, bought.

Exercise V

On the Compound Articles. Un cappello di seta. La statua dello scultore. Il medico di casa. La busta della lettera. Noi abbiamo ricevuto una lettera da Parigi. Da Londra a Parigi e da Parigi a Roma. I libri degli scolari sono su la tavola. Il signore e la signora sono nel giardino dello scultore. I ragazzi hanno ricevuto un regalo. La figlia del medico ha ricevuto un anello d'oro. Gli amici hanno comprato una casa col danaro ricevuto da Roma. Le lettere per la signora sono su la tavola nella stanza dei ragazzi.

Partitive Article. The partitive sense expressed in English by *some* or *any* is expressed in Italian by the preposition *di*, either simple or contracted with the definite article, thus : *del pane*, some bread ; *uno di voi*, one of you ; *avete del vino ?* have you any wine ?

The partitive sign is omitted :

(1) In negative sentences. *Io non ho amici*, I have no friends.

(2) When the noun is preceded by an adverb of quantity. *Avete molto danaro ?* have you much money ?

(3) When the noun is taken in a general sense. *Egli ha cavalli e carrozze*, he has horses and carriages.

Exercise VI.

On the Partitive Article. Dei cavalli per le carrozze. Delle rose nel giardino. Le signore hanno delle rose. Noi abbiamo ricevuto dei regali. Il ragazzo ha avuto dei libri. Egli ha comprato delle buste e delle penne per degli scolari. Hanno essi molti cavalli ? Le signore hanno ricevuto delle lettere da Parigi. Lo scultore ha avuto cavalli, carrozze case e giardini.

Io sono, I am ; *noi siamo* (seeàhmo), we are ; *tu sei* (sèh-ee), thou art ; *voi siete* (see-èhteh), you are ; *egli è* (èh), he is ; *essi sono*, they are.

Non, not, is placed before the verb, as : *io non ho* (I not have), I have not ; *io non sono* (I not am), I am not.

In interrogative phrases, the personal pronouns may be placed after the verb (*hanno essi ?*), but they are nearly always omitted, as the different persons are sufficiently indicated by the verbal terminations. Thus : *ho*, I have ; *abbiamo*, we have ; *siete* ? are you ? etc.

dov' è ? (dovèh), where is ?
dove sono ? where are ?
vi sono, there are.
risposta (fem.), answer.
scritto (skreètto), written.
si, yes.
no (pronounce the *o* open, as in *not*), no.
ma, but.

Conversazione.

Dov' è il signore ? è in casa ?

Dove sono i ragazzi ?

Il signore non è in casa, ma i ragazzi sono in giardino.

Ha scritto la lèttera al mèdico ?

Sì, ma non ho ricevuto risposta.

Egli non è a Londra, è a Parigi.

Vi sono delle pere nel giardino ?

No, ma vi sono delle rose.

Lo scolaro ha libri, penne, buste ?

Noi abbiamo temperini libri penne, ma non abbiamo buste.

Dove sono gli amici ?

Il mèdico è in casa dello scultore, il signore e la signora sono in giardino coi ragazzi.

By Louis A. Barbé, B.A.

PERSONAL PRONOUNS

1. There are two forms of personal pronouns (*pronoms personnels*) : the conjunctive form and the disjunctive form.

Conjunctive Personal Pronouns. The conjunctive personal pronouns are always closely joined to a verb, and can be used only when the verb is actually expressed—not understood. Used as subjects they are :

1st person : *je*, I ; *nous*, we.
2nd person : *tu*, thou ; *vous*, you.
3rd person : *il*, he, it ; *elle*, she, it , *ils*, (m.), *elles* (f.), they.

The conjunctive personal pronouns as objects, both direct (accusative) and indirect (dative) are :

1st person : *me*, me, to me ; *nous*, us, to us.
2nd person : *te*, thee, to thee ; *vous*, you, to you.
3rd person (direct) : *le*, him, it ; *la*, her, it ; *les*, them (mas. and fem.).
3rd person (indirect) : *lui*, to him, to her, to it ; *leur*, to them (mas. and fem.).

2. The conjunctive personal pronouns as subjects precede the verb : *je parle*, I speak ; *il ne parle pas*, he does not speak.

Exceptions : (*a*) In interrogations and exclamations the pronoun comes after the verb : *avez-vous*, have you ? *parlent-ils*, do they speak ? When, in the third person singular, the verb ends with a vowel, a *-t-*, with a hyphen before and after it, is inserted between the verb and the subject : *parle-t-il*, does he speak ; *a-t-elle*, has she ?

(*b*) The subject follows the verb, when that verb refers to what has been expressed in direct speech : *Sortez, dit-il*, go out, said he. This inversion is optional in English, but obligatory in French, and also takes place when the subject is a noun : *viens ici, dit mon père*, come here, said my father.

(*c*) The subject follows the verb in sentences beginning with *aussi*, therefore, *peut-être*, perhaps ; *encore*, even then, etc. : *Il secourut toujours l'infortune ; aussi a-t-il à son tour trouvé*

des amis; He always relieved misfortune; therefore he, in his turn, has found friends.

3. The conjunctive personal pronouns as objects (accusative or dative) always precede the verb, except when the verb is in the imperative: *je les vois*, I see them; *il me l'a donné*, he has given it to me; but, *donnez-le-lui*, give it to him.

When the verb is in the imperative affirmative, the disjunctive forms ***moi***, ***toi*** are used instead of ***me***, ***te***; *donnez-le-moi*, give it to me; *prêtez-lui votre canif*, lend him your penknife (see 7).

As a conjunctive pronoun, *lui* is both masculine and feminine; thus, *je lui parle* is both I speak to him, and I speak to her; *donnez-lui*, give him, and give her.

4. When a verb has the same person for both subject and object, it is said to be reflexive (*réfléchi*), and the personal pronouns used as objects become reflexive pronouns. There is then a special form, *se*, for the third person, singular and plural. These reflexive personal pronouns are:

me, myself, to myself; *nous*, ourselves, to ourselves.
te, thyself, to thyself; *vous*, yourselves, to yourselves.
se, himself, to himself; herself, to herself.
se, themselves, to themselves (mas. and fem.).

Examples: *Je me flatte*, I flatter myself; *tu te trompes*, thou art mistaken; *il se couche*, he goes to bed; *nous nous levons*, we get up; *vous vous habillez*, you dress; *ils* (*elles*) *s'amusent*, they enjoy themselves.

5. *En* and *y* are pronouns used more particularly, the latter almost exclusively, with reference to inanimate objects. They may be considered as equivalent to English neuter forms. *En* means "of it," "of them," "some." *Y* means "to it," "to them," and also "to that place," *i.e.* "there."

6. When a verb has several pronouns as objects, the order in which they are to be placed is as follows:

1st, *me*, *te*, *se*, *nous*, *vous*; 2nd, *le*, *la*, *les*; 3rd, *lui*, *leur*; 4th, *y*; 5th, *en*.

Examples: *Il me le donne*, he gives it to me; *nous les leur prêtons*, we lend them to them; *nous nous y sommes consacrés*, we have devoted ourselves to it; *vous m'en avez parlé*, you have spoken to me about (of) it; *ils lui en ont donné*, they have given him some.

7. If the verb be in the imperative and affirmative, the pronominal objects follow it, in the same order as in English. *Me* and *te* then become ***moi*** and ***toi***; and ***m'***, ***t'***, before ***en***.

Examples: *Donnez-le-moi*, give it to me; *prêtez-les-leur*, lend them to them; *donnez-m'en*, give me some; *pensez-y*, think of (to) it.

8. If the imperative is negative, this change does not take place, and the pronouns remain before the verb.

Examples: *Ne le leur donnez pas*, do not give it to them; *ne m'en parlez pas*, do not speak to me about (of) it; *ne vous y opposez pas*, do not oppose (yourself to) it.

9. The following table shows the relative position of all the conjunctive personal pronouns, and also of the negative *ne . . . pas* (*point*, *plus*, *jamais*, etc.), when used in connection with them:

1.	2.	3.	4.	5.	6.	7.	8.	9	10.	
je *tu* *il* *elle* *nous* *vous* *ils* *elles*	*ne*	*me* *te* *se* *nous* *vous* *se*	*le* *la* *les*	*lui* *leur*	*y*	*en*	*auxiliary verb, or simple tense.*	*pas,* *point,* *plus,* *&c.*	*past participle of compound tense*	*If the sentence is interrogative, the subjects in* 1 *come after* 8.

Voici and *voilà* are made up of the imperative *vois*, behold, with *ci* for *ici*, here, and *là*, there. Like verbs, they govern the pronoun in the objective case, and are preceded by it.

Examples: *Où est mon canif? Le voici*, where is my penknife? Here it is; *Où est ma poupée? La voilà*, where is my doll? There it is; *Où sont leurs joujoux? Les voilà*, where are their toys? There they are.

EXERCISE XV.

1. I am looking (for) (*cherche*) my book and my pens.
2. You have spoken to my brother and sister.
3. He has given a present (*cadeau*) to his friend.
4. He is looking (for) me.
5. She is speaking to you.
6. We have given him a watch (*montre*, f.).
7. He does not speak to them.
8. Has she given them a present?
9. Has he found his watch?
10. I give thee that, he said to me.
11. Give it (m.) to me, said my father to us.
12. Buy (*achète*) thyself an umbrella (*parapluie*, m.).
13. We get up every day at seven o'clock.
14. They never go to bed before eleven o'clock.
15. We give it (m.) to them.
16. She lends it (f.) to you.
17. He has given us some.
18. You have spoken to us about (of) it.
19. If you have any money, give him some.
20. Do not speak to him about it.
21. We do not oppose (*opposer*) it (oppose ourselves to it).
22. If you are looking for your gloves, here they are.
23. You are mistaken.
24. They flatter themselves.

Disjunctive Personal Pronouns. The disjunctive personal pronouns, whether used as subjects or as objects, have but one form. They are:

moi, I, me, to me　***nous***, we, us, to us
toi, thou, thee, to thee　***vous***, you, to you

lui, he, him, to him	***eux*** (m.), they, them, to them.
elle, she, her, to her	***elles*** (f.), they, them, to them.

The reflexive pronoun *se* also has a disjunctive form, *soi*. Example: *Chacun pour soi*, each one for himself.

2. The disjunctive form is used after prepositions: *nous sommes pour eux et contre lui*, we are for them and against him.

But when a single pronoun is the indirect object (dative), the proposition *à*, to, is not expressed. The pronoun is in the conjunctive form and precedes the verb. If the verb is reflexive, however, the preposition *à* is expressed: *nous nous fions à eux*, we trust to them.

3. When a personal pronoun is used alone, as either subject or object of a verb understood, the disjunctive form is required:

Qui lui a répondu ? Moi, who answered him ? I ; *Qui a-t-il vu ? Eux*, whom did he see ? Them.

4. When a personal pronoun is the "logical subject" of the verb *être*, preceded by *ce*, the disjunctive form is required:

c'est moi, it is I	*c'est nous*, it is we
c'est toi, it is thou	*c'est vous*, it is you
c'est lui, it is he	*ce sont eux*, it is they (m.)
c'est elle, it is she	*ce sont elles*, it is they (f.)

In this construction the verb is plural when followed by a pronoun in the third person plural.

5. When a verb has several subjects, or several objects, those of them that are pronouns must be in the disjunctive form. In this construction it is usual to introduce an additional pronoun in the conjunctive form, including all the others:

Toi, lui et moi, nous serons ensemble, thou, he and I (we), shall be together.

Il nous verra, toi et moi, he will see (us), you and me.

6. The pronoun coming after *que*, than, as subject or object of a verb understood, must be used in the disjunctive form:

J'y ai été plus souvent que lui, I have been there oftener than he.

Il vous voit plus souvent que moi, he sees you oftener than me.

7. A personal pronoun immediately preceding a relative must be in the disjunctive form:

Moi qui vous parle, je l'ai vu de mes yeux, I who speak to you, I saw it with my own eyes.

8. A pronoun is emphasised by being used once in the disjunctive and again in the conjunctive form:

You work and *I* play, *toi, tu travailles et moi, je joue*.

In this construction the disjunctive pronoun may be placed either before the conjunctive or after the verb:

Tu travailles toi, *you* work.

9. If the emphasised pronoun is in the third person, and is the subject of a verb, the conjunctive form may be omitted:

Lui pense ainsi, mais eux pensent autrement, *he* thinks thus, *they* think otherwise.

But if the emphasised pronoun be objective, both forms are used:

Je le crois lui, eux je ne les crois pas, I believe *him*, *them* I do not believe.

10. In elliptical sentences, when the only verb expressed is in the infinitive, the pronoun is used in the disjunctive form:

Moi vous trahir, *I* betray you !

11. The disjunctive form is used with a participle to form an "absolute" construction:

Lui mort, nous n'aurons plus de chef, he being dead, we shall no longer have a leader.

12. The disjunctive pronouns form with the preposition *chez* expressions that mean "at my house" or "at home," etc.:

chez moi, at (to) my house
chez toi, at (to) thy house
chez lui, at (to) his house
chez elle, at (to) her house
chez nous, at (to) our house
chez vous, at (to) your house
chez eux, at (to) their (m.) house
chez elles, at (to) their (f.) house

Il n'est pas chez lui, he is not at home.

Nous sommes toujours chez nous le soir, we are always at home in the evening.

Est-il allé chez vous ? Did he go to your house ?

13. The disjunctive forms, with *même* joined to them by a hyphen, become emphatic personal pronouns:

moi-même, myself	*soi-même*, oneself
toi-même, thyself	*nous-mêmes*, ourselves
lui-même, himself	*vous-mêmes*, yourselves
elle-même, herself	*eux-mêmes* (m.), themselves
elles-mêmes (f.) themselves	

These forms are not reflexive, and may not come immediately after the conjunctive subjects *je, tu*, etc.:

Il me l'a dit lui-même, he himself told me.

They may be used in connection with reflexive verbs:

Il s'habille lui-même, he dresses by himself (*lit.*, he himself dresses himself).

14 In French the second person singular and the second person plural are used as forms of address. The singular implies very great familiarity. The use of this familiar form is called *tutoyer*, as:

Nous nous tutoyons, we "thou-thee" each other.

EXERCISE XVI.

1. They are against me and for them.
2. She does not trust him.
3. Whom have you seen ? Him.
4. Who answered him ? They (m.).
5. Who is there ? It is I.
6. We shall go (*irons*) together, thou and I.
7. He has spoken to him and me.
8. We have been there oftener than they.
9. She is more intelligent than he.
10. They, whom we thought (*que nous croyions*) our friends, have betrayed (*trahis*) us.
11. *He* works, but *you* do nothing but (*ne fais que*) play.
12. He say (*dire*) such a thing !

13. They have supplied (*fourni*) the money ; he has built (*bâti*) the house.

14. If you do not believe (*croyez*) *me*, will you believe (*croirez*) *him ?*

15. That child has written the letter himself.

16. They (f.) have told (*dit*) me themselves that they would come (*viendraient*) this evening.

17. They (m.) are never at home in the evening.

18. Each one for himself and God for all.

Key to Exercise XIV. Page 1877

Le territoire de la République française est d'environ cinq cent trente-six mille cinq cents kilomètres carrés. Sa superficie est à peu près treize fois la superficie de la Suisse et plus de treize fois la superficie de la Belgique. Sa population est de trente-huit millions six cent mille habitants. Chaque kilomètre carré a environ soixante-douze habitants. Il y a en France soixante mille juifs et six cent cinquante mille protestants. Elle a quatre-vingt-six départements. Son climat est tempéré : sa température moyenne annuelle est de soixante degrés. Sa chute de pluies est de quatre-vingts centimètres. La France forme une république. A la tête du pouvoir exécutif est placé le président de la République. Il est élu pour une période de sept ans. Le service militaire est obligatoire en France dès l'âge de vingt ans. La durée du service est de vingt-cinq ans : trois ans dans l'armée active, dix ans dans la réserve de l'armée active, six ans dans l'armée territoriale et six ans dans la réserve de l'armée territoriale. En temps de paix l'effectif est de cinq cent soixante mille hommes environ. La marine française comprend quatre cent cinquante navires de guerre. Ils sont montés par environ cent mille matelots et soldats de marine. Il y a cinq grands ports militaires. Paris, la capitale de la France, a une population d'environ deux millions et demi. Lyon et Marseille sont aussi deux des plus grandes villes de la France. A Marseille il y a quatre cent quatre mille habitants ; à Lyon il y en a quatre cent vingt mille. Paris a plus de neuf cent mille habitants de plus que ces deux villes ensemble. Par ses industries et son commerce Paris est une des premières villes du monde. Marseille est le premier port de toute la Méditerranée et une des dix ou douze places commerciales les plus importantes du globe. Le commerce de la France est très considérable. La valeur moyenne de son commerce extérieur est de sept mille cinq cents millions ou sept milliards et demi : quatre pour l'importation, et trois et demi pour l'exportation. La plus longue rivière de la France est la Loire. La longueur de la Loire est de mille vingt kilomètres. Les lignes des chemins de fer de la France ont une longueur totale de quarante mille kilomètres. Les Anglais mesurent les distances par milles, les Français par kilomètres. Le mille anglais est de mille six cent neuf mètres. Les Français indiquent la valeur par francs et centimes. Le franc vaut un peu moins de dix " pence " anglais. Le centime est la centième partie du franc. Il y a des pièces d'argent de cinquante centimes et des pièces d'or de dix francs. La plus grosse pièce d'argent est la pièce de cinq francs. En France les jours de fête sont le premier janvier ou jour de l'An, Pâques, l'Ascension, la Pentecôte, la Toussaint, et le jour de Noël. La Toussaint est toujours le premier novembre et Noël le vingt-cinq décembre. Pâques tombe entre le vingt et un mars et le vingt-six avril. L'Ascension est aussi une fête mobile. Elle tombe quarante jours après Pâques. La Pentecôte tombe dix jours plus tard, c'est-à-dire cinquante jours après Pâques. Les Français célèbrent leur fête nationale le quatorze juillet, en mémoire de la prise de la Bastille en mil sept cent quatre-vingt-neuf.

GERMAN

Continued from page 1990

By P. G. Konody and Dr. Osten

XXXI. The Reflective Pronouns are used in German to express the reflection of an action on the acting person :

Sing. 1. Ich waſche mir die Hände, I wash my hands [I wash to myself (*dat.*) the hands] ;
2. du wäſchſt dir die Hände, thou washest thy hands [thou washest to thyself the hands] ;
3. er, ſie, es wäſcht ſich die Hände, he, she, it washes his, her, its hands ;
Plur. 1. wir waſchen uns die Hände, we wash our hands ;
2. ihr waſcht euch die Hände, you wash your hands ;
3. ſie waſchen ſich die Hände, they wash their hands.

Alike in the accusative :

Sing. 1. Ich waſche mich, I wash myself ;
2. du wäſchſt dich, thou washest thyself ;
Sing. 3. er, ſie, es wäſcht ſich, he washes himself, etc. ;
Plur. 1. wir waſchen uns, we wash ourselves ;
2. ihr waſcht euch, you wash yourselves ;
3. ſie waſchen ſich, they wash themselves.

In the first and second person the personal pronoun [XI.] is used in the required case. Only the third person (*sing.* : er, ſie, es ; *pl.* : ſie) has a separate reflective pronoun—ſich—for all genders and numbers, both in the dative and accusative.

The reflective pronouns are employed in all tenses with the verbs of which they reflect the action. The imperative is : *sing.* 2 waſche dir die Hände ! (*dat.*) ; and waſche dich ! (*acc.*). Civil address : waſchen Sie ſich die Hände ! and waſchen Sie ſich !

1. The reflective pronoun immediately follows the finite verb in simple sentences. In the

compound tenses it therefore stands between the finite verb and the constant forms: ich unterhal'te mich, I enjoy myself; and ich habe mich unterhal'ten, I have enjoyed myself; ich werde mich unterhal'ten, I shall enjoy myself; etc.

2. The reciprocity of a reflected action is not expressed by ſich, but by einander, each other, one another: ſie liebten ſich, they loved themselves; and: ſie lieb'ten einander, they loved each other.

XXXII. The CARDINAL NUMERALS are:

eins	1	elf	11	dreißig	30
zwei	2	zwölf	12	vierzig	40
drei	3	dreizehn	13	fünfzig	50
vier	4	vierzehn	14	ſechzig	60
fünf	5	fünfzehn	15	ſiebzig	70
ſechs	6	ſechzehn	16	achtzig	80
ſieben	7	ſiebzehn	17	neunzig	90
acht	8	achtzehn	18	hundert	100
neun	9	neunzehn	19	hundert und eins	
zehn	10	zwanzig	20		101 etc.

tauſend 1000   eine Million, a million.

After 20 the unit always precedes the multiple of ten, with which it is connected by the conjunction und: einundzwanzig, 21; zweiundzwanzig, 22; etc., corresponding to the English form one and twenty, etc. The numeral eins casts off the s at the beginning and in the middle of a compound numeral, but retains it at the end: einunddreißig, 31; hunderteinundſechzig, 161; but, hundertundeins, 101; etc. Also: es iſt ein Uhr, it is one o'clock. But if Uhr (o'clock) is omitted: es iſt Eins, it is one [o'clock]. The hundreds, thousands, etc., are formed as in English: zweihundert, 200; fünfhundert, 500; zehntauſend, 10,000; hundert tauſend, 100,000; fünf hundert tauſend, 500,000; etc.

1. (*a*) The numeral ein (*m.*), eine (*f.*), ein (*n.*) takes the declensive inflections of the indefinite article [see V., 4] when preceding the substantive as attributive adjective. It is distinguished from the indefinite article only by the stress laid upon it: er aß nur einen Apfel, he ate only one apple; but, er aß einen Apfel, he ate an apple.

(*b*) If not directly connected with a substantive, it takes the ***strong*** declension of adjectives [see XXVI., 2] with the genitive -es: einer (*nom.*) von den drei Männern, one of the three men; ich ſah einen (*acc.*), I saw one; etc. When used substantively it takes a capital letter: Einer ſagte es mir, one [person] told it me.

(*c*) With the definite article it takes the inflections of the weak declension of adjectives [see XXVI., 1]: der eine von den drei Männern, [the] one of the three men. Der Torni'ſter ein-es and des ein-en Soldaten, the knapsack of one soldier, and .... of [the] one of the soldiers. Einer unter euch, one among you; and der ein-e unter euch, etc.

2. The numerals zwei and drei form the genitive with the suffix -er, and the dative with -en, if the case is not easily recognisable by the inflection of some other noun adjunct (definite article, pronoun, adjective, etc.): Er war der Vater zwei-er [or drei-er] (*gen.*) Kinder; he was the father of two [three] children; and er war der Vater zwei [drei] ſchön-er (*gen.*) Kinder, he was the father of two [three] beautiful children; or, er war der (*gen.*) zwei Kinder, he was the father of the two children. Er war drei-en (*dat.*) Mädchen ein Vater, and er war den (*dat.*) drei Mädchen ein Vater, he was a father to the three girls. The higher numerals which do *not* admit these inflections are usually circumscribed with the preposition von, of: er war der Vater von ſechs Kindern, etc.

3. The numerals 1—19, if not immediately followed by a substantive sometimes take an -e in the nominative and accusative (zwei-e, drei-e, fünf-e,*) neun-e, etc., and -en in the dative: mit (3) vier-en, ſechſ-en, etc. Both these forms are used in idiomatic expressions, when the number is understood to comprise the substantive: wir waren unſer fünf-e, there were five of us [persons]; er fährt mit ſechſ-en, he drives with six [horses]; etc.

4. The numerals are also used as substantives, with a gender and written with capitals: die (eine) Eins (*f.*) 1; also der Einſ-er (*m.*), the one: die Elf (*f.*) 11; das Hundert (*n.*) the hundred; das Tauſend (*n.*); die (eine) Million (*f.*), Billion (*f.*); die (eine) Milliarde (*f.*), 1000 millions, etc; also in compounds: das Jahrhundert, the century, etc.; and they take the declension—masculines and neuters strong, genitive with -s, plural with suffix -e or unchanged: des Einſer-s, des Hundert-s; *pl.* die Hundert-e, die Tauſend-e, die Einſ-er; but die Million-en, die Milliarde-n (weak).

XXXIII. The STRONG VERBS WITH THE STEM VOWEL -i- change it in the imperfect into -a- and in the past participle into -u-, -o-, or -e-. The list of verbs, with their different tenses, given on the next page must be carefully committed to memory.

EXAMINATION PAPER.

1. In which person, and for which declensive cases, does the reflective pronoun take a distinct form?
2. Where is the reflective pronoun placed in the normal arrangement of simple sentences?
3. What alterations does the cardinal numeral 1 undergo in German when placed at the beginning, in the middle, and at the end of a compound numeral?
4. Which is the place of the unit in compound numerals above 20?
5. When does the numeral 1 take the inflections of the strong, and when those of the weak declension of adjectives?
6. What are the suffixes for the genitive and dative of the numerals 2 and 3; when are they employed, and in which numerals is the genitive circumscribed by a preposition?
7. Which vowels are taken in the imperfect, and which in the past participle, by the strong verbs with the stem-vowel -i-?
8. Why do some verbs take the prefix ge- in the past participle, whilst others remain without it?

---

* Those ending in f (fünf, elf, zwölf) pronounced like w: fünfe (pronounced fünwe), etc.

INFINITIVE		PRESENT TENSE INDICATIVE I., II., III., Sing.	IMPERFECT		IMPERATIVE Singular	PAST PARTICIPLE
			Indicative	*Subjunctive*		
bedingen *	to stipulate, contract	ich beding-e, -ſt, -t	ich bedang	ich bedänge	beding(e)	bedungen
binden	to bind	ich bind-e, -eſt, -et	ich band	ich bände	bind(e)	gebunden
dringen †	to press, penetrate, rush in	ich dring-e, -ſt, -t	ich drang	ich dränge	dring(e)	gedrungen
empfinden	to feel	ich empfind-e, -eſt, -et	ich empfand	ich empfände	empfind(e)	empfunden
finden	to find	ich find-e, eſt, -et	ich fand	ich fände	find(e)	gefunden
gelingen	to succeed	es geling-t (used only in the neuter)	es gelang	es gelänge	es geling(e)	gelungen
klingen	to sound	ich kling-e, -ſt, -t	ich klang	ich klänge	kling(e)	geklungen
ringen	to wrestle	ich ring-e, -ſt, -t	ich rang	ich ränge	ring(e)	gerungen
ſchlingen	to entwine, wind, swallow greedily	ich ſchling-e, -ſt, -t	ich ſchlang	ich ſchlänge	ſchling(e)	geſchlungen
ſchwinden	to vanish, dwindle	ich ſchwind-e, -eſt, -et	ich ſchwand	ich ſchwände	ſchwind(e)	geſchwunden
ſchwingen	to swing	ich ſchwing-e, -ſt, -t	ich ſchwang	ich ſchwänge	ſchwing(e)	geſchwungen
ſingen	to sing	ich ſing-e, -ſt, -t	ich ſang	ich ſänge	ſing(e)	geſungen
ſinken	to sink	ich ſink-e, -ſt, -t	ich ſank	ich ſänke	ſink(e)	geſunken
ſpringen	to leap, jump	ich ſpring-e, -ſt, -t	ich ſprang	ich ſpränge	ſpring(e)	geſprungen
ſtinken	to stink,	ich ſtink-e, -ſt, -t	ich ſtank	ich ſtänke	ſtink(e)	geſtunken
trinken	to drink	ich trink-e, -ſt, -t	ich trank	ich tränke	trink(e)	getrunken
winden	to wind, twist	ich wind-e, -eſt, -et	ich wand	ich wände	wind(e)	gewunden
zwingen	to constrain, force	ich zwing-e, -ſt, -t	ich zwang	ich zwänge	zwing(e)	gezwungen
beginnen ‡	to begin	ich beginn-e, -ſt, -t	ich begann	ich begänne also (begönne)	beginn(e)	begonnen
beſinnen	to consider, deliberate	ich beſinn-e, -ſt, -t	ich beſann	ich beſänne (beſönne)	beſinn(e)	beſonnen
gewinnen	to win	ich gewinn-e, -ſt, -t	ich gewann	ich gewänne (gewönne)	gewinn(e)	gewonnen
rinnen	to flow, run	ich rinn-e, -ſt, -t	ich rann	ich ränne (rönne)	rinn(e)	geronnen
ſchwimmen	to swim	ich ſchwimm-e, -ſt, -t	ich ſchwamm	ich ſchwämme (ſchwömme)	ſchwimm(e)	geſchwommen
ſinnen	to meditate	ich ſinn-e, -ſt, -t	ich ſann	ich ſänne (ſönne)	ſinn(e)	geſonnen
ſpinnen	to spin	ich ſpinn-e, -ſt, -t	ich ſpann	ich ſpänne (ſpönne)	ſpinn(e)	geſponnen
bitten	to ask, beg	ich bitt-e, -eſt, -et	ich bat	ich bäte	bitt(e)	gebeten
beſi'tzen	to possess	ich beſitz-e, -eſt, -t	ich beſaß	ich beſäße	beſitz(e)	beſeſſen
liegen	to lie, to be located	ich lieg-e, -ſt, -t	ich lag	ich läge	lieg(e)	gelegen
ſi'tzen	to sit	ich ſitz-e, -eſt, -t	ich ſaß	ich ſäße	ſitz(e)	geſeſſen

* Dingen, to hire [ich ding-e, -ſt, -t]; imperfect indicative: ich dang, but *better:* *dingte*; subjunctive like imperative: ding(e); past participle: gedungen.

† The verbs with infinitives printed in italics are conjugated with *ſein* (to be), all the others with haben (to have).

‡ Note the subjunctive alternative form with ö.

Note in the above verbs the formation of the past participle with and without the prefix ge-, and consider the reasons for its omission in several cases.

EXERCISE 1. Insert the missing reflective pronouns:

Ich beei'le . . . . . ; er beeilt' . . . . ; du
I hasten [myself]; he hastens [himself]; thou
liebſt . . . . . . ; wir retten . . . . . . ; ich ſagte
lovest thyself; we save ourselves; I said
. . . . ; Sie ſagten . . . . : ihr ſagtet
to myself; you said to yourself; you said
. . . . ; ſie fürchteten . . . . ;
to yourselves; they feared [themselves];
ich hatte . . . . geſagt; wir hatten . . . . ruinirt;
I had said to myself; we had ruined ourselves;
er würde . . . getötet haben; ſie unterhält' . . . . . ;
he would have killed himself; she enjoys herself;
wir unterhiel'ten . . . . . ; ſchämen Sie . . . . . !
we enjoyed ourselves; be ashamed of yourself!
raſiere . . . . !
shave thyself!

EXERCISE 2. Insert the missing numerals (fully written) and the declensive inflections.

Ich habe . . . . . Karten; er gab mir . . . . Pfund
I have 21 cards; he gave me £261
für das Jahr . . . .; der Lehrer unterrich'tet
for the year 1901; the teacher instructs
. . . . Knaben und . . . . . . Mädchen, zuſammen
42 boys and 57 girls, together
. . . . . . Kinder. Im ruſſiſch-japa'niſchen Kriege
99 children. In the Russo-Japanese war
wurden . . . . Soldaten verwun'det — . . . .
247,589 soldiers were wounded — 145,437
Ruſſen und . . . . . . Japaner. Wie viel iſt . . . .
Russians and 102,152 Japanese. How much is 19
und . . . . . ? . . . . . ; . . . . . und . . . . ? . . . .
and 13? 32; 14 and 9? 23.
Ein . . von euch hat es genommen.
One of you has taken it. —
Ich glaube es war der ein . . von den . . . . Soldaten;
I believe it was [the] one of the five soldiers;
er war der Vater zwei . . . Söhne,
he was the father of two sons, (or
with preposition): er war der Vater von . . . . Söhnen

KEYS TO EXERCISES IN EXAMINATION PAPER VIII. (PAGES 1879–80).

[The exercises being now more advanced, Keys are given in each lesson to the exercises set in the previous Examination Paper.]

EXERCISE 1 (*a*). Der Griff meines Stockes iſt ſchön; ich gab meinem Freunde deinen Stock; ſie brach ihre Uhr; der Deckel ihrer Uhr iſt zerbrochen; er fuhr mit ſeinen und mit ihren Pferden; ich ging zu ihrem Arzte; ſie gingen mit ihren Eltern in unſeren Garten und bewunderten die Schönheit unſerer Blumen. Eu(e)re Freunde und die Brüder eu(e)rer Freunde waren in eu(e)rem Garten und pflückten eu(e)re Blumen.

(*b*). Ihr Freund iſt auch der meine (or unſere); er brach nicht blos ſeine Uhr, ſondern auch die deine, die ihre, die unſ(e)re, die eu(e)re, die ihre und die Ihre; die Schnelligkeit deines Hengſtes iſt größer als die des meinen, des ſeinen, des ihren, des unſ(e)ren, des eu(e)ren, des ihren, des Ihren; ſeine Dogge lief hinter der meinen, der deinen, der ihren, der unſ(e)ren, der eu(e)ren, der ihren, der Ihren; mein Pferd ſchlägt das deine, das ſeine, das ihre, das eu(e)re, das ihre, das Ihre; deine Freundinnen ſind auch die unſ(e)ren, die ihren. Die Wolle meines Schirmes iſt beſſer als die Seide des deinen, des ſeinen, des ihren, des unſ(e)ren, des eu(e)ren, des ihren, des Ihren; ich glaube deinem Freunde mehr als dem meinen, dem ſeinen, dem ihren, dem unſ(e)ren, dem eu(e)ren, dem ihren, dem Ihren; er liebt ſeinen Freund mehr als den meinen, den deinen, den ihren, den unſ(e)ren, den eu(e)ren, den ihren, den Ihren, etc.

(*c*). Der Stock iſt meiner, deiner, ſeiner, ihrer, unſ(e)rer, eu(e)rer, ihrer, Ihrer; die Dogge iſt meine, deine, etc.; das Pferd iſt meines, deines, etc.

(*d*). Insert the suffix -ig- between the possessive pronoun and its declensive termination, wherever the pronoun does not precede the substantive.

EXERCISE 2 (*a*):

ich ſtehe auf	ich biete an	ich gebe aus
du ſtehſt auf	du bieteſt an	du gibſt aus
er ſteht auf	er bietet an	er gibt aus
wir ſtehen auf	wir bieten an	wir geben aus
ihr ſteht auf	ihr bietet an	ihr gebt aus
ſie ſtehen auf	ſie bieten an	ſie geben aus
ich ſchließe bei	ich ſchlafe ein	ich komme hin
du ſchließt bei	du ſchläfſt ein	du kommſt hin
er ſchließt bei	er ſchläft ein	er kommt hin
wir ſchließen bei	wir ſchlafen ein	wir kommen hin
ihr ſchließet bei	ihr ſchlaft ein	ihr kommt hin
ſie ſchließen bei	ſie ſchlafen ein	ſie kommen hin
ich nehme mit	ich falle um	
du nimmſt mit	du fällſt um	
er nimmt mit	er fällt um	
wir nehmen mit	wir fallen um	
ihr nehmt mit	ihr fallt um	
ſie nehmen mit	ſie fallen um	

(*b*). Ich verſtehe, du verſtehſt, etc.; ich ſtehe bei, du ſtehſt bei, etc.; ich verbiete, du verbieteſt, etc.; ich biete auf, du bieteſt auf, etc.; ich ſchließe aus, du ſchließt aus, etc.; ich beſchließe, du beſchließt, etc.; ich gefalle, du gefällſt, etc.; ich falle auf, du fällſt auf, etc.

(*c*). Steh' auf! Stehet auf! Stehen Sie auf! Biete an! Bietet an! Bieten Sie an! Gib aus! Gebet aus! Geben Sie aus! Schließ' bei! Schließet bei! Schließen Sie bei! Schlaf' ein! Schlafet ein! Schlafen Sie ein! Komm' hin! Kommt hin! Kommen Sie hin! Nimm' mit! Nehmet mit! Nehmen Sie mit! Fall um! Fallet um! Fallen Sie um! Verſteh! Verſteht! Verſtehen Sie! Steh' bei! Steht bei! Stehen Sie bei! Verbiet! Verbietet! Verbieten Sie! Biete auf! Bietet auf! Bieten Sie auf! Schließ aus! Schließet aus! Schließen Sie aus! 'Beſchließ! Beſchließet! Beſchließen Sie! Gefalle! Gefallet! Gefallen Sie! Fall' auf! Fallet auf! Fallen Sie auf!

EXERCISE 3. Der Schüler hat (hatte) gelernt; der Lehrer hat (hatte) das Fenſter geöffnet; der Künſtler hat (hatte) ein Bild gezeichnet; das Mädchen hat (hatte) gelächelt; der Gärtner hat (hatte) im Garten gearbeitet; das Schiff iſt (war) geſegelt; die Kinder haben (hatten) geſpielt; die Mädchen ſind (waren) errötet; ich habe (hatte) meine Eltern geliebt; er hat (hatte) Unſinn geredet; du haſt (hatteſt) eine Cigarre geraucht; ihr habt (hattet) im Fluſſe gebadet; ſie haben (hatten) die Glocke geläutet; die Kinder haben (hatten) ihr Spielzeug zerſtört; er hat (hatte) an der Türe gelauſcht; du haſt (hatteſt) den Vater begrüßt.

EXERCISE 4 (*a*). Die Väter, die Löffel, die Äpfel, die Fenſter, die Eſel, die Brüder, die Onkel, die Vögel, die Reiter, die Fäden, die Veilchen, die Käſe, die Sättel.

(*b*). die Berge, die Hunde, die Jahre, die Kenntniſſe, die Hirſche, die Bewandtniſſe, die Pferde, die Haare, die Kürbiſſe, die Labſale, die Abende, die Preiſe, die Mooſe, die Fließe, die Schuhe, die Sproſſe (also Sproſſen) die Geheimniſſe.

(*c*). Die Ärzte, die Gänſe, die Köpfe, die Bräute, die Hände, die Zähne, die Töpfe, die Fäuſte, die Füchſe, die Brüſte, die Ströme, die Würſte, die Krüge.

(*d*). Die Tücher, die Länder, die Kinder, die Gewänder, die Weiber, die Kräuter, die Lieder, die Fäſſer, die Dörfer, die Glieder, die Würmer, die Geſpenſter, die Völker.

(*e*). Das Roß, des Roſſes, dem Roſſe, das Roß, die Roſſe, der Roſſe, den Roſſen, die Roſſe; das Los, des Loſes, dem Loſe, das Los, die Loſe, der Loſe, den Loſen, die Loſe; das Hindernis, des Hinderniſſes, dem Hinderniſſe, das Hindernis, die Hinderniſſe, der Hinderniſſe, den Hinderniſſen, die Hinderniſſe.

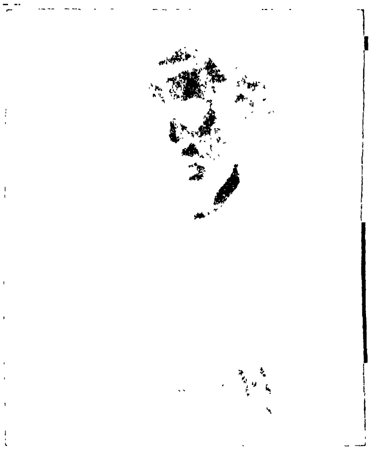
EIGHTEENTH CENTURY PROSE

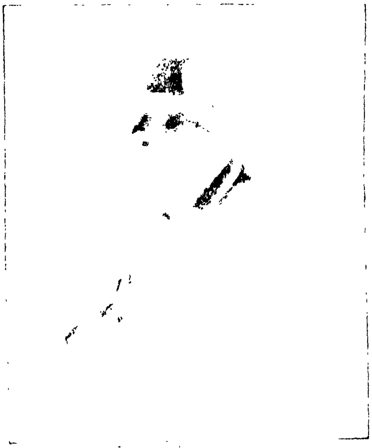
2. In which the Study of this Period is continued from Dr. Johnson to Adam Smith. Specimens of the Writings of Burke and Gibbon

By J. A. HAMMERTON

Dr. Johnson. SAMUEL JOHNSON (b. 1709; d. 1784), poet, essayist, dramatist, biographer, critic, novelist, lexicographer, and the "great Cham" of English literature, cannot be considered here in relation to his unrivalled position as a great and wise talker. There is only one way of realising Johnson's greatness: by mastering Boswell's biography. As to his influence on prose literature, Macaulay says: "His constant practice of padding out a sentence with useless epithets till it became as stiff as the bust of an exquisite; his antithetical forms of expression, constantly employed even where there is no opposition in the ideas expressed; his big words wasted on little things; his harsh inversions, so widely different from those graceful and easy inversions which give variety, spirit, and sweetness to the expression of our great old writers—all these peculiarities have been imitated by his admirers, and parodied by his assailants, till the public has become sick of the subject." Gibbon, the historian of Roman decadence, lived to write; Johnson, an infinitely greater man, wrote to live. To-day, Johnson's "Lives of the Poets" are read more, perhaps, than anything he wrote, but not for the accuracy of their data or their infallibility of judgment. They disclose to us not fine literary instinct so much as fine human sympathy. His prose tale of "Rasselas, Prince of Abyssinia," written to defray the cost of his mother's funeral, has been aptly described as a prose version of his poem on "The Vanity of Human Wishes." His great "Dictionary" was the first of its kind. It stands almost alone as the work of one man. Its value and influence have been great, and even to-day, except for its weakness on the side of etymology, a weakness due to the fact that Johnson's Latin learning was not approached by his knowledge of Anglo-Saxon, it is a standard book of reference. The ordinary reader should have some acquaintance with the "Lives of the Poets," and "Rasselas" he is not likely to miss. For the rest, to know this grand old character in Boswell's biography is, as it was to love "Aspasia," "a liberal education."



DR. SAMUEL JOHNSON



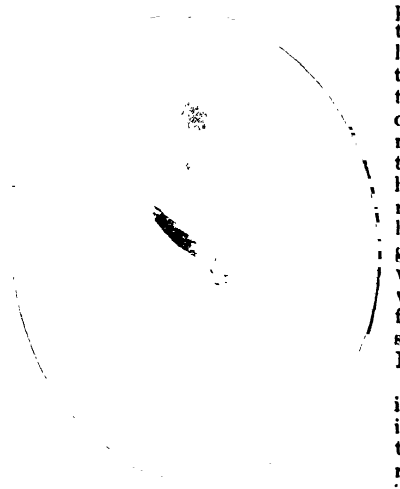
OLIVER GOLDSMITH

Oliver Goldsmith. The friendship between Steele and Addison was not greater than that between Johnson and OLIVER GOLDSMITH (b. 1728; d. 1774). But no greater contrast could be imagined than that afforded by the writings of the two men. "In prose style, as in poetic," says Mr. Gosse, "it is noticeable that Goldsmith has little in common with his great contemporaries, with their splendid burst of rhetoric and Latin pomp of speech, but that he goes back to the perfect plainness and simple grace of the Queen Anne men. He aims at a straightforward effect of pathos or of humour, accompanied, as a rule, with a colloquial ease of expression, an apparent absence of all effect or calculation." Goldsmith's prose approximates to that of Addison. The best examples of it are to be found in his "Citizen of the World" and the "Vicar of Wakefield." The first-named work consists of a series of letters supposed to have been written by a Chinaman resident in London, who was jotting down his experiences for the benefit of his friends in the Far East. The idea was not original, and it has since been imitated by innumerable writers, but the delightful wit and humour of Goldsmith's work have never been excelled. Ninety-eight of the letters appeared in the periodical called the "Public Ledger" in 1760. Twenty-five more were added when the letters were printed in volume form in 1762.

The "Vicar of Wakefield," Goldsmith's chief prose work, must be considered in its relation to the history of the Eng'ish novel, which will form the most important part of our future study.

Historians and Philosophers. A number of historians, philosophers, theologians, and essayists must now be dismissed with the briefest possible mention :

ANTHONY ASHLEY COOPER, third Earl of Shaftesbury (b. 1671 ; d. 1713), wrote a volume entitled, "Characteristicks of Men, Manners, Opinions, Times," the views expounded in which influenced the Scottish philosopher Hutcheson, attracted attention on the Continent, and found reflection in Pope's "Essay on Man." HENRY ST. JOHN, first Viscount Bolingbroke (b. 1678 ; d. 1751), occupied himself with that side of philosophy affected by Shaftesbury, but is better known as a statesman. GEORGE BERKELEY, Bishop of Cloyne (b. 1685 ; d. 1753), was a man whose life apart from his writings is full of interest. As a philosopher he aimed at the overthrow of materialism. He was an acute and original thinker, he possessed a style of great force and elegance, and he is one of our most accomplished writers of dialogue. JOSEPH BUTLER, Bishop of Durham (b. 1692 ; d. 1752), was the author of a work on the "Analogy of Religion, Natural and Revealed, to the Constitution and Course of Nature," which won for him the name of "The Bacon of Theology," and remains a standard work in its own department of inquiry. DAVID HUME (b. 1711 ; d. 1776) was distinguished as an essayist, a philosopher, and a historian. Possessing wonderful clearness of mental vision, his style is marked by exceptional lucidity. An opponent of popular government, he was yet the first of our writers to recognise the importance of the social and scientific as well as the constitutional and political factors in the making of history. His influence as a philosopher was not inconsiderable in Scotland and Germany. The REV. WILLIAM ROBERTSON (b. 1721 ; d. 1793) was a painstaking historian of "Scotland," "Charles V.," and "America."



EDMUND BURKE

Gibbon's Great Work. EDWARD GIBBON (b. 1737 ; d. 1794) dedicated the best part of his life to the writing of his monumental history of "The Decline and Fall of the Roman Empire," and has been described as the one historian of his time "whom modern research has neither set aside nor threatened to set aside." The magnitude of his subject "is nobly sustained by the dignity of the treatment. The glowing imagination of the writer gives life and vigour to his rounded periods and to the stately and pompous march of his narrative. Perhaps his most unique merit is his supreme and almost epic power of moulding into a lucid unity a bewildering multitude of details, and giving life and sequence to the whole." (We retain in this quotation from a competent critic his error in "most unique." Since unique means "without like," it is incapable of degree. Anything that is "unique" cannot be so more or less.) Gibbon's great work, begun in 1768, was completed in 1788. The following brief passage, referring to the foundation of Constantinople, illustrates some of the chief features of the historian's style :

"The prospect of beauty, of safety, and of wealth united in a single spot was sufficient to justify the choice of Constantine. But as some mixture of prodigy and fable has in every age been supposed to reflect a becoming majesty on the origin of great cities, the Emperor was desirous of ascribing his resolution not so much to the uncertain counsels of human policy as to the eternal and infallible decrees of Divine wisdom. In one of his laws he had been careful to instruct posterity that in obedience to the commands of God he laid the everlasting foundations of Constantinople ; and though he has not condescended to relate in what manner the celestial inspiration was communicated to his mind, the defect of his modest silence has been liberally supplied by the ingenuity of succeeding writers, who describe the co-eternal vision which appeared to the fancy of Constantine as he slept within the walls of Byzantium."

"The Decline and Fall" is one of the inevitable items in any list of "books to read" and while there may be many who will find its stately poise of phrase and processional style of narrative monotonous, it is difficult to understand how any reader with a moderate endowment of imagination can fail to obtain from its study a continuous delight. No man is well read, or thoroughly furnished in his knowledge of one of the most momentous periods in the world's history, who has not gone through Gibbon's great masterpiece at least once.

Burke's Command of Prose. EDMUND BURKE (b. 1729 ; d. 1797) was, like Bolingbroke, a statesman and orator as well as an author. Matthew Arnold has described Burke as the greatest master of English prose style that ever lived. Mr. Gosse says: "Notwithstanding all its magnificence, it appears to me that the prose of Burke lacks the variety, the delicacy, the modulated music of the very finest writers. . . . The greatest of English prose writers, we may be sure, would be found to have some command over laughter and tears, but Burke has none. . . . In short, the prose of

Burke may be felt to be the finest expression of a particular phase of the eighteenth century mind—a phase from which all the coarse fibre of the Renaissance, to its very last filament, had been extracted, where all is civilised, earnest, competent, and refined, but where the imagination is almost too completely under control." Apart from his speeches, Burke's principal prose works are: "A Vindication of Natural Society," written to ridicule Bolingbroke's views on religion; an "Inquiry into the Sublime and the Beautiful," and "Reflections on the Revolution in France" (1788). In the last-named work Burke set forth with much impressiveness his view that constitutional government, not revolution, was the true remedy for the troubles of the French nation. Here is a striking extract:

Specimen of Burke's Writing. "It is now sixteen or seventeen years since I saw the Queen of France, then the Dauphiness, at Versailles; and surely never lighted on this orb, which she hardly seemed to touch, a more delightful vision. I saw her just above the horizon, decorating and cheering the elevated sphere she had just begun to move in—glittering like the morning star, full of life and splendour and joy. Oh! what a revolution! And what a heart must I have to contemplate without emotion that elevation and that fall! Little did I dream, when she added titles of veneration to those of enthusiastic, distant, respectful love, that she should ever be obliged to carry the sharp antidote against disgrace concealed in that bosom. Little did I dream that I should have lived to see such disasters fallen upon her in a nation of gallant men, in a nation of men of honour and of cavaliers. I thought ten thousand swords must have leaped from their scabbards to avenge even a look that threatened her with insult. But the age of chivalry is gone. That of sophisters, economists, and calculators has succeeded, and the glory of Europe is extinguished for ever. Never, never more shall we behold that generous loyalty to rank and sex, that proud submission, that dignified obedience, that subordination of the heart which kept alive, even in servitude itself, the spirit of an exalted freedom. The unbought grace of life, the chief defence of nations, the nurse of manly sentiment and heroic enterprise, is gone! It is gone, that sensibility of principle, that chastity of honour, which felt a stain like a wound, which inspired courage whilst it mitigated ferocity, which ennobled whatever it touched, and under which vice itself lost half its evil by losing all its grossness."

EDWARD GIBBON

Importance of Studying Burke. Of all the eighteenth century writers, perhaps Burke is the one whom the student can least afford to palter with. De Quincey, who was no hasty eulogist, considered him the supreme writer of his time. Whether that judgment can be entirely justified, it is not easy to show, unless we could enter at much greater detail into comparisons between Burke and his contemporaries; but the fact remains that for much that makes for true citizenship as well as for the literary graces the student must have recourse to the works of Edmund Burke—his speeches not less than his writings. He helps us marvellously to a clear understanding of the public life of our country, though he may not always convince us. Indeed, his purpose was not to persuade and convince so much as to expound, in the most logical and reasonable manner of which he was capable, his own conclusions; and by our observing the process of his mind, we also acquire, in our own varying capacities, something of the orderly command of ideas and facts of which he was so able an exponent. We must not be content with knowing Burke in "The Sublime and the Beautiful"; his "Reflections on the Revolution in France," though far less known to the ordinary reader, is even more worthy of study, and his speeches present a rich field whence we may glean knowledge of life and wisdom.

Horace Walpole and Adam Smith. HORACE WALPOLE, fourth Earl of Orford (b. 1717; d. 1797), set up a private press, whence he issued "A Catalogue of Royal and Noble Authors." He also wrote "Anecdotes of Painting in England," a tragedy, "The Mysterious Mother," and a romance entitled, "The Castle of Otranto." He left nearly 3,000 letters and a "History of the Last Ten Years of the Reign of George II." Byron described Walpole as the "father of the first romance and the last tragedy in our language," an absurd piece of hyperbole. Walpole, however, possessed a brilliant style, which will long serve to keep his works alive and render his letters readable independently of their historical value.

ADAM SMITH (b. 1723; d. 1790) wrote a work entitled "The Wealth of Nations," which originated the study of "political economy" as a distinct branch of science, inspired a world-wide interest in the sources of wealth, and was responsible for the rise of the theory of Free Trade. "The Wealth of Nations" is a book that may still be studied with pleasure and profit. It affords an example of the way in which a "dry" subject may be treated so as to appeal to the popular mind.

THE PRINCESS GOWN

Double-breasted Coat—continued. Making and Putting on the Collar. Sleeves. Drafting a Princess Gown. Materials Required

By Mrs. W. H. SMITH and AZÉLINE LEWIS

The Outside Collar. This must be cut ½ in. longer and 1 in. wider than the pattern, so as to get the same well under, and also give sufficient scope for the curl given to the inside collar by the padding stitches. It is generally cut without a seam, and the pattern must be placed across the material—*i.e.*, with the weft of the cloth (not on the bias, as the inside collar), otherwise, should there be any pattern on the material, the effect would be far from satisfactory.

Before putting on the outside collar fold the cloth, place the pattern on, chalk-mark the centre-back, the crease-row, and round the collar. Having done this, remove the pattern, open the collar on the table, wrong side uppermost, with the stand towards the worker, slightly damp the crease-row, and press the stand back until it lies flat on the fall; shrink the crease-edge and well stretch the stand. The fall also must be stretched, so as to give plenty of leaf edge—*i.e.*, length from centre-back to end of collar; if this is not attended to the shrinking and stretching will have failed in their object. On no account must the crease-row be stretched.

Now place the cloth on the table right side uppermost; place the collar on the cloth, canvas uppermost, centre seam to the fold of cloth, and the crease-rows together; run a thread through the latter to hold the collar and cloth together, turn the collar over and pare he cloth away to within ⅜ in. of edge of fall and ends (*not* the stand).

Place the edge of cloth to edge of collar and baste thickly from end to end, well fulling the cloth on at both ends 1½ in. each side of corner, and easing it along the edge of fall. Now stitch the edge from end to end close to edge, with the fulness underneath just escaping the canvas when stitching. Remove all the basting stitches from the seam and crease-row, turn the cloth over, work the corners out evenly; baste round the edge, working the seam back under so that it will not show on the right side, put a few basting stitches across the corners, with the point of corner rolled over the finger while so doing, and pressing the cloth towards the point; baste through the centre, still pressing a little cloth towards the edge of fall.

Now run another thread through the crease-row of cloth and collar together, beginning and terminating ½ in. from each end. If the cloth is of a ravelly nature, it must be turned up and felled to the canvas, but if a good firm make, such as Melton, the edge can be left raw.

Sewing on the Collar. Place the coat on the knee right side uppermost; secure the centre of collar to the centre of back, and crease-row of collar to crease-row of lapel; baste the collar to the coat, beginning at the right hand, keeping it rather tight till the crease-row is reached, and long—*i.e.*, eased well, in the hollow of neck or gorge, and slightly easy from thence to the centre.

The other side of collar must be basted in the same way. Fell to the coat, holding this well over the hand; and having done so turn the coat over.

Before felling the collar-facing to coat, serge the canvas and lining to the seam. This acts as a stay to the collar and keeps it firm and in its proper position; if this is not done the collar will not be a success.

Basting the Edges together. Now turn in the edge of collar from the end to a little beyond the break, or crease, and baste; then treat the facing the same. Now baste the edges close together. Take a No. 7 or 8 needle and fine silk and draw the edges together with what is called the drawing-stitch, as described in BOY'S TAILORING. This must be done with great care, the object being to hide the stitches. Turn in the remainder of collar to the shoulder seam, which should be notched and cut away to within ¼ in.; fell till the shoulder is reached; tack the edge of collar at the back across the seam.

Work the left side of collar the same as the right. Now turn in the lining and fell to the collar, then take a needle and silk and stitch finely ½ in. below the crease right through the collar, starting 1 in. beyond the break, and terminating 1 in. from the break at the other side.

Having sewn the collar on satisfactorily, machine the edge to match the front of coat; remove the basting, and press.

A duplex board is almost a necessity; however, if this is not obtainable the next best thing is the pressing pad already described. Well press the inside of collar and lapels over a damp, clean cloth, which must be wrung practically dry; the edges of fronts should be pressed on the wrong side on a bare board.

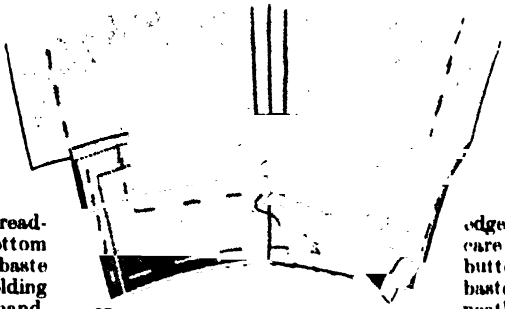
There are two ways of putting on a collar—the one is to seam it on, the other to fell; the latter, which we have given, is preferable, as it gives the thinnest and neatest finish.

The Sleeve. Baste and stitch the forearm seam, remove the basting, notch the seams three or four times in the hollow of the arm, open and press.

For the cuff, cut a piece of very fine canvas 4½ in. deep and wide enough to go right across the bottom of sleeve; this is to give firmness to the cuff and act as a stay for the buttons and buttonholes. Place the canvas on the sleeve

½ in. below the thread-marks of sleeve-hand, baste in position, run a thread along the depth of cuff, *i.e.*, 4 in. from the turn-up. If the inlay has not been left on the under part, a piece of cloth 1 in. wide must be seamed on to take its place. If it is a thick material it should be stoated [see Boys' Tailoring]. But if inclined to ravel it must be notched ½ in. above the thread-marks of cuff, and the edges of both canvas and material turned in together. If of a firm, close make, the edges need not be turned in.

Now join a piece of cloth, 2 in. wide and 2½ in. long, on the buttonhole side and press the seam; this must be done on the buttonholes side whether the material is ravelly or not. Turn the facing in ½ in. inside the thread-marks, turn up the bottom to thread-marks, and baste two or three times, holding the cuff over the hand. Be very careful over the corner on the buttonholes side, as the sharp angle at that point should be worked in with the needle to give a rounded appearance. Baste the edge, then turn in the facings on button stand ½ in. from the edge; make the point neat, and baste. Secure firmly the edge of turn-up to canvas, and fell both edges neatly; remove the basting, but not the serging, and give a good press to make the edges as thin as possible.

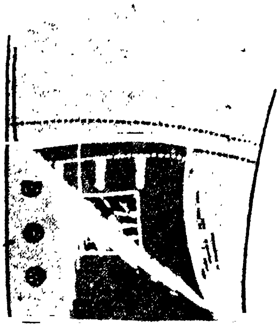


65. CUFF READY FOR MACHINING.

Machine the cuff, starting at the bottom on button side; stitch close to the edge, then along the thread-mark of cuff, down the buttonhole side, close to the edge, and back again ¾ in. from the first row, keeping the corners quite square, and terminating at the top of cuff at the back seam [65].

Space the buttonholes and work them (three will be sufficient); they should be 1 in. apart, the first one being 1 in. from the bottom; work them according to directions given in the Boys' Tailoring section.

Now place the edge of buttonholes side close to the thread-marks on under part; mark through the eyes with chalk for the position of buttons, and put a thread-mark in each. Place the edge of buttonholes side on the thread-marks of button side, with the buttons quite even; the machining should meet at the top of cuff if it has been done evenly. Baste the seam, from the bottom to the top, and stitch; remove the basting, open and press [66].



66. CUFF COMPLETE.

Linings. The lining must be cut from the same pattern as the cloth, allowing ¾ in. extra on the top of both parts; be sure and leave the same amount of inlays on hind part of top sleeve, and cut the bottom 1 in. shorter; baste the seams and stitch them, leaving the back seam open for the cuffs.

Now insert the lining. Both sleeve and lining must be inside out. Place the sleeve on the table, under-arm uppermost; place the lining on, under-arm to under-arm, leaving the lining ¾ in. above the top of sleeve; baste to the seams on both sides, beginning 3½ in. from the top, and keeping the lining very easy; place the hand through the top of lining, take hold of the bottom of sleeve, and draw through. Smooth the lining, notch it at the top of cuff, 1½ in.; turn in the edges all round, taking care that it escapes the buttonholes by ½ in.; baste the sleeve, and fell neatly to cuff.

Pressing. Place the narrow end of sleeve-board in the sleeve and well press the cuff; now turn the sleeve, and it is ready to insert in the coat. Turn the lining back from the top, to keep it out of the way while basting in the sleeve. Take the coat and cut away any superfluous canvas there may be from the armhole, secure a narrow linen stay to the back of armhole, as from J^a to 1 in. beyond I, holding the stay rather tight at that part. Secure the lining to the armhole, and thread-mark the turning—*i.e.*, ¾ in. from the edge of cloth.

Inserting the Sleeve. Secure the back seam to the back pitch (J^a), and the front seam to the front pitch, which is generally ¾ in. up from bust-line on armhole curve; baste the sleeve from the back pitch to the forearm pitch, easing it under the arm, and slightly easing it 2 in. above the front pitch.

We must now arrange the pleats. There should be a box-pleat in the centre of top, *i.e.*, the centre of pleat should be on a line with shoulder seam. Two pleats are arranged at the back of box-pleat, and three in the front, all in a downward direction. The fold of the last pleat should be on J^a, and the bottom one on fore part 2 in. above the front pitch of sleeve. Two pleats only can be put in the fore part, if desired, instead of three.

Now baste the top of sleeve to armhole, and either machine or stitch by hand; remove the basting and press the seam open on the edge of a duplex board, very slightly damping the seam first, and pressing with a very narrow iron. If a narrow one is not available, use the point only of a flat iron. Serge the turned-back seam to the lining; cut a piece of canvas (the shape of a dress-preserver) the length from first to last pleat, 2 in. to 3 in. deep in the centre—this is to make the head of the sleeve stand out nicely—serge the canvas to the seam, leaving the rounded part free. Now pleat the top of lining to match the top of sleeve, and fell to the lining of coat.

On no account must the sleeve lining be a tight one.

If the material is thin the canvas or muslin can be pleated in with the cloth. If the former is used it must be very fine.

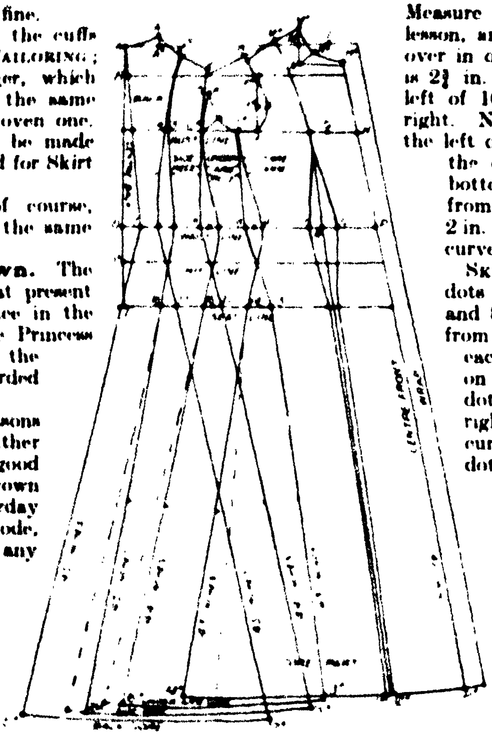
Sew the buttons on the cuffs as described in BOYS' TAILORING; and, finally, the hanger, which last can be either of the same lining as coat or a woven one. If the former, it must be made and sewn on as directed for Skirt in DRESSMAKING.

Both sleeves are, of course, made and inserted in the same way.

The Princess Gown. The two styles which are at present striving for pre-eminence in the world of dress are the Princess and the Empire, and of the two the former is accorded the greater favour.

There are various reasons for this, as, though neither is suited to any but good figures, the Princess gown is more adapted to everyday use than the Empire mode, and does not mean any alteration of waist-line. We have therefore selected this for instruction in our next lesson.

Measurements. Neck, 14 in.; top of collar, 13 in.; back, 16 in.; chest, 34 in.; waist, 24 in.; nape to waist, 21 in. Front length, 42 in. from waist; side piece, 43 in. Second side piece, 44 in.; back, 45 in; sleeve from centre back to elbow, 20 in.; elbow to wrist, 10 in. Working scale half chest, 17 in.; ¼-in. turnings are allowed on all seams.



67. DRAFTING FOR PRINCESS GOWN

Drafting. For the system, see 58, page 1841.

Two large sheets of paper are required, also a long rule or blind lath, and an inch tape.

First square the lines A, B, C, D and E, as in previous draft [67].

D to 1, 1¼ in.; draw line from A through 1 to E; 1 to 2, 1½ in.; make 3 in the centre of back line and C^a; and 4, ½ in. to the left of 3.

C^a to I, 1½ in.; F to I^a, 1½ in. Raise J ½ in. and connect to shoulder; J^b is in the centre; make a dot ½ in. to the right of J^b. J^a to K, ½ in. Raise H^a ½ in., connect to M^a.

Draw front shoulder line, make M^b in the centre. Curve the armhole from O to K. M^a to P, the length from nape to waist, omitting the back neck less ½ in., i.e., two seams (as from A to A^b). This should not be omitted, as it determines the waist, and is a most important measurement. Draw waist line from 1 to P.

SIDE PIECES. 2 to 5, 1¼ in.; 5 to 6, 2½ in.; 6 to 7, 1½ in.; 7 to 8, 2½ in.; 8 to 9, 1½ in. Draw line from 2 through 4 to J^b; from 5 through 3, ½ in. to the right of J^b, and 6 to C^a.

Curve from 7 through C^a to K; from 8, ½ in. to the left of I^a, and from 9 to I^a.

DART. Make 10 in the centre of 9 and P. Measure the waist as in previous lesson, and put the amount left over in one dart; in this case it is 2½ in. Make 11 1½ in. to the left of 10, and 12 1½ in. to the right. Now make a dot 1½ in. to the left of G. Draw a line from the dot through 10 to the bottom of garment. Curve from 11 and 12 to within 2 in. of bust line, and slightly curve from thence to M^b.

SKIRT OF ROBE. Make dots in the centre of 6 and 7, and 8 and 9. Square down from the centre of dart and each dot, and make dots on the seat line. Make dots ½ in. to the left and right of centre dart and curve upwards from the dots to 11 and 12.

13 is 1 in. to the right of next dot on seat line; 14, 1½ in. to the left; 15, ½ in. to the right of next; 16, 1 in. to the left.

Square down from centre of 2 and 5 to seat line; make dot, place 17 and 18 ½ in. to right and left of same. Make a dot ½ in. to the left of E. Curve from 14 to 9, 13 to 8, 15 to 6, and 16 to 7. Draw lines from 18 to 5 and 17 to 2.

FRONT. P to P^a, 42 in.; 11^a and 12^a are ½ in. to the left and right of centre of dart. Connect these to the dart on seat line. Place the ruler on 9 and 14, draw a line to the bottom of garment.

Now take an inch tape and measure from 9, round the curve through 14, and make 14^a 1 in. longer than front, i.e., 43 in. Draw line from 14^a to P^a.

UNDER ARM. Place the ruler on 9 and 13, draw line to the bottom. 8 to 13^a is the same length as from 9 to 14^a (43 in.).

Place the ruler on 7 and 16, draw line to the bottom; measure from 7, and make 16^a 1 in. longer than from 8 to 13^a (44 in.). Connect 13 to 16^a.

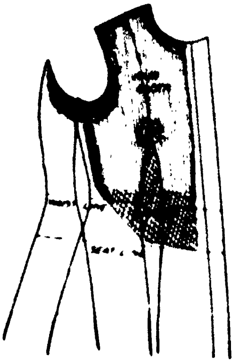
SIDE PIECE. Place the ruler in the centre of 6 and 7, with the edge resting on 15; draw line to the bottom, make 15^a the same length as 7 to 16^a (44 in.).

Place the ruler on 5 and 18, draw line to bottom, make 18^a 45 in.; connect 18^a to 15^a.

BACK. Place the ruler on 2 and 17, make 17^a 45 in. Place ruler on 1 and the dot to left of E; make E^a 45 in. Draw line from E^a to 17^a.

For sleeve draft, see **59**, page 1842.

If the material is not wide enough to cut the fronts without joins, 3 in. can be taken off the gore gradually to seat line. If this is done, the 3 in. must be divided and put on the left side of the two gores, and taken gradually to seat line [see broken lines].



69. LEFT FORE PART OF GOWN

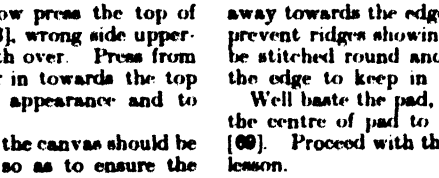
Materials Required. 4½ yd. of 54-in. material will be required, or 8 yd. single width, and the same quantity of lining; ¾ yd. of the finest French canvas (it must on no account be a heavy make); 10 strips of whalebone (not composition), 8¾ in. long, or according to length required, for button and buttonhole, or 12 for edge to edge fastenings; ½ yd. linen.

Trace and cut out the linings the same as material, but ½ in. extra must be allowed on the turnings.

The Making. Before beginning to make the robe the reader should turn to LADIES' TAILORING, page 1840 etc., as, with a few exceptions, which we shall give, the making, pressing, and shrinking will be practically the same as in the ladies' tight-fitting jacket.

Take the left fore part, baste the dart down from M^a to 11^a and 12^a. When stitching, keep ¼ in. outside 11 and 12, and taper to a point at the top; begin to stitch from bottom.

Cut through the dart, notch it on both sides at the top to make it lie flat, and pare the cloth away ¼ in. from the seam.



68. PRESSING PAD

Open and press the dart on a bare board. Now press the top of dart on the pressing pad [**68**], wrong side uppermost, and with a damp cloth over. Press from the side, front, and shoulder in towards the top of dart, to give a rounded appearance and to form a receptacle for bust.

It is most important that the canvas should be basted in with great care, so as to ensure the fore parts fitting well; to guard against this part of the work being a failure, the instructions which follow should be strictly carried out. First prepare the canvas—*i.e.*, shrink it as in previous lesson; cut it crosswise by folding at opposite corners and cutting through the fold.

Now cut it for the fore part, as indicated in **69**. Trace the dart, and cut away to within ¼ in on either side. It is not necessary to stitch the dart; all that is required is that one edge shall overlap the other, and that the two be thickly serged together.

Nick the top of dart to permit of the edges overlapping without causing a fold in the canvas.

Now place the canvas on the table, lay the fore part on the top with the darts together evenly; baste down the centre of dart from the waist to the bottom, then from the waist to the shoulder.

Now baste all round, keeping the canvas easy both in length and width, particularly across the chest; this should be done by holding the fore part over the knee while basting. The darts must be secured together, but the stitches should not show on the right side.

The Hair Cloth. The hair cloth must also be on the bias, cut the same shape as canvas but smaller—that is, it must be 1 in. clear of the edge all round and 1½ in. above the waist. It must be well basted to the canvas only as the stitches will remain in, and have a strip of linen placed over the edges as has been already described. The dart must be treated in the same manner as in canvas.

A round pad of wadding 4 in. in diameter must now be prepared for the top of each dart in this manner. It must be fairly thick in the centre, and thinned away towards the edges as evenly as possible, to prevent ridges showing through; it should then be stitched round and round from the centre to the edge to keep in position [**69**].

Well baste the pad, to the canvas only, placing the centre of pad to the centre of top of dart [**69**]. Proceed with the fore part as in previous lesson.

THE PHYSICS OF HEAT

Radiation, Absorption and Conduction of Heat. Thermodynamics. Theories regarding the World's End. Universal Death. Conservation of Matter

By Dr. C. W. SALEEBY

BRIEF reference has already been made to the fashion in which heat travels. We distinguished between *convection* and *conduction*. But heat may also travel, as everyone knows, by *radiation*; and the heat so conveyed we may term *radiant heat*. The sun gives us not only light, but radiant heat; so does a fire. As we sit in front of a fire we know that air intervenes; but we also know that the space between us and the sun is not filled with air. Radiant heat is conveyed by, or consists of, vibrations, not of the air, but of the *ether*—the so-called *luminiferous* or *light-bearing* ether. Now, as we shall see later, light and radiant heat are essentially identical; they both consist of precisely the same kind of vibrations of one and the same medium. The difference between them is the same as the difference between one octave of the keyboard of a piano and another. Thus the laws and the manner of the transmission of radiant heat are in every respect identical with those of the transmission of light.

Laws of Radiation. What must we conceive to happen as a hot body radiates heat from its surface? We conceive the heat of the body to consist of a form of motion. We must regard this heat energy, which is really kinetic energy, as being transformed, at the surface of the radiant body, into the energy with which the ether around it is caused to vibrate. When some other material body is struck by these rays, they are retransformed into the previous form of heat or into heat and light.

We have said that the laws of the transmission of radiant heat are those of the transmission of light. It is true of the waves of both that they are propagated strictly in straight lines. This can be proved for heat almost as easily as for light. Similarly, it is true for both, as, indeed, for all forms of ethereal wave motion, that the intensity of the radiation, or its energy per unit of its area at any point, varies inversely as the square of the distance from the source of the radiation. We may compare this law with the similar part of the law of gravitation.

The reflection of radiant heat, again, follows the same laws as the reflection of light—as we must expect, since we believe them to be essentially identical. Again, radiant heat and light are similarly subject to refraction, when passing through a solid medium, or from 'one solid medium to another.

"Transparency" to Heat. We purposely employ this unusual phrase in order to insist still further upon the identity of radiant heat and light. We know that exactly as substances differ in their transparency to light, so they differ in their transparency to radiant heat—a property which is technically known as *diathermancy*. Substances which are transparent to light are not necessarily transparent to heat, however. But this fact is only another aspect of the fact of light—that light waves of different wave length are variously transmitted or reflected by various material substances. Water readily transmits light, just as glass does, but it is quite opaque to radiant heat; whereas liquid bisulphide of carbon is highly "transparent" to radiant heat, transmitting nearly two-thirds of the rays.

A classical proof of the presence of rays of heat in sunlight, and their essential identity with those of visible light, is to be found by spreading out the various waves in sunlight into a spectrum by means of a prism. Everyone knows that in such a case we see a band of colours, shading off from red to violet. If, now, a thermometer be put in various parts of the spectrum, it is found to be heated in varying degrees; but in greatest degree when it is passed quite beyond the red end of the coloured band, and exposed to the invisible heat rays which lie there.

Absorption of Radiant Heat. Just as light may be absorbed and radiated, so may radiant heat, the rule being that the absorption and radiation of bodies with dull surfaces is greater than that of bodies with bright surfaces. It must be evident that as a body radiates, it cools. If its immediate surroundings were "opaque" to radiant heat, the body could not radiate and could not cool. Other things being equal, however, we may assert that the rate at which a body cools is proportional to the difference between its temperature and that of its surroundings—that is to say, if the difference be 20 degrees, the body will cool twice as fast as it would if the difference were 10 degrees.

The importance of radiation as a cause of cooling is most marked in the case of planetary bodies. Probably owing to its small size, the moon has been unable to retain its atmosphere; hence it has been able to radiate its own proper heat with great rapidity. Furthermore, while the heat upon its surface when exposed to the sun must be terrific, on the other hand, it must radiate away such heat at a very great speed when the sun is hidden from it, producing the most intense cold. The earth is always radiating its heat into space. So far as the usually recognised constituents of the air are concerned, this heat can readily escape, oxygen and nitrogen being *transparent* to radiant heat, or *diathermanous*, to use the technical term. But water vapour is a constant constituent of the atmosphere, and this, being relatively opaque to radiant heat, arrests a great deal of the radiation. The reader who is interested in this subject must turn to the discussion of radium and radio-activity in the course on chemistry, since we now know that the radio-activity of the earth's crust is sufficient to compensate completely for the amount of heat which it constantly loses by radiation.

The Conduction of Heat. Of the convection of heat we need say no more than has already been said ; but the conduction of heat is a much more important matter. We are all familiar, in the first place, with the fact that the thermal conductivity of different substances varies within wide limits, metals being conspicuous instances of good conductors ; while most products of living matter, such as wool and bone and wood, conduct heat very badly. But metals themselves vary in this respect. We have noted elsewhere, for instance, that copper and silver are exceptionally good conductors of heat, as also of electricity. It is obviously necessary to invent a standard by means of which we may readily express the *thermal conductivity* of a substance. This, then, is defined as the number of thermal units which are conducted per unit of time per unit of surface through a slab of unit thickness, the sides of which differ in temperature by one degree. We cannot here wait to discuss the various experimental methods by which the relative thermal conductivity of different substances may be estimated.

The Results of Differing Conductivity. But, at least, we must spare space to note some of the most obvious consequences of the wide differences that obtain between various substances in respect of thermal conductivity. The most important of these results are those which affect the bodies of warm-blooded animals. Nearly all such animals are covered with a coat made of one kind or another of non-conducting substance. Feathers are of some value in this connection, hair of greater value, wool more valuable still, and fur most valuable of all. It is needless to say how animals in various regions of the world are adapted in these respects.

Man is conspicuous among warm-blooded animals in being naked, and finds it necessary to cover himself with substances having a very low thermal conductivity. The most valuable of these are all derived from the non-conducting coats of other animals. We speak of warm and cool clothing, but the reader is well aware that, according to the Laws of Temperature [see page 1563], all bodies tend to become equal, not in amount of heat, but in heat level. Thus all the various kinds of clothing are, in general, of the same temperature. What we call warm clothing is merely that which has a low thermal conductivity, or is a bad conductor ; while cool clothing is that which has a higher thermal conductivity, or is a better conductor. In this connection it must be noted that an important part is played by the air which our clothing confines. Loose clothing is far warmer and in every way better than tight clothing of the same weight and material. By means of loose clothing we are covered with many broken layers of air—air which soon comes to have the same temperature as the body, and which also tends to be saturated with water vapour. Such air must thus necessarily tend to arrest radiation and evaporation—two of the most important means by which the body tends to be cooled.

The Safety Lamp. Everyone who has spent even an hour in a laboratory must be familiar with the experiment of controlling a flame—such as the flame of a Bunsen burner—by means of a sheet of wire gauze. Such gauze may be made to confine the flame beneath itself ; while, on the other hand, if the gauze be held an inch or two above the burner before the gas is ignited, the gas can be made to burn above the gauze, but the flame will not spread beneath it. The obvious explanation of this is that the metal of the gauze is a good conductor, and so rapidly carries away the heat produced that the temperature on the far side from the flame (whichever that be) is not high enough for the combustion of the gas. This fact is utilised in the famous safety lamp invented by Sir Humphry Davy. This is simply an oil lamp surrounded by a cylinder of wire gauze. If coal gas be present in the air of the mine, it will burn when raised to an adequate temperature by means of the flame of the lamp ; but the gauze will prevent the flame from spreading beyond it, while the harmless burning of the coal gas affords an important warning to the miner.

Heat and Work. We must now pass to consider what is, in some respects, the most important aspect of the science of heat. We are already agreed that heat is not a material thing, not a fluid, or a *phlogiston*, but a mode of motion—a form of energy convertible into any other form of energy, as in an engine or an animal body. In many ways we can produce heat by doing work, as in every kind of machine, or as in the case of a savage who lights a fire by rubbing two pieces of dry wood together. Now the question arises whether there is a definite amount of heat that corresponds to any particular amount of work done ; and the answer is that such a definite and necessary relation does exist. The famous name in this connection is that of Joule, of Manchester, and his work is about 60 years old.

The *mechanical equivalent of heat* is now frequently represented by the letter J, and this has been variously estimated since the time of Joule. We may say that the mechanical equivalent of one British unit of heat (the amount of heat which can raise one pound of water from 60° to 61° F.) is 778 foot-pounds. The establishment of this equivalent—or, rather, the establishment of the fact that there is an equivalent—leads to the foundation of the science which is now known as *thermodynamics*, and which deals with the relations between heat and kinetic energy. It is largely the study of this science which has led to the establishment of the great principle of the conservation of energy, which we must shortly consider.

Laws of Thermodynamics. In accordance with this principle, what is known as the *first law of thermodynamics* states that *the amount* *of heat evolved in doing a given amount of work*—assuming that the work results exclusively in the formation of heat—*is constant*; and, on the other hand, that *the consumption of heat in producing mechanical energy is equally constant*. We have already stated the figure which expresses the relation between heat and work. So far as the first law of thermodynamics goes, there is absolute and reversible equivalence between heat and work; but to it we must add a *second law of thermodynamics*, which states, as we already know, that heat cannot pass from a body at a lower temperature to one at a higher. Hence, we have a new significance for temperature or heat level You may have heat enough and to spare, but unless you have a balance of temperature in your favour, you will never get any work out of it. Thus, while the first law of thermodynamics expresses the conservation, equivalence, and convertibility of energy, the second law expresses what we may call the doctrine of the *availability of energy*. This second law (as well as the first, in some small measure) we owe to the genius of Lord Kelvin, formerly Sir William Thomson The years 1851 and 1852 saw his contribution to the Royal Society of Edinburgh of the two classical memoirs in which the science of thermodynamics is put upon a firm foundation.

Lord Kelvin. At this point we cannot do better than quote from Dr. J. T. Merz, whose "History of European Thought in the Nineteenth Century" is the most valuable work of its kind in any language. He says: "It was Thomson who first clearly saw that the axiom of the impossibility of a perpetual motion would be infringed if the first law of thermodynamics—the indestructibility of energy—was accepted without the second. For practical use, for doing work, it is not sufficient that energy be not lost; it must be available—get-at-able. Energy may be in a condition in which it is useless—hidden away—and to bring it forth again may be for us either impossible (if it be dissipated), or may require an expenditure of work—*i.e.*, of energy—to do so." But to this subject we must return after we have discussed the great generalisation of the conservation of energy, to which the first law of thermodynamics affords such signal support.

The Conservation of Energy. The doctrine of the conservation of energy has well been described as the greatest of all exact generalisations. The idea is far older than its proof. Indeed, the philosopher Thales, as long ago as 600 years before Christ, said—or, at least, is reported to have said: *Ex nihilo nihil fit*—*i.e.*, "from nothing, nothing is made." This, however, is only one-half of the doctrine, being the other half to that which is alone expressed by the usual name of the doctrine. On the one hand, the doctrine denies *annihilation*, declaring that energy is persistent and conserved; and, on the other hand—as in the saying we have quoted—it denies *creation*. These two denials are equally essential and complementary parts of the doctrine.

Now, the reader who remembers our discussion of Newton's laws of motion cannot but observe how consistent those laws are with the doctrine of the conservation of energy—in this case kinetic energy. The word energy was introduced by Dr. Young at the beginning of last century, but the idea which it conveys was more or less definitely present to the mind of Newton himself; and Lord Kelvin and the late Professor Tait have shown in addition that Newton was on the very verge of recognising completely and formulating the modern doctrine of the conservation of energy. Notably, we may remind the reader of the simple expression of his third law, that *action and reaction are equal and opposite*.

Perpetual Motion. The laws of thermodynamics teach that while energy is always conserved, it is capable of endless and indefinite transformations—as, for instance, from heat into work or vice versâ. Now all the workers—French, German, and English—whose labours went to consolidate the science of thermodynamics used language which was incompatible with the old idea commonly known as *perpetual motion*. The phrase is an unfortunate one, since the universe must in all probability be regarded as itself a perpetual motion machine; but by the impossibility of perpetual motion is really meant not a denial of Newton's first law of motion—that is to say, the doctrine that all motion is perpetual until force interferes to alter and modify it—but rather the principle that such a perpetual motion is of no use, since no work can be done with it except by using it up or annihilating it. And this statement reminds us of the second law of thermodynamics. It was all very well to assert—as various workers did assert in the 'forties of last century—that power cannot be created or destroyed, and that its various forms are mutually convertible without end, but such assertions are equivalent to saying—are they not?—that perpetual motion is possible.

Energetics. It was Lord Kelvin who first recognised "that the old phantom of a perpetual motion was turning up again in a new form." Thus we must never remember the doctrine of the conservation of energy without also recalling the subsequent doctrine that though energy is never *lost*, it becomes for our practical purposes *unavailable*. Hence the great German scientist, Professor Ostwald, in framing the terminology of the science which he calls *energetics*, describes the doctrine of the conservation of energy as the first law of energetics, and then goes on to say: "A perpetual motion could, however, be attained if it were possible to induce the large store of energy at rest to enter into transformations." The fact that this is impossible Ostwald calls the second law of energetics. We may associate it in our minds with the second law of thermodynamics already stated.

Dissipation of Energy. So far as the law of the conservation and the equivalence of the different forms of energy is concerned, it would appear that these are all of the same value. When work is done no energy is consumed—it is merely changed. Why may it not be changed back again? So far as the law of the conservation of energy is concerned, all natural processes—all mechanical processes at any rate—must surely be reversible. But Lord Kelvin showed that this is not so. In 1851 he said—and this is practically his second law of thermodynamics: "It is impossible by means of inanimate material agency to derive mechanical effect from any portion of matter by cooling it below the temperature of the coldest of the surrounding objects."

Available and Unavailable Energy. Thomson saw that, notwithstanding the work of Joule, natural processes do not work as well backwards as forwards—in other words, the *Cosmos* is not a perfect machine, if even it be a machine at all. He realised that there is in nature a general tendency towards, not a destruction, but a degradation or dissipation of energy. The energy is not lost, but it is lost so far as its utility is concerned. All forms of energy tend to assume the form of heat, which is the least available form of energy. For all practical purposes, and also for our philosophical view as to the future of the universe, the distinction between available and unavailable energy, or between useful and useless energy, is all-important. Other workers showed that in practically all natural processes a certain quantity of energy is thus accumulated and lost. This energy was called *entropy* by Clausius, who introduced that much controverted term; and what Lord Kelvin had expressed as the universal tendency in nature towards the dissipation of energy, Clausius expressed by saying "the entropy of the world is always on the increase."

The Coming of Universal Death. But what does this signify if we take a large enough view of it? It signifies that the universe is travelling towards universal death. It makes us think of the universe as resembling a clock or watch, made and wound up once and for all, and destined ultimately to run down and stop. It seems clearly to imply a beginning, and, as clearly, to imply an end. At present there is a great difference of heat potential between the different parts of the solar system, one consequence of which is the presence of life upon the earth. But in time to come the heat will have distributed itself so that the system which corresponds to the solar system of to-day will be all of one temperature, and life will be impossible. The case must be the same, if Lord Kelvin's doctrine be correct, with the whole universe. In time it will all have assumed a uniform temperature; its other forms of energy will have been resolved into heat, and the cosmic life will have run its course.

Furthermore, since natural processes are irreversible, there must be no possibility of a phœnix-like resurrection. "This remarkable property of all natural processes," says Dr. Merz, "seems to lead us to the conception of a definite beginning and to shadow forth a possible end—the interval, which contains the life or history of nature, being occupied with the slow but inevitable running down or degradation of the great store of energy, from an active to an inactive or unavailable condition." The recent discovery of radium and radio-activity, and of all the hitherto unsuspected energy—available energy, too—which these reveal to us, does not militate in any degree against the doctrine of the dissipation of energy. These discoveries may show that the "watch" will run for millions of ages longer than we had thought, but they do not affect the apparent fact that it *is* running down.

Doubt of the Issue. Almost overwhelming as the evidence for this doctrine would appear to be, it is yet very far from being accepted by contemporary physicists. It is not, indeed, accepted without grave reservations by Lord Kelvin himself. If, for instance, we regard the universe as a closed system, one conclusion emerges, and, if not, another emerges. We do not in the least know what is the destiny of the heat and light energy which are incessantly being radiated from the solar system. When the doctrine of the dissipation of energy was framed, there was scarcely any conception of the idea, now current amongst astronomers, that the universe—or, rather, *our* universe—may be finite. We are now entitled to suggest that even if *our* universe be running down, something may be going on elsewhere which shall wind it up again. From the doctrine of the conservation of energy there is no escape; it has survived even the revelations of radium. But the doctrine of the dissipation of energy must not be regarded as more than an extremely important proposition which demands further consideration.

The Conservation of Matter. As the reader of the course on Chemistry has already learnt, the doctrine of the conservation of matter can no longer be maintained, at any rate, in its original form. But the doctrine of the conservation of energy stands—"this grand principle," as Professor Tait used to call it. Recognising that the law of the conservation of matter must really be regarded as only an aspect of the law of the conservation of energy, Herbert Spencer formulated, nearly half a century ago, the phrase *persistence of force*. But force, as the reader knows, is a term now used in a special sense by the physicist, and so Spencer's term has not gained currency. Quite recently, Professor Haeckel, of Jena, included the doctrines of the conservation of energy and the conservation of matter under the term, the *law of substance*—meaning by substance the thing that stands under—the underlying something. This is really another name for Spencer's persistence of force. If now we turn back from Spencer to Thales, whom we have already quoted, we see the importance which philosophers have attached to the conception that there is at bottom some kind of reality which is eternal, and which, however many transformations its appearances may undergo, suffers neither increase nor loss.

Our Conclusions Summarised. Here we must conclude the most fundamental and philosophically important part of our subject. The great truths which we have learnt so far may thus be summarised. We have learnt to observations or experiments whatever, and in contradiction, indeed, of appearances, such as those of apparent destruction by fire—but which was, *in the first place*, based upon a law of the mind, which compelled it to believe that something could not be created out of nothing nor ever reduced to nothing. This part of our subject has therefore led us to the confirmation of an *à priori* or necessary truth by the special method which is characteristic of science, and which is known as the *à posteriori* method of reaching general from particular truths.

Physics and Materialism. Lastly, our study of energy as essentially the only external reality, has endowed us with an effective weapon against materialism. It must also have suggested to the most thoughtful of us the limits and partial character of the human understanding, of which there is no more striking feature than this: that it is almost compelled to think in the terms and conceptions of materialism. Directly we come upon such a conception as this of energy, we find it impossible to form any adequate conception of what it is *in itself*. Many of its appearances or manifestations we know, but only through them do we know *it*, nor do they guide us to any clearer conception than that it is an underlying Power. If we attempt to clear up this conception, we find that it either resolves itself into a material conception, or else is lost in a mist of words. But however imperfect our ultimate conception of energy may be, physics has performed an incalculable service for philosophy in framing the conception at all, and in showing how all things—even including matter itself—conform to it. Well may Bacon, the founder of the

The study of sound is of the greatest interest for the psychologist, since sound and hearing must be studied together, and it is also of very great interest in relation to a science or department of science which is only nowadays beginning to be recognised and placed upon secure foundations—*viz.*, *æsthetics*, or the science of the beautiful and of the affecting elements in all the various kinds of art. In the following study of acoustics, then, we shall strive to recognise the fact that this subject is important not only on its own account, but also because of the light which it throws upon other studies of still greater interest and subtlety.

Methods of Studying Sound. Our first need is identical with that which we recognised when we began the study of heat. In that case we saw that the study has subjective and objective aspects. Subjectively, we said, we are familiar with sensations of heat and of cold, but directly we attempt to analyse the facts we observe that these sensations are in ourselves, and are due to external causes, which can be sharply distinguished from the sensations.

Substitute *sound* for *heat and cold*, and this sentence remains true. Just as in the discussion of heat we must not mix up psychology and physics—until, at least, we know which is which. Our present concern, as students of physics, is not with sensations but with the external objects or facts which cause them—that is to say, we are dealing with sound as an objective thing, and for the present it would be all one to us if our bodily organisation were altered, so that, as might quite well be, sound were visible or palpable or odorous or sapid instead of being audible.

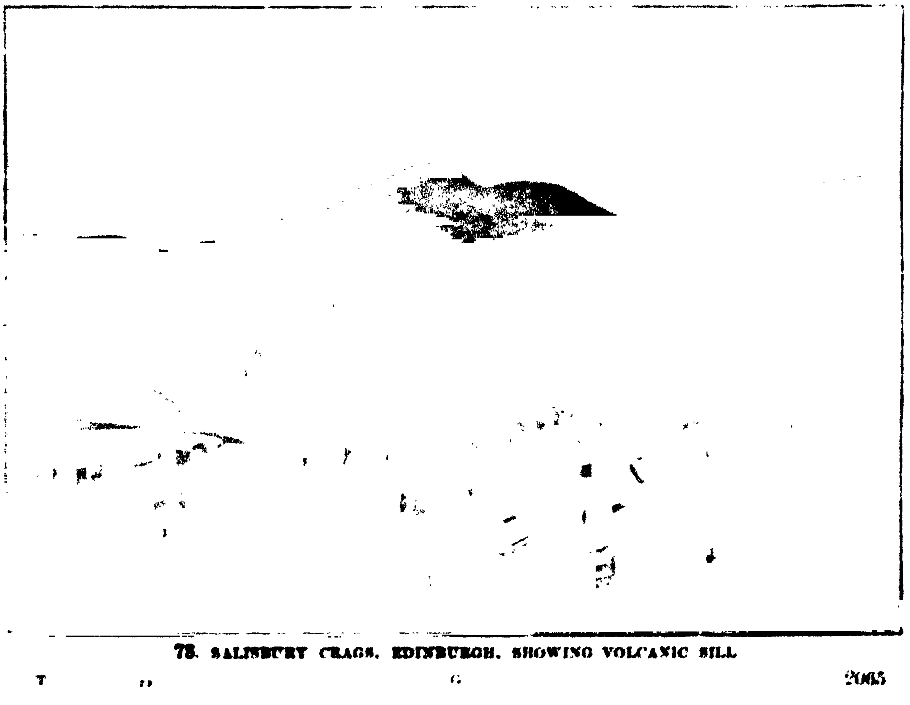
Non-sedimentary Rocks. The Geological Record of the Earth's Development. The Story of the Strata. Chronology of the Earth

By W. R. GARRETT FISHER

IN order to complete our survey of the rocks which compose the visible portion of the earth's crust it remains to consider the non-sedimentary rocks, which form a very noticeable, though not by any means the larger, part thereof. These are the igneous rocks which come to the surface in parts where for various reasons the later sedimentary rocks have not been deposited above them, or have been entirely worn away by denuding agencies, leaving the bare, igneous rock cropping out, as in the granite tors of Dartmoor or in the volcanic sill which forms the Salisbury Crags in Edinburgh [78].

Non - sedimentary Rocks. These igneous rocks, as we have seen, are known as *plutonic* or *volcanic*, according to the manner in which they were originally formed. The plutonic rocks are those which were originally formed deep beneath the surface of the earth, and have since been revealed by the removal of the overlying strata. The volcanic rocks are those which have been brought up to the surface by hypogene activity, and have frequently been arranged in stratified sheets, often alternating with the true strata produced by epigene agencies. Of course, there is no absolute distinction between these two classes of rocks, since the volcanic rocks which appear on the surface must obviously be connected with the plutonic rocks remaining in the subterranean reservoir. But it is usually thought convenient to distinguish between volcanic and plutonic rocks, which, indeed, show somewhat different characteristics.

Plutonic Rocks. The plutonic rocks with which we are here concerned have usually been thrust up from the lower parts of the earth's crust by hydrostatic pressure, have been intruded into other rocks of more ancient formation, but have solidified beneath the surface of the earth, and therefore under considerable pressure. The fluid masses which were thus squeezed upward from the lower or molten parts of the earth's crust naturally took the line of least resistance, and the various shapes into which they expanded depended on the local conditions. We now find them mainly in one of four distinct formations—as *bosses* [79], or shapeless lumps of rock, often many miles in extent; as *sills* [78], or flat and roughly horizontal sheets of rock; as *dykes* [80], or veins of rock which have filled up



78. SALISBURY CRAGS, EDINBURGH, SHOWING VOLCANIC SILL

the cracks or fissures in earlier formations; and as *volcanic rocks*, which occupy the pipes and craters of ancient volcanoes.

There are many examples within our own islands of each of these formations. Vast intrusive masses of granite characterise the scenery of Dartmoor and the South-west of Scotland. The Salisbury Crags, beside Arthur's Seat at Edinburgh, consist of a thick sill of dolerite; another forms the rock on which Stirling Castle is built; while the great Whin Sill can be traced for a distance of 80 miles across the North of England. Veins or dykes of intrusive rock are often found on seashores, as at Elie, in Fifeshire, where the wearing down of the softer adjacent rock has left them standing up like walls. The mineral veins in which many ores are found are generally intrusive dykes which have been run into cracks in the older rock. The hardened lava plugs of ancient volcanoes form the conical hills which are so common in the South-east of Scotland, like Arthur's Seat, North Berwick Law, and Largo Law.

Volcanic Rocks. Volcanic rocks are distinguished from the plutonic formations by the fact that they are usually found with a kind of false stratification, in which the volcanic *lavas* and *tuffs* are found alternating with true sedimentary beds. It is easily seen how this state of things has come about. Volcanic action is seldom continuous; the eruptions are usually separated by long periods of quiescence. At each period of activity the volcano sends sheets of lava welling out in all directions from the vent. When the flow ceases, these sheets harden into rock. The ordinary atmospheric agents then set to work to cover this sheet of igneous rock with the débris of which we have seen all sedimentary formations to be composed. After this layer has attained a certain thickness, which depends upon the length of time during which the volcanic activity is suspended, a new eruption takes place, and a second sheet of lava covers the sedimentary formation, baking, hardening, and perhaps chemically altering it. Thus in the lapse of ages we get a characteristic piece of *volcanic stratification*, in which sheets of lava alternate with layers of true sedimentary rock. There is a very interesting illustration of such a structure near the mouth of the Severn, which in ancient times was a centre of considerable volcanic activity.

All that was said in a preceding section as to the curvature, tilting, crumpling, and dislocation of sedimentary rocks applies equally to igneous formations, which display well-marked examples of joints, faults, and cleavage planes, though the other division into strata, or bedding planes, which characterises the sedimentary rocks, is usually absent, and when present, as in the schists, has been produced by different agencies, generally those of subterranean heat and pressure due to gigantic earth movements.

The Geological Record. We have now taken a general survey of the leading facts of geology. We have inquired into the existing structure and materials of the earth's crust, and we have examined the agencies which have brought about that structure and modified those materials. It now remains to see to what extent geology is able to trace the past history of the earth through the long ages during which these alterations have been taking place to produce our habitable earth. This record, though full of gaps and imperfections due to our limited opportunities of study, is written deeply upon the rocks, and has been read by geologists with wonderful precision.

Palæontology. The reader has already seen how the fact that the majority of superficial rocks are arranged in strata enables us to tell their relative age. Where we are dealing purely with sedimentary rocks it is quite clear that the upper strata must be younger than those that lie beneath them, and on the top of which they were originally laid down. There are some apparent exceptions to this rule—as when the strata have been so crumpled as to undergo actual *inversion*; when the oldest layers have been brought to the top, and might by a hasty observer be mistaken for the youngest; or when a mass of eruptive rock has been intruded into the midst of strata which are all really its superiors in age. To read this wonderful record with ease and accuracy requires the training of a lifetime; but the general results that it has yielded can be briefly explained. This geological record has a very important bearing upon the history of life. We have seen that the strata frequently contain fossil remains of the plants and animals which lived at the time when they were being formed. They naturally share the relative age of the strata which they inhabit, and thus we are able to discover the order in which the various forms of life have appeared upon the earth, and to provide trustworthy materials for the development of the great theory of organic evolution. This part of the subject, known as palæontology, lies really outside the scope of this course, and must be studied by the student of biology in the special articles on that subject. The geologist's share in the matter is confined to expounding the order in which the various forms of life have come into existence.

The Story Told by the Strata. It must not be supposed that the strata which make up the crust of the earth are everywhere arranged in the same order, or that the complete history of the rocks can be learnt by the simple method of boring into the earth at any convenient spot and tabulating the strata through which the shaft passes. The earth has so long been moulded by the agencies of change, which we have already studied, that the geological record has become extremely complicated, and it has required the labour of more than a century to elucidate its mysteries and entanglements. The work is something like that of the historical student who has to build up the coherent story of his chosen episode from books that he finds in the great national libraries of London, Paris, and St. Petersburg; dusty documents that he has to spell out in the London Record Office, among the archives of the Vatican, or the Royal Charters of Simancas. So the geologist reads one fragment of his

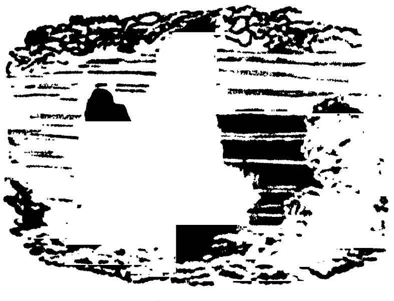
EXTINCT MONSTERS OF EARLIER AGES

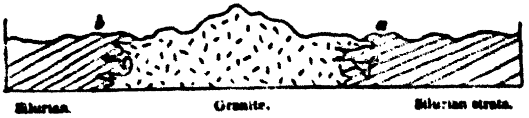
story on the coast of Scotland, another in the gorges of Colorado, another in the mines of the Rand, and yet another in the contorted strata of the Andes. The whole thickness of the rocks that have been built up since the earth's crust first solidified amounts to many miles, and there is no place in the world where the whole vast series is conveniently displayed to the study of man.

The Chains of Geological Evidence. But everywhere the story is the same, and the fragments of knowledge which one geologist has won from his lifelong study of the Scotch granites dovetails in with that which another has obtained among the cañons of America. Everywhere it is found that there is a definite order in which the strata follow one another. There are often gaps and imperfections in the history of the rocks wherever we study them, but the gaps are never quite the same, and the knowledge which we gain in one locality helps to fill in that which is gained elsewhere. In this way it has been ascertained that there is a definite order of succession among the rocks now visible on the surface of the earth, and that this succession everywhere holds good. Thus, to take a simple instance, we find that the coal measures everywhere overlie the Old Red Sandstone, which is of earlier formation. In any part of the world we may find Old Red Sandstone where coal measures do not exist at all, or conversely we may find coal measures without the presence of the Old Red Sandstone. But we can say with certainty that wherever we find a layer of Old Red Sandstone, it is absolutely useless to bore through it in the hope of finding coal below. The value of such knowledge to the miner will be apparent; and it is never falsified.



80. DYKE

Chronological Classification of Rocks. The various stratified rocks which have already been described fall into certain series, each of which appears to have been formed at a definite time in the earth's history. Geologists are now pretty well agreed as to the main classification of these series, although there are still points of difference among them when it comes to minute detail. They all divide the rocks into five main divisions, each of which corresponds to a chronological epoch.



79. INTRUSIVE BOSS OF GRANITE

The oldest rocks of all, which were first formed when the crust solidified, are known as *Archæan*. Their successors, down to the rocks which contain the coal measures, are known as *Primary*, because they come first in the geological record; the later rocks, down to the cretaceous rocks which form the great chalk deposits of southern England, are known as *Secondary*; while the remaining rocks, which are of comparatively modern origin, are divided into *Tertiary* and *Quaternary*. Each of these periods is subdivided for convenience into a number of shorter periods of rock formation, which are known as systems, and it will be found that the rocks in each of these systems are distinguished by a certain number of common characteristics. The following table, beginning with the most recent, gives a brief summary of the various divisions and systems into which the rocks of our islands are divided.

THE ORDER OF THE STRATIFIED ROCKS.

Division	System.	Typical Rocks.
Quaternary	Post-glacial or Recent	Alluvium and river gravels
	Glacial or Pleistocene	Boulder clay
Tertiary	Pliocene	Norwich Crag
	Miocene	Lacustrine deposits
	Oligocene	Isle of Wight fluvio-marine series
	Eocene	London clay
Secondary	Cretaceous	Chalk and greensand
	Jurassic	Portland stone and lias
	Triassic	New red sandstone
Primary	Permian	Magnesian limestone and sandstone
	Carboniferous	Coal measures
	Devonian	Old red sandstone
	Silurian	Slates and sandstones
	Cambrian	Welsh slates
Archæan	Pre-Cambrian	Gneisses and schists

THE END OF ROME

Rome under Titus. Destruction of Pompeii and Herculaneum. Hadrian. Marcus Aurelius. The Thirty Tyrants. Founding of Constantinople

By JUSTIN McCARTHY

VESPASIAN'S successor was his son Titus. This time there was no struggle for supremacy, and Titus succeeded as a matter of course. He had served with great distinction as a military Tribune in Britain and in Germany, and was left to conduct the war against the Jews after his father had been proclaimed Emperor. When he came back to Rome he shared with his father in the great public triumphs given to celebrate the conquest. The title of Cæsar was conferred upon him, and he took an active part, under Vespasian, in the administration of Rome. With the successes of his early life Titus combined a love of pleasure, and even actual dissoluteness, which had made many leading Romans doubt his fitness for the position of Emperor. But when he became invested with the responsibility of such a position, he showed himself capable of rising to a thorough appreciation of his duties, and of ruling the country with the genius of a statesman.

Rome under Titus. His career was an early Roman anticipation of that of Shakespeare's Prince Hal. Not only did he cast away all his habits of self-indulgence, but he showed himself genial and gracious in manners, and sympathetic with all who deserved sympathy. His subjects called him by the title " Delight of the Human Race," which had been given him by his admirers. It is told of him that he always regarded a day as lost in which he had not had the opportunity of doing a good action. His heart and mind were set on improving the condition of his people, or relieving the wants of all in distress, or spreading education, improving public and private morals by advice and example, and, according to his own phrase, on keeping his own hands free from human blood.

Fire and Plague. He completed the building of the Coliseum and built great public baths which were called by his name. Some heavy calamities visited the country during his reign—calamities of Nature which Titus did his best to alleviate. A great part of Rome was destroyed by one of those sudden conflagrations which from time to time broke out over the capital. A severe and widespread visitation of plague came almost simultaneously over many parts of Italy. At the opening of November, 79 A.D., a tremendous explosion of Vesuvius brought destruction on some of the neighbouring towns, amongst which Pompeii and Herculaneum were almost entirely destroyed by a flood of lava. Herculaneum had been severely injured by an earthquake fifteen years earlier, and it was almost altogether overwhelmed by this eruption of Vesuvius. The city was buried under masses of ashes and lava, and its actual site was only discovered in 1720, when the sinking of a well brought the workers to the remains of many of its buildings. A large part of its site had been covered by the successive building of villages on the new surface which the outpouring of ashes and lava had left. Pompeii was more fortunate than Herculaneum because it stood farther away from the burning mountain, and was covered not so much with the destroying lava as with ashes. The city was, however, completely hidden from sight for many centuries.

Pliny. Pliny the Elder, the celebrated scholar, naturalist, and historian, who was also a soldier, lost his life because of that memorable eruption. He had been put in command of the Roman fleet stationed off the coast near to Vesuvius. When the explosion broke out he was so anxious to study its phenomena that he landed on the shore, but had not gone far when the stifling vapours from the mountain overcame him. The ruins of Pompeii have been for generations one of the most interesting sights in Italy.

Among the latest benefactions rendered by Titus were those which he liberally bestowed upon the surviving sufferers from the Vesuvian eruption. Titus had become beloved and almost adored by his people, but he was not destined to reign over them for long. He died in September of 81, after a reign of a little more than two years, when he was only in his forty-first year. There were at the time suspicions, which historians have thought serious enough to record, that the early and unexpected death of Titus was brought about by poison, and was caused by the ambition of his brother Domitian, who was growing impatient for the succession.

Domitian and Nerva. Domitian succeeded at once to the throne. During the earlier part of his reign he pursued a course of moderation and justice; but when he undertook several campaigns, which were for the most part unsuccessful, he began to reveal the jealousies and passions that afterwards made his reign a calamity. He became jealous of the rising fame of Agricola, and recalled that great soldier to Rome from his military command ; but that act, unjustifiable as it was, could not be compared for atrocity with many of his deeds of cruelty and oppression. We can read impressive descriptions of the worst chapters of his reign in the life of Agricola by Tacitus, while his vices and his wanton cruelties are pictured in the satires of Juvenal. His death was what might have been expected from his life. There were several conspiracies against him, and one proving successful brought him and his reign to an end.

Domitian was succeeded by Nerva. Nerva had won high reputation as a Consul, and his reign did credit to the choice which placed him on the throne. He was a man of great humanity and enlightenment, who did his best to restore tranquillity, civil equality, order, and peace to the State which had so long suffered from rulers of a very different kind. One of his reforms was directed towards the repression of informers—men who made a living by inventing accusations against conspicuous personages, hostile to some powerful party, and either obtained a reward from those who were ready to welcome accusations against political enemies, or from the fears of those who were willing to pay a liberal bribe rather than brave the danger of being accused.

Accession of Trajan. Nerva was not endowed with much physical energy, and his reign only lasted for two years. He had adopted as his son and successor Trajan, who had made himself famous as a general in many wars, and who was conducting operations both civil and military in Germany. The news of Nerva's death and the news of his own succession reached Trajan at Cologne, where he was engaged in important work for the maintenance of peace along the frontiers, and the better discipline of the army. He made no haste to go to Rome, and spent some months over his work in Germany. Then he returned, and, according to his own desire, entered Rome on foot, with his Empress Pompeia Plotina at his side.

Trajan's accession was received with demonstrations of joy everywhere in Rome and throughout the Empire. Trajan was well qualified in appearance and bearing to represent the Imperial dignity. He began his reign as a reformer, and in certain paths of reform he remained consistent to the end. He greatly reduced the amount of taxation, and sold for the public benefit many palaces which some of the Emperors preceding him had obtained by confiscation. He employed much of the public money for the help of the poor, and especially for their children. He restored to the Senate much of the power which had been taken from it by some of his despotic predecessors, and revived the representative principle in the conduct of public affairs. He promoted public works partly as a means of finding work for the unemployed, the making of roads, the draining of marshes, and the creation of new seaports, some of which were created at his own cost.

Trajan and the Christians. He founded a great library and caused the erection of many splendid public monuments, among them the Trajan Column, which to this day symbolises his fame. Against his many noble qualities must be set his strong animosity towards the Christians, the persecution of whom he did not make any worse—for that would have been impossible—but which he did not mitigate in any manner worthy of his general character. He prohibited the hunting down of Christians as if they were wild beasts whom any citizen was entitled to discover and put to death, but when they made themselves conspicuous by teaching their doctrines he authorised the severest punishments of the criminal laws to be applied to them. Under his authority more than one Christian, holding high priestly office, was cast to the lions.

Trajan did not seem to be absorbed by a longing for war and conquest, and yet his reign saw as many military enterprises and invading expeditions as that of any Roman Emperor. Some of these he conducted himself. He created by conquest the Roumanian provinces, which still retain on the Danube the traditions of old Rome, and brought many Asiatic regions under the sway of Rome. Historians tell us he declared that if he were a younger man he would undertake the subjugation of the Indies. But his conquests were not, in most cases, of a lasting character. The vanquished races were always rising in rebellion against Rome; the Jewish colonies were ever in rebellion and the closing part of Trajan's reign was stained with continuous bloodshed.

During the warlike operations which Trajan was conducting in the East, he was taken with sudden illness, and set out at once for Italy. He died on his way home in August, 117, after a reign of nearly twenty years.

Hadrian's Prosperous Reign. Trajan left no son to succeed him. His successor was Hadrianus, who in English histories is called either Hadrian or Adrian—usually the former. Hadrian had been approved by Trajan and by Trajan's wife, and it was in great measure owing to her influence that, when the succession became vacant, Hadrian was chosen Emperor. The new Emperor displayed many great qualities as a statesman. He abandoned as far as possible the policy of conquest in the East which so many of his predecessors had followed, and showed, indeed, little inclination for war. He endeavoured to secure Rome's possessions in Britain against the daring incursions of the Caledonians by constructing the famous wall from the mouth of the Tyne to the Solway Firth, some fragments of which still help to preserve his memory in those regions where Roman conquest is now but a tradition. The only fierce struggle that disfigured his reign and was encouraged and carried on by him was that against the Jews who would not sacrifice their religion to their Roman conquerors. Hadrian, although a man of enlightenment and of equity in most spheres of thought and action, was fiercely intolerant towards the Jews, and endeavoured to suppress by force their forms of worship and their sectarian ordinances. The result was a general uprising of the Jews in the Imperial dominions and a struggle lasting for nearly three years, in which more than 600,000 Jews lost their lives, while many who survived were sold into slavery. But for this dark stain upon its memory the reign of Hadrian was one of the most peaceful and prosperous in the history of ancient Rome.

Roman Art. Hadrian passed a great part of his life travelling through his dominions in order that he might acquire a close personal knowledge of their conditions, and of the improvements that might be made. He had a great love for Athens, which he often visited, and was thoroughly acquainted with the language and literature of Greece. He strove also to preserve peace with foreign States, and gave no encouragement to the national ambition for conquest. Many public works of general utility were constructed during his reign, and he left to his country many splendid monumental records of his love for art and architecture. Some remains still exist of his abode at Tibur, sixteen miles north-east of Rome, where several exquisite specimens of Roman art have been discovered. A mausoleum Hadrian erected to receive his remains forms the groundwork of the castle of St. Angelo in Rome.

It would be gratifying to conclude the record of such a reign without disparaging comment. But the private life of Hadrian was sometimes disfigured by sensuality, and, while his rule was generally one of equity and humanity, he gave way occasionally to anger which displayed itself in summary acts of severity towards men accused of plotting against him, and to whom nothing like a reasonable form of trial was accorded. He died in 138, after a reign of 21 years.

Antoninus Pius. Hadrian was, during the latter part of his reign, much impressed by the high character of Antoninus, who had served as Consul with distinction. He sent him later into Asia to act as Pro-consul, and more lately adopted him as his successor because of the capability and virtue he saw in him. The choice was well justified. The year of his adoption was the year of Hadrian's death and the succession of Antoninus to the throne. He will always be known as Antoninus Pius, that honourable epithet being given to him because of the devoted tributes he paid to the name and fame of his great predecessor. He lived a temperate and unselfish life, was peaceful, public-spirited, and benevolent, and won the credit of having always acted as the father of his people. His reign will ever be remarkable for the fact that he was the first Roman Emperor who tried to put a stop to the persecution of the Christians.

Justin, who was known as Justin Martyr, a brilliant Stoic and, later, a Platonist who became converted to Christianity, was a conspicuous figure in the reign of Antoninus, and addressed to the Emperor his " Apologia " of the Christian Faith, the title of which is to be understood in the Latin, not in the modern English sense, for it was a vindication, not an apology. Justin afterwards earned the martyr's crown, but not until after Antoninus had passed away. The influence of Justin helped to strengthen his resolve to put some limit to the persecution of the Christians, who were already numerous and were ever increasing in numbers throughout the provinces and in Rome. Antoninus did his best to establish the principle of toleration for their doctrines, and to enforce on the magistrates and other authorities orders that Christians who had committed no crime against the civil laws should not be subjected to trial or punishment because of their Faith. It was to him that the noble saying that "The wealth of a prince is public happiness " was ascribed.

"Father of the Human Race." He took care that the finances of the State were administered with economy, and that means should thus be left him to help any region which might be visited by some sudden calamity causing sickness and poverty. His grateful people gave him the title of " Father of the Human Race." His reign was altogether peaceful, containing no record of war more serious than some expeditions for the suppression of disorders here and there on the frontiers. There were two conspiracies started against him by some of his enemies, for his toleration of Christianity was in itself enough to create enemies for him in those days. The conspiracies, however, were discovered in time, and thus came to nothing, and Antoninus, with his usual magnanimity, insisted that only the chiefs of these conspiracies, when tried and condemned, should be put to death. He died in his seventy-fifth year, leaving as his successor Marcus Aurelius, whom he had adopted, and who was married to one of his daughters.

Marcus Aurelius. Marcus Aurelius was called " The Philosopher," and his " Meditations " well established his claim to the title. He was tried by many severe troubles during his reign ; there were incessant risings throughout the subjected provinces ; there were devastating earthquakes in many parts of Italy, and a destructive pestilence raged for a long time in Rome. Marcus Aurelius sold the jewels and other treasures of his Imperial palace in order to meet the expenses imposed upon him by the wars and other calamities. He was indeed as innocent of any share in the creation of those wars as he was in the creation of the earthquakes and the pestilence, but he devoted himself as unsparingly to the mitigation of the one set of troubles as of the other. He had inherited from his predecessors those foreign conquests which brought about unceasing and, in most cases, justifiable uprisings of the native populations, and that inheritance brought with it his fate. He died near Vienna of an illness which came upon him while he was still prosecuting a war. The only cloud on the fame of Aurelius was that, unlike his predecessor, he encouraged the persecution of the Christians.

Commodus. Marcus Aurelius was succeeded by his son Commodus, who was but nineteen when he came to the throne in 180. He had served with his father in the war then going on, and as he had no inclination for military service he concluded a peace on almost any conditions, taking many thousands of his enemies into employment under the Roman Empire. This would appear to be magnanimous and statesmanlike conduct, but what we know of the general character of Commodus forbids us to come to any such conclusion. When peace was restored, and he returned to Rome, he soon became a sort of later Nero. He loved to show himself doing battle with wild animals in the Amphitheatre at Rome, and revelled in licentiousness of every kind. In one of his fits of what must be regarded as insanity he proclaimed himself to be Hercules, and demanded that his subjects should worship him. He was as cruel as he was profligate, and scattered death sentences so broadly against some of the noblest and best of his subjects, and even against some of his relatives, that it became impossible for his rule to be longer endured. One of his favourites, with whom he quarrelled, and who believed that her life was not safe while he lived, formed a plot against him; and with the help of some men of influence who knew that they too were under his ban, had him strangled by a professional athlete.

An Empire at Auction. The authors of the plot immediately proclaimed Pertinax, Prefect of the city, Emperor. He was recognised by the Senate but was unpopular with the soldiers, who put him to death eighty-six days later. The next movement was that the soldiery, the most powerful body in the State, adopted a course which can best be described as putting the Empire up for sale by public auction. They made it known that the man who could best satisfy their demands, and especially who could offer the largest sum of money to the army, should have their choice, which meant, at the time, the election. The soldiers in and about Rome, by whom this astonishing proposition was made, chose their candidate because of his liberal promises; but two difficulties soon presented themselves in the way of his actual elevation to the throne. One of these was that the chosen candidate had not money enough in hand for the purpose of prompt and full payment; and while this difficulty was under consideration another arose. The arrangements thus far had been conducted by the army in and around Rome, but the Roman armies in foreign States refused to countenance such disposal of the Empire, each having a candidate of its own. The troops in Albania had Septimus Severus as their favourite, and he at once set out with a strong force of his martial supporters to advance upon Rome and claim his election. The senators, believing Severus the more formidable claimant, and therefore the candidate whom it was their interest to support, ordered the man already chosen to be put to death, and proclaimed Severus Emperor.

A Typical Roman Emperor. Severus proved to be a ruler of almost the typical order of rulers who left in Rome no noble memories behind them. Perhaps the one good thing that can be told of him is that he was careful and economic in his administration of the finances. He attempted some wars of conquest, and subdued rebellions in foreign settlements. In Britain he lost so many soldiers in struggles with the Caledonians that he found it convenient to raise a great wall of defence to shelter the southern regions according to the practical principle of Agricola. During some of his later wars he had a severe illness. He had two sons, one of whom is always known as Caracalla, although his real name was Bassianus. The popularly accepted title was only a nickname, as in the case of another Roman Emperor, because of a peculiarity in his dress—caracalla being the name of a Gallic garment which it was his custom to wear. The other son was Geta, and the two princes had already made themselves conspicuous by their incessant quarrels. It was commonly believed that Caracalla, growing impatient for his father's death and for his own succession, endeavoured to procure the assassination of the Emperor. It is at least certain that his illness suddenly increased in intensity, and he died soon after. We are told that the last words he spoke declared that he had been everything and had found that everything was nothing. Caracalla and Geta acted as co-regents for a time, and Caracalla was subsequently elected Emperor. His reign was one of cruelty and outrage; he had his brother put to death, and charged a large number of Geta's friends with having plotted with him against his own Imperial position; he further carried out a course of actual slaughter among all whom he suspected of participation in that conspiracy. More than 20,000 victims, it is declared, perished in this outburst of Caracalla's fury. Caracalla had six years of senseless cruelty until a centurion whom he had injured ridded the country of him.

An Ignoble Reign The Roman Empire was now falling into utter confusion so far as its governing system was concerned. The Emperors were chosen by whatever part of the army happened to be nearest and most powerful when a vacancy occurred, and there were frequently several men at the same time claiming to be Emperor. Some of those who actually reigned were of the most ignoble character. Heliogabalus, who was now on the throne, gave himself up to the basest profligacy and lavish expenditure while indulging in the most whimsical eccentricities. He dressed himself as a woman, and established a Senate of women to help him in the government of Rome. Some of his soldiers at last rose against him and put him to death after he had reigned four years. Then his cousin Alexander Severus was made Emperor, and under his rule and his peaceful and noble guidance the Empire passed through some years of quiet and prosperity. Trouble, however, broke out in Persia, which involved a war with Rome. Severus was successful, but new troubles broke out in Germany, and Severus, who hurried to the command of the Roman legions, was killed near the Rhine.

The Reign of the Thirty Tyrants. The Empire, then, had six Emperors in rather less than nine years. There was a period known as that of the Thirty Tyrants, because Rome was under the dominion of a number of men—not, however, quite so many as thirty—who exercised a sort of contemporary military control, or military anarchy, over the Empire. Claudius, the most distinguished military commander then in the service of Rome, was elected Emperor in 268, but died soon after of pestilence while engaged in an expedition against the Goths. Aurelian then succeeded to the throne. Aurelian had great military capacity, and was, in many of his characteristics, superior to most of his recent predecessors, but his time was practically taken up in resisting invasions and in conducting expeditions for the suppression of invasion. He is best remembered among modern readers because of his war against Zenobia, Queen of Palmyra, who is famous for her intelligence, her charms, her plans for the creation of a great Eastern Empire, and perhaps more than all else, because she had for her principal minister Longinus, author of the celebrated treatise " On the Sublime."

Longinus was a Greek philosopher and writer who had taught philosophy at Athens for many years, and afterwards went to the East and settled in Palmyra, where his merits were discovered by Zenobia, who made him first her teacher of Greek literature and then her chief minister. Zenobia had the bold desire to throw off her allegiance to Rome and make herself Sovereign of a great Eastern Empire, and in this she seems to have been encouraged by Longinus. She was, however, completely defeated, and had to fly from her capital in the hope of escaping her Roman pursuers, but was eventually captured and handed over to Aurelian. Aurelian kept her to grace his triumph in Rome. He spared her life and gave her a fine residence at Tibur, where she passed the remainder of her days. Longinus had been put to death on the capture of Palmyra.

Aurelian did his best to restore order in the government of Rome and discipline in the army, but he came to his end in the year 275, by the hand of his own secretary, who, being accused of extortion by his master, probably thought his only chance of escape lay in the assassination of the Emperor.

Rome's Decline and Fall. We need not follow minutely the history of Rome's decline and fall. The only Emperors who could be said to have deserved and maintained such a title were Diocletian and Constantine, one of the Sovereigns to whom the world has accorded the title of the Great.

The Roman Empire was fast going to pieces. Many of the foreign populations which Rome had conquered, and which constituted part of her dominions, had long been forming themselves into distinct nationalities, and were striving, with every prospect of success, to become separate and self-ruling States. In the East Rome was losing one after another the possessions on which she had lavished so much money and so much blood in making part of her Empire. The Britons, the Gauls, the Germans, the Spaniards, were becoming not only independent nationalities but dangerous neighbours. An immense change was coming over Europe and even over regions outside Europe by the growth of Christianity. The peoples who had become Christian regarded themselves as in direct opposition to the persecuting power of the Roman Empire, and were compelled by the progress of events and by the necessity of preserving their Faith to sympathise with every attempt to break down the domination of Rome. Even in Rome the Christians were now a powerful body, and were making converts daily among all classes.

During the days of Diocletian there were so many incursions of foreign races into the dominions Rome still claimed as subject provinces that Diocletian divided the government of Rome among four rulers, he himself being one. Each of these rulers had a different region to govern, and thus accustomed the Roman people to the idea of an Empire which did not have its seat of supreme and central government in Rome.

The Emperor Constantine. Constantine first distinguished himself as a soldier during Diocletian's reign, and became one of the Roman rulers when, after Diocletian's time, there had come to be no less than six Roman rulers at one time. There were incessant disputes and struggles among these rival potentates, but Constantine proved himself the strongest of any, became sole Emperor of the West, and finally supreme Emperor, bringing Rome back to the rule of one Sovereign just before her extinction as the great ruling power of the world. Constantine was much drawn towards the Christian Faith, and soon after becoming sole Emperor of Rome he issued a decree giving civil rights and full toleration to Christians throughout the Empire. It is told of Constantine by his biographers that in one of his military marches he saw in the sky a cross of light bearing the inscription which rendered into English is, " In This Conquer," and that the sight first filled him with the belief that the Faith typified by the cross must have a Divine origin. It is also told of him that in sleep he had a vision commanding him to inscribe on the shields of his soldiers the letters which constituted the sacred name of Christ.

Meanwhile he had resolved to remove the seat of Empire from Rome to Byzantium, in Turkey, for the reason no doubt that he believed Rome to have outgrown her power as a capital, and that her dominions could best be preserved by establishing a seat of Empire in some eastern city. He named after himself the city we now know as Constantinople, and lived there in peace for the remainder of his life. Before his death he received public baptism as a Christian. He died in May, 337, and with his death may fitly end the history of ancient Rome. From that time Rome ceased to be a ruling Empire, and a new world of Empires and of Republics, of progress and of civilisation, was coming into existence.

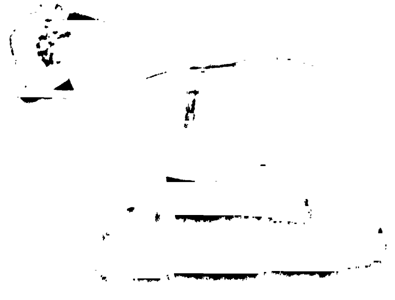
Famous Breeds. Rations for Horses at Rest and at Work. The Farm Horse. Care of Foals. Breaking in Colts. The Age and the Teeth

By Professor JAMES LONG

Our Breeds of Horses—The Shire. This magnificent breed was formerly known as the Old English cart horse, and was practically made in the counties of Lincoln, Cambridge, Derby, and Notts, but it gradually extended to adjoining counties, and subsequently to every part of England. Since the establishment of the Shire Horse Society the Shire has become one of the most popular horses with farmers and landowners. It is chiefly black or dark brown, with white marks on the face and feet; bays are occasionally seen, but other colours are rare. It often reaches 17 hands in height, and in a good specimen the girth is from 7 ft. 9 in. to 8 ft. 6 in. While highly symmetrical in form, it may be described as "much in little." In build the Shire is square and massive, possessing a big chest, a short back, powerful shoulders and loin, long quarters, deep, well sprung ribs, muscular thighs, legs short below the knee, heavily clothed with fine silky hair or feather, and short pasterns. The head is long and fine, but broad between the eyes; the neck arched, and the feet large and wide; the lines of the body are highly symmetrical, while the weight of good specimens exceeds 2,000 lb. The Shire is a fast and active walker, and is largely bred by farmers, many of whom keep pedigree mares for the purpose, which they employ in their teams on the land. The produce is chiefly sold for heavy draught purposes to brewers, carriers, and the like. The Shire is perhaps the most powerful horse in the world. It is docile and intelligent, and is believed to have descended from the old English war horse, an animal of much smaller size. Great prices are often obtained for prize-taking stock, and, chiefly owing to exhibitions, the breeding of this animal has become an important industry. Pedigree stallions owned by wealthy landowners and farmers or hired by societies travel through most parts of England.



A SHETLAND PONY

The Clydesdale. The Clydesdale is the draught horse of Scotland, chiefly used for the heavy work on the farm and the drawing of heavy loads in the great centres of population. In colour it is usually dark brown or black with white markings; not quite so large as the Shire, it reaches a height of 16 to 16½ hands. While symmetrical in form, it is massive and powerful, possessing a gentle disposition and great activity for its size. The head is well formed, the neck arched and strong, the shoulders oblique, the back short and hollow, the chest wide and deep, the ribs round and well sprung, the quarters strong, the thighs powerful, the legs muscular and straight, and the bone, like the knee, flat, the pasterns sloping, and the feet broad and strong. The Clydesdale is a fast and free walker, and is on one side descended from stock imported from France.

The Suffolk. This variety, which is chiefly confined to East Anglia, is, on account of its heavy body and short limbs, known as the Suffolk Punch. Its colour is almost invariably chestnut, although varying in shade. It is active, courageous, and strong, walking and trotting easily; averaging about 16 hands in height, it sometimes reaches 16·2, and weighs from 1,850 up to 2,200 lb. The Suffolk possesses a neat head, a short neck, powerful shoulders, a well-rounded body or barrel, which is massive as compared with the legs which support it. The forearms are short and stout, the thigh muscular, while the legs are light in comparison with those of the Shire and Clydesdale, and carry no long hair. The pasterns are short and strong, and the feet smaller than those of other heavy breeds.

The Thoroughbred. The thoroughbred, or race horse, is the produce of our ancient native breed crossed with the Arab and other horses of Eastern origin. It is a somewhat nervous creature, exhibiting great speed, spirit, courage, and endurance. In build it is graceful, with fine skin, silken hair, and plenty of sinew. Under the management of a Royal Commission money is annually awarded to selected sires, which are distributed throughout the country for the use of farmers and others at low fees. The object is the production of hunters, carriage, and other saleable horses, which the thoroughbred is well adapted to produce when crossed on selected mares. The head, although wide in the nostril and the forehead, is fine, especially at the muzzle. The neck is long and slender, the shoulders long and black, the loin short, the quarters muscular, the legs long and flat, but short from the knee to the pastern, which is elastic, the forearm and thigh long, the chest high, and the constitution exceptional. In colour the thoroughbred is usually bay, brown, or chestnut, other colours being comparatively rare. In height it reaches up to 17 hands; according to one of our best authorities, Sir Walter Gilbey, the height of the racehorse was 14 hands in 1700, 14·3 in 1800, and 15·25 in 1900.

The Cleveland Bay. This is an improving breed, which is bred in the Cleveland and adjacent parts of Yorkshire and Durham. It is employed on the farm for light draught work, for the saddle, and even for carriage work, the mares being specially adapted for the production of carriage-horses when crossed with the thoroughbred. In height it reaches from 16 to 16·2 hands, and its colour is the richest bay of any of our native breeds. The mane and tail are black, and the legs dark. The head is not well formed, but the neck and shoulders are well set, the latter sloping and powerful. The chest is deep, the back short, the barrel round, the loins powerful, the quarters long and especially well formed, and the legs clean.

The Coach Horse. Chiefly bred in Yorkshire, this variety has, like the Cleveland bay, to which it is closely allied, improved in form and quality owing to the establishment of a society. The mares are largely employed for the breeding of coach horses and hunters. In colour the coach horse is usually brown or bay with dark legs; the head is neat and the crest arched, the shoulders sloping, the loins powerful, the quarters symmetrical and strong, the legs flat, and the feet good. The coach horse has excellent action, and stands from 16 to 16·3 in height.

The Hackney. This is, perhaps, the most striking and popular of the light horses of British breed. Its stepping, its high action, and its speed in harness and saddle combine showiness with the usefulness of the horse. The Hackney is bred in almost all colours, although the chestnuts are the most popular. It stands over 15 hands, 15·3 being its outside height. The breed is the result of crossing—it has Arabian blood in its veins—and of selection. Its neck is of moderate length, shoulders deep and sloping, ribs nicely rounded, back short, fore arms short and strong, and hind quarters broad and muscular. The tail is placed high, and is invariably docked. The Hackney is altogether smart, spirited, and symmetrical. When moving, its action should be from the shoulder and not from the knee. The Hackney Horse Society, which has vigorously promoted the extension of this breed, the home of which may be regarded as Norfolk and Yorkshire, was established in 1883, and holds its annual show at Islington.

The Polo Pony. The polo pony is a wonderful production of the art of the trainer. Although the variety has scarcely become a definite breed, really good animals are remarkable for their speed, courage, stamina, and intelligence. The polo should not be under 14 hands. It may be of any colour, while its formation should be such as will enable it to accomplish its work most perfectly. Many crosses have been made in breeding, especially with the Barb and the thoroughbred, the former mated with polo mares being preferred by some authorities, who regard the Hackney as unsuitable for this purpose. There is now a Polo Pony Society, the work of which is telling on the breed.

The New Forest Pony. This pony, which may be of any colour, although usually black or brown, stands from 12 to 14 hands. It is a plucky, hardy breed, and may be regarded as the survival of the fittest, for large numbers of ponies have died in the Forest in the past, where they are frequently turned out for the whole winter. Useful animals may be obtained at the Lyndhurst and other annual fairs, but many are difficult to break.

The Exmoor Pony. Standing about 12 hands, the Exmoor pony is usually bay in colour, thickly built, strong, quick, short-legged, and provided with plenty of stamina. A really good animal is not common.

The Welsh Pony. The Welsh pony, standing from 12 to 13 hands, is a thrifty animal, varying in colour, duns being frequently met with, possessing sound, flat legs and good feet.

The Shetland. The smallest of British breeds is the Shetland, standing from 7½ to 10 hands high. It is short in the neck and back, gentle in disposition, furnished with muscular quarters and sound feet.

Methods of Feeding. Although horses are kept by all sorts and conditions of men, feeding is generally practised upon very similar lines. The most popular foods in the British Isles are hay and oats. There are, however, wide differences in the quality of these two foods as employed respectively by the costermonger and the huntsman. Good oats should be used, and they should be hard and thin skinned. Hay should be the finest early-cut mixture, containing a sufficiency of clover herbage, and it should be fragrant and sweet. Oats are preferably crushed for aged horses and horses with bad teeth, while the hay should be chaffed, the allowance never exceeding 12 lb. daily unless the circumstances are exceptional. Two or three pounds of sweet oat or wheat straw-chaff may be added to a day's grain ration in accordance with the size of the animal. Whether crushed maize, barley, malt, or beans, bran, middlings, or linseed meal or cake, or an occasional mangel or carrot, be added to the ration, depends upon circumstances, to which reference will presently be made.

Maintenance Ration. Food is supplied to the horse, first, for the purpose of maintenance, and next, for the purpose of providing for the energy expended in labour. A horse at perfect rest practically requires a maintenance ration only—*e.g.*, sufficient food to maintain the heat of the body and the wear and tear of tissue, without loss of weight. According to Zuntz, a horse weighing 1,000 lb. can be maintained on a daily ration of hay and grain which provides 6·4 lb. of digestible nutritious matter, of which not more than 3 lb. in the total ration should consist of crude fibre. Grandeau, whose experiments in France are so deserving of atten-

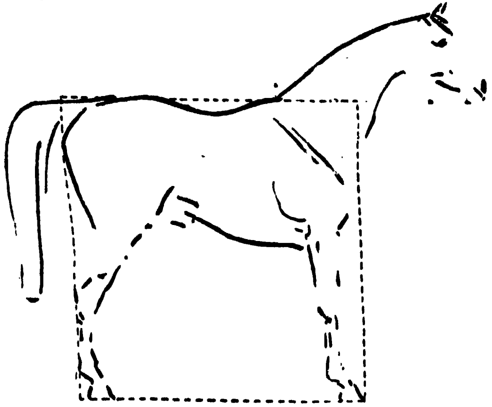
tion, experimented with three horses averaging 852 lb. in weight, which he maintained upon 17·6 lb. of hay daily, of which, on the average, 6 lb. were digested by each, this being the quivalent of 6¾ lb. for a horse weighing 1,000 lb.



A WELL-FORMED HORSE

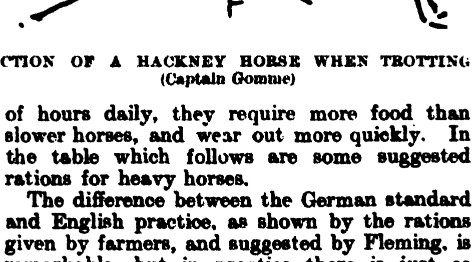
His height equal to his length. Note the dotted lines forming a square. (From Captain Gomme's "Hints on Horses": Murray)

Wolff found that a horse at rest weighing 1,100 lb. required 7¼ lb. of digestible matter excluding fibre, this, too, being equal to 6¾ lb. of fibre-free food for a horse weighing 1,000 lb. It should be pointed out that horses digest coarse fodder less perfectly than cattle and other ruminants, so that, although they require less for maintenance purposes, they need about the same quantity for this reason. Jordan accepts a daily ration of 6·6 lb. of digestible nutritious matter for a resting horse weighing 1,000 lb., and suggests among other formulæ, 10 lb. of hay and 5 lb. of oats, or 12 lb. of hay and 3½ lb. of bran, or 3 lb. of oats, or 2½ lb. of cracked maize.

Feeding the Working Horse. We have seen that a horse of given weight can be maintained when at rest on some 6½ lb. of digestible matter—*i.e.*, on that portion of the dry material of food which is nutritious and digestible, this being regarded as the maintenance ration. What the feeder next requires to know is what additional quantity of food should be provided for the accomplishment of a given amount of work by a horse of given weight. When we speak of food in this connection we mean the digestible portion of the additional ration provided. An addition to a ration having been made, it is important to understand, although the fact can only be approximate, what it means when translated into energy; nor must we forget that energy is expended as well when the animal moves itself as when it is moving its load. Let us again refer to the work of Zuntz, who found that about a third of the total energy provided by food could be utilised in the form of labour. This experimenter points out that a horse weighing 1,000 lb. when walking a mile at the rate of from two to three miles an hour would "expend a total energy of 473 foot-tons, 44·4 per cent., or 201 foot-tons of which belong to the effort of walking over and above the energy needed for mere maintenance."* Thus, although we

performed would be equivalent to the lifting of 9,300 tons one foot. In feeding a horse it should be remembered that speed tells as well as weight. Thus, a fast draught horse expends more energy is accomplishing the same amount of work than a slow draught horse, and consequently it requires more food, although, let us remark in passing, the additional food supplied for the accomplishment of additional work should be rather in the form of grain than of hay, a large quantity of which is not adapted to the limited capacity of the digestive organs of the horse. Many authorities regard 12 lb. of hay as a limit. This being so, it follows that the ration of a horse should be concentrated, well-balanced, and mixed with chaff, and supplied more frequently than in the case of ruminants.

The Food for the Fastest. A hackney or nag horse employed for any fast work requires more food, weight for weight, than a draught horse, more energy being expended in a given time. Thus, a hackney trotting 12 miles in an hour expends more energy than a draught horse, weight for weight, which takes three hours to cover the same distance with the same load, and consequently requires more food. The cost of horse labour increases with the speed with which it is performed. It is the pace that kills, quite apart from the increased consumption of food and wear and tear. In practice, however, horses kept for fast work are kept at rest during more hours daily than draught horses; consequently a balance is struck, the total food consumed is not materially increased, and time is given to the animal to recuperate. Farmers, as a rule, prefer fast horses on the land, but if such animals are worked the full complement of hours daily, they require more food than slower horses, and wear out more quickly. In the table which follows are some suggested rations for heavy horses.



ACTION OF A HACKNEY HORSE WHEN TROTTING
(Captain Gomme)

The difference between the German standard and English practice, as shown by the rations given by farmers, and suggested by Fleming, is remarkable, but in practice there is just as

RATIONS FOR HEAVY HORSES.
(Per Cent.)

	Dry matter.	Albuminoids.	Fat.	Carbohydrates.	Ratio.
Horse at heavy work, weighing 1,000 lb. (Wolff)	25·5	2·8	0·80	13·4	1–5·5
Do. moderate work .	22·5	1·8	0·60	11·2	1–7
Heavy horse at regular work (Fleming). Oats, 18 lb.; beans, 2 lb.; hay, 18 lb.; straw-chaff, 2 lb.	32·8	3·1	1·05	16·5	1–5·9
Farmer's summer ration (McConnell). Oats, 10½ lb.; beans 2 lb.; chaff, 2 lb.; grass, 100 lb.	34·8	3·4	0·9	18·6	1–6
German standard for a horse weighing 1,000 lb., in moderate work	—	—	11·4	—	—
Do. in average work	—	—	13·6	—	—
Do. in heavy work..	—	—	16·6	—	—

much difference in the weight of the rations supplied by farmers themselves. In many cases meadow, mixed, or clover hay are freely supplied, apart from the chaff used in mixing with the corn, while the oats provided on one farm may reach three bushels per week and on another only two bushels. Much depends upon the weight of the horses, upon the condition in which their owner prefers to keep them, and upon his particular views as to what constitutes a sufficient ration.

Proportions of Food. A French observer of wide experience finds by direct experiment that a draught horse in ordinary work requires 12 lb. of digestible dry matter per 1,000 lb. live weight, the proportion of fatty matter increasing with size. On the basis of the argument of Zuntz, if we assume that 6½ lb. of dry digestible matter are required for the purposes of maintenance of a horse of 1,000 lb., some 14 lb. of additional digestible dry matter would be required were such a horse engaged in walking with a draught of 1,000 lb. on a level road for 20 miles. We have seen that the ratio between the albuminoids of food on the one hand, and the fats and carbohydrates on the other, varies. Experience suggests that with increased work the albuminoids should be increased, and consequently the ratio reduced. It is for this reason that in heavy work beans are constantly added to oats, especially where such work is fast; but, inasmuch as the carbohydrates (sugar, starch, gum) and fats are chiefly employed in the animal economy in supplying the necessary energy, they may be provided in larger proportion for slow work, with the result that the ratio will be wider.

The employment of maize in the ration of a horse depends largely upon circumstances. It is inadequate for fast work, it may be used with judgment for medium or slow work. Maize, however, is not so safe a food nor so well balanced as the oat, although when the price of both foods is moderate, there is a wide difference in the cost of the feeding matter supplied. Let us suppose that maize costs 25s. per quarter of 480 lb., and oats 20s. per quarter of 320 lb.—this weight providing a good sample. According to the following figures, 100 lb. of maize will provide 73·8 lb. of digestible dry matter, while 100 lb. of oats would provide only 57 lb.; the cost of the former would be 5s. 2½d., and of the latter, 6s. 3d., or, in other words, the nutritious matter of the maize would cost ·85d. per lb., and of the oats, 1·3d. per lb. [See table.]

Food.	Bushel. lb.	Price.	Digestible and Nutritious.			Digestible lb. per cent.	Cost of 100 lb.	Cost per lb. Digestible. Pence.
			Albuminoids.	Carbohydrates.	Fat.			
Maize ..	60	3.1½	8·4	60·6	4·8	73·8	5/2½	0·85
Oats (good)..	40	2 6	9·0	43·3	4·7	57·0	6 3	1·3

Food.	Dry Organic.	Albuminoids.	Carbohydrates.	Fat.
12 lb. Hay ..	9·7	·70	5·15	·15
6 lb. Oats ..	5·0	·53	2·50	·25
5 lb. Maize ..	4·2	·42	2·90	·25
2 lb. Straw-chaff	1·6	·02	—	·70
	20·5	1·67	10·55	1·35 = 13·57

The third table is a suggested ration, to include maize, for a horse weighing 1,000 lb. in moderate work, the figures being approximate. With the same weight of maize and hay the oats might be replaced with 5 lb. of barley or 6 lb. of bran, or 6 lb. of desiccated grains; but a change should be gradual, the complete alternative never being immediately effected. Horses fed on such a ration should, when subjected to severe work, receive an increase in the quantity of oats, in addition to 2 lb. of beans daily. In all cases the horses of the farm benefit by an occasional warm bran mash, which it is customary to supply on the Saturday night, or an occasional handful of linseed meal, or of crushed linseed cake, the albuminoid ratio being maintained at about 1-5. The meaning of this ratio it is now necessary to explain.

Albuminoid Ratio. This term means the proportion between the albuminoid and the non-albuminoid digestible matter of food. Nitrogen is a leading element in all albuminoids; it is not present in either fats or carbohydrates. Were we, however, to describe the two sets of constituents as nitrogenous and non-nitrogenous, we might mislead, inasmuch as a portion only of the nitrogenous constituents of food are utilised in the animal economy.

The Purchase of Horses. In buying a horse an expert may be deceived. The amateur is, therefore, advised to employ professional help, and thus to minimise his risk. Those accustomed to horses, however they may trust their own judgment in other respects, will do well to employ a veterinarian to examine a proposed purchase for health and soundness. A horse should first be seen at home in the stable, and overhauled in every particular. The object should be to ascertain if there is vice, unsoundness in body or limb, and that the age given is correct, as shown by the teeth. Whether led at the walk or the trot, driven or ridden, it is well that a disinterested and capable groom or coachman should be employed unless the purchaser can trust himself. For his first examination the animal should be led to a level spot, where his teeth, eyes, wind, hearing, mane, withers, and limbs may be examined in turn. Something may be learned from the way he stands; hence he should be looked over from both front and back. He should stand firmly and four-square, not resting a weak limb or tender foot. He should be walked and trotted, ridden or in harness, and in the case of a draught horse, be placed in a loaded cart, which he should be required to draw and to back. Again, he should be tested for shying, kicking, and even bolting, as well as for any other vices which may be suspected. A sound horse should be able to see and hear clearly, and be afraid of nothing he sees or hears, including the motor-car. On return to the stable, he should not exhibit timidity, or temper, or weakness of wind or limb either immediately or after a lapse of an hour. For such troubles or diseases as spavin, ringbone, splints, sandcrack, navicular, fistula, pollevil, and the like, as already suggested, an expert should be employed. In selling a horse a warranty should never be given, either verbally or in writing, if there is a shadow of doubt on any point, for it includes faults of which the owner knows nothing. On the other hand, a buyer should endeavour to obtain a warranty for self-protection.

Horses for the Farm. The farm horse, being required for heavy draught work, as ploughing and rolling, drawing loads of manure to the fields and corn to the station or the merchant, requires great strength and endurance, as well as speed in walking. The object in breeding, therefore, is to obtain these qualifications. He must be of large size, well formed, the muscles being prominent where they are most needed, and the legs and feet absolutely sound and strong. Constitution demands plenty of room in the thorax—a prominent chest, which is deep and broad, and long, well-arched ribs, providing plenty of room for play of the heart and lungs. Add to these points docility and good temper, and we shall not be far wrong

In selecting stock for breeding, it is important that the stallion, or sire, should have a long, straight head and broad forehead; short, wide, muscular loins; prominent, well-curved ribs; a belly proportionate to the size of the animal; fore legs which are straight, squarely set when looked at from the front, and not too far under the chest. The hind legs should be equally square, well formed, straight, without tendency either to bowness or what is termed "cowhock." The feet should be well formed, sound, neither turned inwards nor outwards, and always firmly planted on the ground. There should be neither defect of either eye or ear, still less of breathing. In a word it is imperative that for reproductive purposes both sire and dam should be in perfect health and vigour, and as nearly perfect in form and temper as possible. Farmers, however, are compelled to do the best with the means at their command.

The Mare. In many cases, mares are kept for field work and used for breeding purposes. The plan is a good one, but under no circumstances should a weedy, unsound animal be employed as a dam, however good the sire, for the practice means vexation, disappointment, and loss. If a mare has a pedigree, which in large part means reliability of constitution, so much the better. She should be in good condition, and without any serious fault, and the younger the better, although in many cases mares are employed for breeding up to an advanced age. Both sire and dam should be in the full vigour of life. The mare comes into season from seven to ten days after foaling. The breeding mare may be worked nearly to the date of foaling, but she should obtain a rest of a few days under any circumstances. Parturition occurs about 11 months after service, the date of which should be kept, and as the time closely approaches, it will be noticed that the udder commences to expand. The mare usually foals without assistance, whether on the pastures in sufficiently mild weather, or in the loose-box, where she should be subsequently kept for a few days prior to turning out with her offspring on a fine warm day in a paddock. After foaling she should receive a few bran mashes and an occasional mash of boiled roots, with crushed oats and sweet hay. The box should be specially cleaned, purified, and littered with clean straw before foaling. Should green food be available, it should be gradually introduced, unless the animal has been receiving green rations beforehand. Until mare and foal have been hardened off to outside exposure, they should return to the loose-box at night; subsequently both will benefit by remaining altogether upon a dry, yet soft, turfed pasture, on which they may be fed from a movable crib or manger from day to day. The mare should be kept in condition as well for the benefit of the foal as for her early return to work, while the foal should be liberally fed from weaning onwards. Without good feeding, size is unattainable, especially on poor soil. In the rearing of young horses, it is important that the best grass should be placed at their disposal, but it should neither be short nor wet, many foals being lost upon both, and on many parasites abound.

Weaning Foals. When the mare returns to work, the hours during which she should be employed should be gradually increased, but she should never work too long in the day before weaning, nor return to her foal while still warm, both practices being liable to cause diarrhœa, or scour, in the youngster. A strong foal may be weaned at the age of six months. If he feeds well, his ration of oats may then be increased, but the food supplied should always be of the best. Extra care should be taken with young stock in winter, and yet there should be no coddling. Colts may be turned in a well sheltered, or covered yard, where they can lie dry, and where they are protected against biting winds and driving rains. The colt may be submitted to castration at from 12 to 15 months, the modern system being adopted.

Breaking. Farm colts and fillies are more easily broken than those of almost any other class. The breeder should make a practice of making friends with his young stock from birth. They may be handled, or even fondled, daily, as far as possible. Under such circumstances, breaking becomes extremely easy, and almost without any extra effort a young animal submits to the halter and subsequently to harness for the plough or the waggon. There should be no suspicion of harshness or cruelty in word or deed. When, by the gradual introduction of the halter, the bridle, plough chains, and other harness, the young animal is submissive, he may be placed in harness by the side of a steady old horse, and induced to assist in drawing a log of wood, then a bush harrow, made on the framework of a hurdle or an old gate. This will prepare the way for attachment to a chain harrow, and subsequently to the plough, the roller, the waggon, and the cart. At first, the experiment may be a short one, gradually increasing until the colt becomes fit for a short day's work. He should be encouraged by word and act, and rewarde on his return to the stable, learning to recognis that he has given satisfaction. In this way colt may be gradually brought into the daily wor of the farm at the age of two and a half years.

The Age of the Horse. The adul male possesses 40 teeth, and the female 36, the temporary teeth in each sex numberin 24. These teeth are succeeded by the permanen teeth, which commence to appear at from two to two and a quarter years from birth Where horses mature early, and where they ar accustomed to eat coarser food than usual, th permanent teeth sometimes appear earlier thar is normal. The 12 front teeth, top anc bottom, are known as incisors, while the molar number 24, of which only 12 are temporary In the male, however, although they ar occasionally found in the female at fror eight to nine years, there are four canine, o corner, teeth. In the young animal the mout is complete with the temporary teeth at tw years, and with the permanent teeth at five year old. The corner teeth at this age—those nex to the middles—are but shells, while the middl and central teeth are well developed. When horse has reached eight years and is aged, th marks on his teeth have been worn away, and i is next to impossible to mistake him for a animal of younger years. The trained expert i able to fix the age of a horse for some year afterwards, but this is scarcely a study for an but the dealer or veterinary surgeon.

THE REALITY OF THE ATOM

The Root Question of Chemistry. Physical Chemistry. The Atomic Theory is not Destroyed. Analysis of the Atom

By Dr. C. W. SALEEBY

OUR study of radium has prepared us in some measure to consider anew a question which is of far greater importance than any fact about radium as such, but a question to which the study of radium is gradually providing an answer. It may be said, perhaps, that the root question of chemistry is the nature of matter. That is also a question for the physicist, though not his root question. The physicist is, at least, as much concerned with the impalpable something we call *energy* as with matter; while the chemist concerns himself with energy only in so far as he needs to do so in order to understand the changes which matter undergoes—changes which, for convenience, we usually distinguish as chemical.

All Things are One. But it is now far too late in the day to speak or think as if there were any fundamental line of demarcation between Physics and Chemistry. Even ten years ago there was some little excuse, perhaps, for assuming that they were two distinct sciences, though this was not a notion which could ever be held by any would-be philosophical, still less by any distinguished student of either.

Nowadays, a man may call himself a chemist or a physicist, but he will be of exceedingly small importance as either unless he be both. Endless instances might be accumulated that serve to show how closely the sister sciences are interconnected. It is probably safe for the present writer to assume that there is no reader of this course who is not also a reader of the course on Physics. We may make distinctions, for convenience, between them, but ultimately the two sciences are one. Serious thinkers have always recognised—perhaps more as an article of faith than as an article of demonstration—that the distinctions between the sciences are, in the last resort, *man-made*. At bottom, the universe is a universe indeed, not a multiverse. " It is a flawless unit of fact," as a great American thinker has said, and when we isolate from it any particular aspect and proceed to study that, we must remember that we have performed an artificial process, the necessity for which is imposed upon us by the limitations of our minds, but which we must not permit to become a snare after being an aid.

Unity of Chemistry and Physics. There is no correspondence in nature—no fundamental correspondence, that is to say—to the distinctions between the sciences. Properly speaking, there are no sciences, but only science. The student might as well attempt to understand the anatomy of man without physiology, or the physiology of man without anatomy, as to study physics or chemistry independently. This is one of the reasons why we have, as frequently as possible, inserted cross-references between the courses upon these two subjects, and why one and the same topic has not infrequently been dealt with in both—now from the more distinctively chemical, now from the more distinctively physical point of view. But, indeed, the more the sciences advance the more they come to depend upon one another, and so the man who would be master of any one science must have some knowledge of all—the more the better.

Now, what has been the tendency in the case of the two sciences under discussion? Do they still stand on a level? Are they sisters? to repeat the common term. The answer most emphatically is that they are not. One has gained supremacy over the other. Nay, more—it has actually been able to include the other as one of its own subdivisions. The reader will not need telling which has become the dominant science. Were he in such need, we might again quote the profound saying of Bacon, who, centuries before the truth of his words were verified, declared that natural philosophy—a term practically equivalent to physics, which is, of course, derived from the Greek word for nature—is the " great mother of the sciences."

The New Science of Physical Chemistry. Modern chemistry must acknowledge its filial relation to modern physics. If not to-day, then to-morrow, or the day after, all the phenomena of chemistry must be not merely included amongst the phenomena of physics, but must be explained in physical language and regarded as physical phenomena, differing in kind not one whit from the phenomena which men have long recognised as coming under the heading of physics.

From one point of view, we may say there has been born a new science—*physical chemistry*, and this term does afford convenient means of indicating a certain series of inquiries; but all chemistry is really physical chemistry, and is more clearly seen to be physical chemistry the more nearly it approaches perfection. Thus, this question of the ultimate nature of matter is equally and alike a physical and a chemical question. Here we must attempt to discuss it more especially, of course, from the chemical point of view, asking questions which are especially suggested by chemistry—questions as to so-called chemical energy, as to valency, as to the nature of forces which determine the combination of elements for the formation of compounds, as to the decomposition of compounds, and, in short, all those interrelations of matter which are commonly distinguished as chemical.

The Limit of the Older Chemistry. And, in the first place, we must decide how far the older chemistry takes us, and the answer, of course, is that the older chemistry takes us as far as the atom. The standard chemistry is, indeed, based in the main upon the theory of atoms. On the other hand, students of this and its companion course have already found reason to see that the atom is not an ultimate ; and here we must insist upon an extremely important truth which is in very grave danger of being neglected at the present time. The casual reader is extremely apt to be misled, and, unfortunately, the casual writer as well. So soon as the physicists rudely disturbed the equanimity of the chemist by resolving the atom into smaller particles, people arose who said that, for instance, "the whole structure of modern chemistry has been swept away at a blow." That is, indeed, a nice comprehensive statement. For just a century chemists have been accumulating facts in thousands and tens of thousands which seemed capable of explanation on the atomic theory, and on that alone. Our notions of molecules, and of molecular constitution, our conceptions as to what constitutes a compound, and differentiates it from a mixture, our positive and experimental knowledge—not theoretical knowledge, be it observed—of the laws of valency and of atomic heat, the law of Avogadro, and many more—all these, forsooth, are to be swept away at a blow because the old conception of the atom can no longer stand. On page 1596 we spent half a dozen lines in protest against this view, as was indeed necessary before we could discuss the laws of compounds. But let us consider the matter, since otherwise we are not likely to go far in our search for an answer to the root question of chemistry.

A Grave Error. A still more recent writer than the one whom we have already quoted makes very short work of the atomic theory, and this in the course of praise showered upon Professor J. J. Thomson—whom the following sentence would scarcely gratify: "The atomic theory, which we were taught at school to regard as the foundation of chemical science, has been 'scrapped' on the dust-heap of antiquated hypotheses." The present writer finds that this notion is to be found not merely among amateur commentators but even among competent students of sciences other than chemistry. The case is plausible enough. An atom is, by the derivation of the word, a thing which cannot be cut. It is an ultimate, an everlasting "foundation-stone," as Clerk-Maxwell thought, as Dalton himself thought, and well-nigh three generations of chemists after him. This assertion concerning the atom would appear to be the most essential assertion that can be made of it. Whatever else may or may not be true of the atom, at least it is a chemical ultimate as distinguished from a physical ultimate. However closely you examine iron you can never get any further than an atom of iron ; similarly with sulphur, while the difference between the atom of iron and the atom of sulphur is radical and eternal.

Upon the theory of atoms there has indeed been erected the imposing and seemingly stable structure of modern chemistry. Our scribe is correct when he says that "we were taught at school to regard the atomic theory as the foundation of chemical science."

Complexity of the Atom. But now there comes the physicist, who tells us that an atom is not an ultimate but is a complex body, consisting, at the very least, of a thousand smaller particles, which bear some such relation of size to it as a full stop bears to St. Paul's Cathedral. The hasty observer has, indeed, some ground for thinking that the foundation has been swept away, to the utter ruin of the superstructure ; and unquestionably this view would be not merely plausible but also correct, *if the essential part of the conception of the atom were its indivisibleness.* Now, it is this part of the conception which is usually regarded as essential. The present writer was taught that this is the essential of the atom. The textbooks regard it as such : the less philosophic chemists, generally, have regarded it as such ; and the very meaning of the name goes to confirm this view. Nevertheless, we maintain and propose to prove that, during all this time, the emphasis has been laid upon a part of the conception of the atom which is not essential, which is of no importance whatever for the atomic theory, and which, to boot, is demonstratively false. To the latter assertion every one must now agree, but the two former will surprise all, save those very few who have attempted to understand the logic of scientific thinking.

John Stuart Mill's Anticipation. The explanation of the whole matter is to be found in a really remarkable paragraph occurring in Mill's "System of Logic," which dates from as long ago as the year 1843, the year before the death of Dalton. There are few passages in the writings of this great philosopher which more strikingly demonstrate the measure of his genius than this, or more signally show how the greatest minds, seeing all round a subject, are able to correct the narrow views taken by men who may quite well be distinguished workers in this or that field—chemistry, biology, or what not. In the introduction to his great work, Mill attempts to define logic and estimate its province. He declares that he must "attempt a correct analysis of the intellectual process called reasoning or inference," and then he goes on to say:

"With respect to the first part of this undertaking, I do not attempt to decompose the mental operations in question into their ultimate elements. It is enough if the analysis, as far as it goes, is correct, and if it goes far enough for the practical purposes of logic considered as an art. The separation of a complicated phenomenon into its component parts is not like a connected and interdependent chain of proofs. If one link of an argument breaks, the whole drops to the ground ; but one step towards an analysis holds good, and has an independent value though we should never be able to make a second. The results of analytical chemistry are not the less valuable, though it should be discovered that all which we now call simple substances are really compounds. All other things are, at any rate, compounded of those elements; whether the elements themselves admit of decomposition is an important inquiry, but does not affect the certainty of the science up to that point."

How the Atomic Theory is Affected. Mill's argument is that it does not matter whether the atoms of the elements may be shown themselves to admit of decomposition, since, however important that question may be, the answer to it has no bearing upon the conclusions to which the atomic theory has already led us. The notion that the atom is indivisible does not constitute a link in the chain of argument which we call the atomic theory. *Mill admits that if it did so the whole theory would drop to the ground.* To-day many people think that the alleged indivisibility of the atom is an essential part of our conception of the atom, and is, therefore, a link in the argument. They know that the link—if it were a link—is broken, and they conclude, by correct logic from a wrong premise, that the whole structure of modern chemistry has been swept away at a blow.

But observe how remarkable is the applicability of Mill's illustration to our present difficulty. We have gone far to prove, and, beyond a doubt, will shortly go all the way to prove, that "all which we now call simple substances (elements) are really compounds." But this does not matter. Neither chemist nor physicist doubts that, as Mill said, "all other bodies except those so-called elements are at any rate compounded of those elements." This fact remains a fact, as is the nature of facts, and is affected in no degree at all by the modern discovery of the decomposition of the elements.

What then must we give up? Certainly, we must abandon what may perhaps be called, in order to distinguish it, the "atomic theory of the atom," the theory that the atom is literally atomic or indivisible. Indeed, it has been suggested that the term atom must be transferred to the corpuscles, or electrons, of which atoms are now known to be composed—corpuscles which seem to be, indeed, atomic or indivisible. But it would be a great mistake to transfer the name in this fashion, even though on the score of its derivation it is quite inapplicable to what we now call atoms. The name may remain, and will serve the students of countless generations as a convenient text for the illumination of one most important phase in the history of thought.

Atoms are Realities. But whether or not we give up the name, certainly there is no chance of our giving up the conception. No one again, indeed, will ever liken atoms to foundation-stones, or declare that they bear upon them the "stamp of the manufactured article." Such phrases cannot be permitted in the light of the conclusive evidence which we now possess of the evolution of atoms, the heavier and more complex having been demonstrated in several instances to break down into the lighter and simpler. But, as the present writer has said elsewhere—and the illustration is perhaps significant—"we no more question the existence of atoms because we are beginning to understand their structure and the nature of the actual elements of which they are composed than we question the existence of animal organisms because we know they are all composed of cells; of cells because we know they are all composed of molecules; or of molecules because we know they are all composed of atoms." Mill's remark was that one step towards an analysis holds good, and has an independent value though we should never be able to make a second. Well, chemists have made several steps towards an analysis, and these do not hold the less good simply because the physicists have taken a further step yet. But, indeed, for the steps taken by chemistry physics could not have gone further.

The Theory is Really Strengthened. But this is not all. So far are these new discoveries from having swept away at a blow the whole structure of modern chemistry, that they have actually afforded signal support to this great structure, which stands far more securely with their assistance than it previously did. Let us take an instance. The reader is familiar with the periodic law—to which we have already been compelled to pay an amount of attention which would have seemed ridiculous ten years ago. The law asserts, the reader will remember, that if the elements are arranged in the order of their atomic weight, certain groups of characters are found regularly to recur, so that the characters of an element are a periodic function of its atomic weight. This law has vindicated itself by leading its propounder, Mendeleef, to predict the discovery of elements which have now, indeed, been discovered, and which actually have the characters that he assigned to them, just as the law of gravitation vindicated itself by leading to the discovery of Neptune. We may also remind the reader that the group of rare gases found in the air have astonishingly fitted into the periodic table. But upon what is the periodic law based?

Value of the New Conception. Most evidently the periodic law is based upon the conception of atomic weight, and this, of course, upon the atomic theory; and this, forsooth, far more certain to-day than ever it was, is declared to have been "swept away at a blow." But we have declared that the law will furnish an illustration of the view that the new conception of the atom makes still more secure the structure of modern chemistry, and the fact to note is that it is the new theory of matter, the theory which implies the disintegration of the atom, that alone affords an explanation of the manner in which the elements are related to one another, the manner in which the atoms of various elements display a tendency to unite with one or more atoms of other elements, and the manner in which the properties of elements seem to recur as one passes onwards from those of less to those of greater atomic weight. There is no essential part of the atomic theory which has done anything but gain in consequence of recent work. The notion that in the atom we have the ultimate result of analysis has never satisfied philosophers—as our quotation from Mill suggests—and, although on a superficial view this notion may appear to be the essential part of the atomic theory, it is really not essential at all. To quote another illustration from astronomy, we may say that Kepler's theories of planetary motion were not in the smallest degree affected because his great successor Newton was able to refer the ultimate cause of that motion to gravitation, whereas Kepler still retained the ancient notion that the movements of the planets were directed by spiritual beings whose abode they were.

The "Life" of Atoms. We have then to conceive of matter, in all its common forms at any rate, as being reducible—not ultimately, but still at a certain stage in analysis—to bodies which we still call atoms. These atoms themselves may be immeasurably complex, but they are no more without individual existence of their own on this account than St. Paul's Cathedral is without an individual existence because it is made of stones, or than the body of an animal is without an individual existence because it is made of cells. For the *ordinary* purposes of chemistry these atoms may indeed be regarded as ultimates, and they are a surer, because a truer, foundation for chemical science than they were when we had no better conception of them than Dalton's or Clerk-Maxwell's. But since they are not ultimates, they are subject to the common fate of everything else that is not an ultimate—they are subject to birth, development, disintegration, and decay. The chemist studies them mainly in what we may call their adult stage. Their lives are extremely long in the great majority of cases, and thus there are immense periods during which, for the purposes of the chemist, at any rate, they may be regarded as permanent. The law of the conservation, or indestructibility, of matter—that is to say, of atoms—cannot stand rigorous criticism, dictated by recent knowledge. But the periods of stability are so prolonged in the case of all but a very few atoms that the chemist is able to proceed as if the law of the conservation of matter were really true.

The Change in 12,000,000 Years. In the course of ordinary chemical decompositions and the like, atoms do not disappear; chemical equations such as those of which we have seen many examples are not fictions, but correspond to truths; and when it is demanded of a chemical equation that the same number of atoms and the same number of each kind must always be represented on both sides of the equation, or else it is no equation and falsely represents the chemical facts, we are making no unreasonable or imaginary demand, but one which is imposed upon us by the facts. In the course of ordinary chemical actions atoms do not disappear, nor, on the other hand, do they come into being. The physicists tell us, and provide abundant proof of the assertion, that these atoms of which we write as if they were so many permanent bricks are really undergoing slow change—that in 1,200 years atoms of one kind will have changed into atoms of another, or that in 12,000,000 years atoms of a third kind will have changed into atoms of a fourth. Meanwhile, we, whose observations are confined to minutes or days or a few years, are at liberty to assume, for practical purposes, that the stable period of atoms, except in the case of the very heavy ones, is permanent.

Man and the Atom. And here we are in a position to make an important distinction. Just as in the case of a member of a society, we may raise two inquiries concerning an atom, a man may be considered from two points of view. We may ask concerning his internal processes, as to what he thinks in his heart of hearts, as to how his mind develops and changes and reaches, perhaps, a changeless period, as most minds do in later life; and, on the other hand, we may consider the man in his relation to other men. On the one hand, we consider him simply as an individual, on the other as a member of a greater whole; but while we observe this distinction we must remember the principles laid down in the beginning of this article, and realise that at bottom the distinction is an arbitrary one. A man's life is not made up of two independent sets of processes—one individual and the other social. On the contrary, these are incessantly reacting upon one another.

Now let us see how this analogy helps us. In the case of atoms, we thought until the other day that there was only one set of processes to consider—the social processes, so to speak. Chemistry accepted atoms as changeless and permanent, and its business was, and, indeed, still is, to ascertain the way in which atoms behave in relation to one another. If we could ascertain this in its entirety, we should have, it seemed, a perfect chemistry. There did not seem to be the slightest reason to suppose that there were any other processes than these. But now we know better. Physicists have taught us, not, as incompetent commentators aver, that atoms are a "baseless fiction," but that atoms have their individual processes as well as their social processes. It is with the latter that chemistry, as it used to be conceived at any rate, is concerned. It is the former, the existence of which was until lately unsuspected, that is now exciting the interest of all students of science. We may use two convenient terms to express the difference.

Social and Individual Processes. The material processes which we have to study may be described as belonging to two groups—the inter-atomic and the intra-atomic (from Latin *inter*, between, and *intra*, within). But this analogy between the human and atomic organism—for which the present writer must take the responsibility—is even more complete and, we think, valuable than has yet been indicated. For we have said that it is impossible in point of fact to consider the social and individual lives of men as if they were independent. On the contrary, the truly wise student of society knows that the key to social phenomena is human nature. What does this mean? Plainly, that the social processes can never be really understood so long as we assume either that they are all the processes to consider, or that the individual processes have no relation to them. In order to understand the relations of human beings—their unions and disunions, attractions and repulsions, marriages and divorces, combinations and separations—it is absolutely necessary to study the characters of individual men, which determine all these processes, and these characters can be understood only if we study the internal individual processes of men. *As a man thinks so is he.*

The Atom Vindicated. And it is so with the atom. The facts are directly opposed to the statements of those who say that the discovery of the intra-atomic processes has swept away the structure of modern chemistry, which is concerned with the inter-atomic processes. It is as if men had been thought to have no internal conscious life, and society had been studied on this assumption; but one day it was realised that men had their own internal processes of thought and feeling, upon which commentators asserted that all that was hitherto known concerning the social relations of men was false. On the contrary, the new discovery would explain and immeasurably amplify such knowledge. No commentator would say anything so silly as that men had no real existence because they were discovered to undergo *internal change; though a parallel assertion has been made of the atom.*

The discovery of the intra-atomic forces and processes is already illuminating, and will more and more continue to illuminate and amplify our knowledge of the inter-atomic processes; just as, in the state of affairs we have imagined, the study of individual psychology would amazingly explain and add to our knowledge of the facts of sociology. Furthermore, our knowledge of the intra-atomic processes is leading us to our first real comprehension of the already known characters of atoms and their behaviour. King Solomon, the wisest man of antiquity, has declared of man "For as he thinketh in his heart so is he" (Prov. xxiii. 7). And the modern chemist is just coming to realise—as we shall see ere long—that the internal processes of the atom determine its character, and thus its relations to other atoms—that is to say, its inter-atomic processes, its chemical behaviour. Was anything more ludicrous ever said than that these new discoveries have caused the atomic theory to be "scrapped on the dust heap of antiquated hypotheses"?

Analysis of the Atom. We have deliberately discussed this subject at great length, since it is absolutely necessary to do what may be possible in order to counteract a misconception which is extremely widespread, which is rapidly gaining ground among the uninitiated, and which, unfortunately, strikes at the very root of any real understanding of chemistry. Atoms unquestionably exist, and constitute the ultimates of the elements as we know them.

Now, it may not unreasonably be argued, one would think, that the business of the chemist stops at this point; that directly we begin to analyse the atom, to concern ourselves with the intra-atomic processes, we are wandering from our subject, which is, properly speaking, the social aspect of atomic life; we are committing the fault of the sociologist who begins to study individual psychology. But these barriers and distinctions and delimitations are relics of an outworn order of thought, or, to change the metaphor, they are like temporary scaffolding arrangements which can be removed as the building approaches completion. If it be true that the key to sociology is to be found in human nature, the sociologist is right in studying individual psychology.

The Chemical Processes. Similarly, if it be true that the key to chemical processes is to be found in the internal individual processes of atoms, the chemist is right in considering them. They are the key to everything that interests him, and even if his means of study have to be modified, even if he can dispense with nearly all his test-tubes, even if he require to leave his own laboratory and enter the laboratory of the physicist, and be told that he has forsaken his first love, he must "see this thing through." He cannot be arrested at the edge of the atom. On these grounds and on those other grounds which we began by stating, we offer no apology for proceeding to study this subject in this course instead of the course on Physics. In any case we have failed in our task if the interdependence of the two courses has not been made manifest.

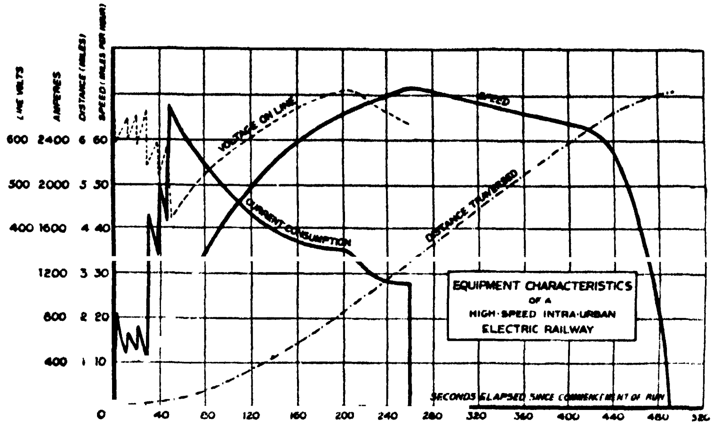
ELECTRIC RAILWAYS

Types of Railway Service. Comparison between Steam and Electric Locomotives. Methods of Electric Propulsion. Collection of Current

Continued from page 1938

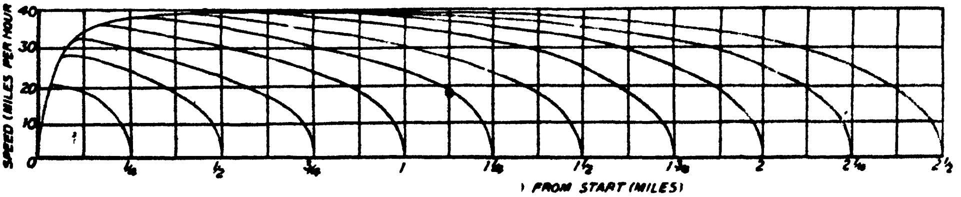
By Professor SILVANUS P. THOMPSON

WE shall begin our discussion of the electric railway by a short consideration of the typical classes of railway service necessary for present-day requirements. Modern train services may be roughly classified under two headings—namely, (*a*) main line services, in which the stations are some miles apart, and (*b*) suburban services, in which the stops are very frequent, often as many as three or four to the mile. The former of these types of service has yet to be electrically developed, but the greater part of the latter has now passed out of the domain of the steam locomotive.



147. ELECTRIC RAILROAD CHARACTERISTICS

All travel must nowadays be expeditious. To attain a high-speed main-line service one requires only to arrange for a high maximum speed without much regard to starting and stopping. For suburban service, however, attention to these last is all-important, for whereas in the previous case the train is running for most of the time at its top speed, in this case the maximum speed can be kept up only for short periods, for a large part of the time between stations is taken in speeding up or accelerating the train after a stop and in slowing down or retarding it for the next stop. It is obvious that time, under these conditions, can be saved only by getting up to a maximum speed as quickly as possible, and by bringing the train to rest as quickly as possible. These questions of acceleration and retardation become more and more important as we deal with systems in which the stations are nearer and nearer together. To illustrate this point from actual practice, an experiment, from which the curves in **148** have been plotted, was carried out a few years ago, and a steam train made a series of journeys of varying lengths over a level piece of track and observations were made of the time taken. The train was first taken a quarter of a mile from a station and the driver was instructed to run to and stop at the station as in actual service, and the times and speeds were noted. The train was then taken half a mile away and was run into the station as before, and the experiments were continued in this way until the run was for 2½ miles. In **148**, distances from the start of each run are plotted horizontally and speeds in miles per hour are plotted vertically. We learn from the curves that this train with the type of engine used had a maximum speed just under 40 miles per hour, and that it required to travel half a mile before this speed was attained. In consequence of this, and also of the time spent in braking, the average speed was much reduced, as shown by the final results worked out in the following table.



148. SPEED TESTS ON STEAM TRAIN FOR VARYING RUNS

149. ELECTRIC LOCOMOTIVE

Distance between stops (miles).	Maximum speed attained during run (miles per hour).	Average speed during run (miles per hour).
¼	20	15·3
½	27·5	20·8
¾	31·7	24·2
1	35	26·8
1¼	37·2	28·6
1½	38·5	30·1
1¾	39·5	31·3
2	39·5	52·3
2¼	39·5	33·1
2½	39·5	33·7

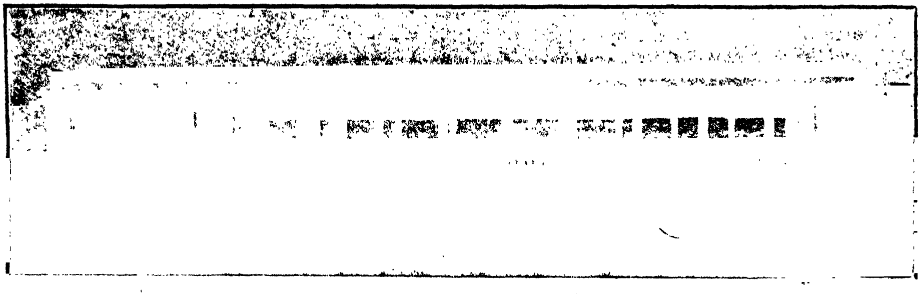
***Accelerating Power of Electric and* Steam Locomotives.** It will be seen from the above that for suburban work the locomotive, apart from any capabilities it may have of propelling a heavy train at a high speed, must be able to exert a very large effort at starting ; an effort which may be several times greater than that required at the maximum speed, much in the same way as a horse can exert at starting a pull which is several times greater than that required afterwards to keep the vehicle at top speed.

It is because the electric locomotive fulfils these conditions so admirably that it has been so extensively adopted for this class of work.

There are other advantages, among which are that the driving units can be split up conveniently to drive long or short trains at will, that in tunnels and tubes so much in vogue in suburban lines it produces no smoke or steam to contaminate the atmosphere, and that the method of generating the whole of the energy at one big central station is more economical both in the quantity of coal consumed and in the total labour charges over the system.

Railroad Characteristics. Just as we plotted a set of curves [129, page 1931] to show the characteristic properties of a series motor, so, in order to show the performance of a certain equipment on a certain railway, the railway engineer plots a set of curves such as is shown in 147.

The various curves are plotted to a common time base, generally graduated in seconds, and the various curves represent (*a*) the current consumed from instant to instant, (*b*) the voltage on the motors, (*c*) the speed of the train during the run, and sometimes (*d*) the total distance traversed from the starting point. By reference to these curves we can see at a glance whether the equipment has been used in a proper manner or whether it is suitable for the work in hand. Let us consider the current curve. At the start it consists of a series of irregular peaks, showing how the current increases when successive resistances are cut out by the controller, and how it then decreases as the train acquires more speed. After the final running notch is reached the current then continuously decreases until, at a certain distance from the



150. MOTOR COACH ON LANCASHIRE AND YORKSHIRE RAILWAY

151. MOTOR TRUCK ON LANCASHIRE AND YORKSHIRE RAILWAY

end of the run, it is shut off altogether, and the train is allowed to coast for the rest of the journey until the brakes are applied as it enters the station.

Looking at the voltage curve, we see that every time the current rises the voltage goes down owing to the increased voltage drop in the rails and feeding cables. The speed curve is the most interesting of all, in that by its initial slope we gauge the quickness with which the train gets under way at starting and the quickness with which it is brought to rest. We can also state the proportion of the time during which it was running at full speed. In the curve this is about 180 seconds, or only 37 per cent. of the whole time taken on the run.

Methods of Adopting Electric Propulsion. In the first electric equipments which were put into service, the practice of using a separate locomotive, as in the steam lines, was adopted, but the considerations given below soon pointed to another method—namely, of distributing the units of propulsion—*i.e.*, the motors, in different carriages along the train, a system which for obvious reasons could not be adopted in steam locomotion.

In the first place the electric locomotive is much lighter than the steam locomotive. The Great Northern Railway has recently introduced on its suburban lines a new type of steam locomotive which is, perhaps, the most powerful yet made in this country for its purpose. Comparing the performance of this with the electric locomotives of the Central London Railway which, however, have now been discarded for a still better arrangement, we have :

Locomotive.	Weight.	Tractive effort.	Tractive effort per ton weight of locomotive.
Steam (G.N.R.)	70½ tons	35,000 lb.	500 lb.
Electric (C.L.R.)	31 tons	20,000 lb.	650 lb.

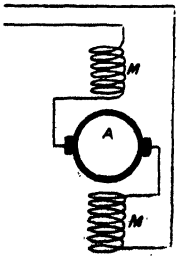
It is to be further noted that with the steam locomotive the tractive effort rapidly falls, but that with electric propulsion the effort is continued throughout the period of acceleration.

The decreased weight of locomotive, shown in the last column, is, of course, an advantage, for the extra weight is dead weight and carried to no useful purpose. The drawback, however, is that a certain weight on the wheels is necessary in order to obtain the grip on the rails for driving [see remarks on page 1934], and as the electric locomotive was lighter, the scope for further increasing its effort was limited. The result, then, was that the motors were divided into two or even three sets and were installed on the different coaches so that the weight of the coaches themselves might be used to give the necessary grip on the rails. Further, the weighty locomotive has been entirely done away with and only the weight of the motors has been added to the train. The following figures from the practice on the Central London Railway illustrate this point.

Original Equipment. Locomotive and seven coaches. Total weight of train, 137½ tons. Seating capacity, 336.

Present Equipment. Two motor coaches and five trailing coaches. Total weight of train, 113½ tons. Seating capacity, 324.

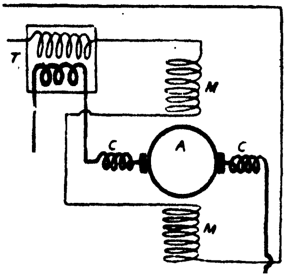
The decrease in the weight of the train is 17·5 per cent. as against a diminished seating capacity of only 3·6 per cent. For special circumstances the electric locomotive is still used, and 149 shows one used on the Metropolitan Railway, London, for propelling coaches formerly used with steam locomotives.



152. DIAGRAM OF SERIES MOTOR

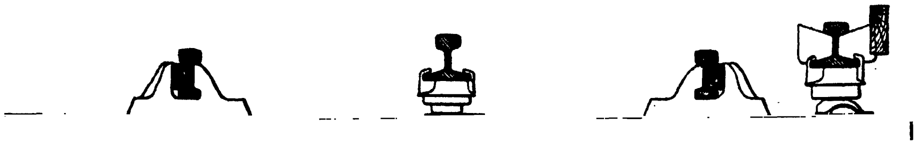
Fig. 150 shows one of the motor coaches used on the Lancashire and Yorkshire Railway. The usual arrangement as here adopted is to partition off the front part of the coach and there to install the controlling apparatus, although in some of the equipments for the London District Railway all the controlling gear is fitted underneath the car.

In the coach shown both the front and rear trucks are fitted with two motors each, but here again practice differs, for on the Central London line, only the front truck is so equipped. Fig. 151 shows one of the Lancashire and Yorkshire motor - equipped trucks and also the arrangement of the collecting shoe at the side.



153. DIAGRAM OF SERIES MOTOR, WITH COMPENSATING WINDING AND CURRENT TRANSFORMER

Systems of Electrical Traction on Railways. At the present time the continuous current system at 500–750 volts is largely used, although other systems using single-phase, three-phase, or high-pressure continuous currents may, except the last, be said to be past the experimental stage and are in use to a limited extent.



154. ARRANGEMENT OF THIRD AND FOURTH RAIL

The continuous current system is the series-parallel arrangement already described for tramways with such modifications as are required for dealing with the increased output of power and for the control of two or more motor-coaches from one platform. These will be described later.

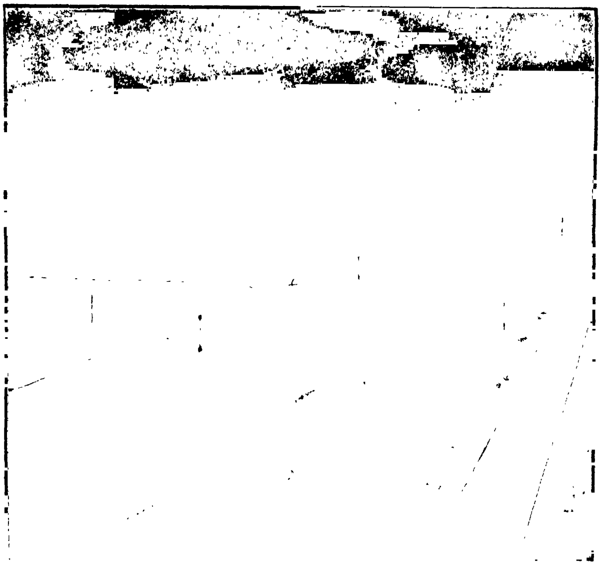
The Single-phase System. It is not practical to transmit for more than a few miles large quantities of electric energy at ordinary voltages, and although it would be practical to *transmit* it, it would appear that commutation and other difficulties in the *generation* of high voltage continuous current have yet to be surmounted.

For transmission purposes, we therefore rely on high voltage alternating currents which have to be converted [see under Systems of Supply] into continuous current at low voltages for use on the railway track. In order to do away with this transformation, engineers have attempted to construct a single-phase motor [page 1595], the principle of whose action is the same as the continuous current series excited motor, but which can take alternating current straight from a high voltage transmission line. The motor is shown diagrammatically in 152, and the connections are just the same as an ordinary tramway motor. [Compare 72, page 1324.] Improvements are, however, effected by the use of the arrangement shown in 153, in which (*a*) the current as it goes to the armature A is transformed up to a lower voltage, at T, and (*b*) an extra winding C, called a compensating winding, is introduced on the magnet system and is so placed that it does not necessarily produce any extra magnetism, but rather opposes the distorting action of the armature current. Both these improvements lead to better commutation. [See mention of auxiliary poles on page 1324, and consult 89, page 1591.]

Action of the Single-phase Railway Motor. The reason why the same motor will act in the same way when supplied with both alternating and continuous current is easily seen from the rule of the right hand explained on page 1104, where, in 43, we have the direction of the magnetic field given as towards the left. The voltage is applied and, therefore, the current flows towards us and we

155. THREE-PHASE LOCOMOTIVE AND TRAIN

see that the resulting motion is upwards. This represents the state of things for continuous current or for one half, say the positive part, of the alternating current wave [83 and 84, page 1362]. Now consider the case of the second half—*i.e.*, the negative part of the alternating current wave. The direction of the voltage and therefore of the flow of the current has altered and the magnetism in consequence has also altered in direction. Now place the right hand so that the first finger points to the right and the second finger points away from one, and you will see that the thumb, indicating the direction of motion, *still points upwards*, thus showing that in whichever direction the current flows through the machine, the direction of motion is the same, whether the current at the moment is flowing forward or backward. For further study, readers should apply the reason to the actual case of a field-magnet and a current-carrying conductor shown in 87. It may be asked, if the direction of rotation is independent of the direction of application of the voltage, how then is the direction of rotation altered? This is done, as explained on page 1591, by reversing the connections of either the field magnets or the armature, and this process also should be thought out by the reader by the use of the right hand rule.



156. HIGH-VOLTAGE OVERHEAD RAILWAY LINE

It is obvious that as the construction and manner of working is the same, the characteristics, so suitable for suburban traction purposes of the continuous current are also obtained in the alternating current series motor, and the remarks on page 1931 regarding the former apply to the latter.

Three-phase Traction. For long-distance traffic, the three-phase motor has been applied in Italy and other places. When once under way the speed of the train varies only within a few points per cent. whether the train is on an incline or a decline, and in this way a high scheduled speed is maintained all along the route. The maximum speed depends of course upon the frequency of supply and the number of poles on the motor, and these have to be considered when the line is planned out. An advantage with the three-phase motor is that when running downhill it may be made to act as a generator; but whereas in the series motor the electrical energy so produced must be absorbed in resistances, in this case it can be returned to the line, and so help in driving another train up the hill.

A disadvantage of the system is that three conductors are required; these are usually arranged as shown in **155**, two as overhead wires, from which current is collected by means of bows, and the third the running rails, or else an insulated rail.

In places, such as at level crossings, where the insulated rails have to be discontinued, the two overhead lines can temporarily run the three-phase induction motors as single-phase induction motors, but the performance of the motors under these conditions is not satisfactory for any length of time.

The Collection of Current. In low voltage continuous current working, where currents at 600 volts are used at starting, the live conductor takes the form of a steel rail, which is laid on a level of the track, the current being collected by shoes or skates, as shown in **149**, **150**, and **151**. Previously only one extra rail was used, and the track rails carried the return current, but now a fourth rail is laid down the centre of the track, as in **154**, and in some systems is, like the third rail, insulated from earth. This figure shows the actual arrangement adopted on the London Metropolitan Railways, and is, but for the question of the insulation of the return, the arrangement mutually agreed upon by the railways of Great Britain.

The method of suspending the wire on railways which have adopted one of the high voltage alternating current systems is shown in **156**. The copper wire which from a current carrying point of view may be smaller than that used on tramways, is not directly supported from the poles by ears, etc., as shown on page 1936, but is suspended from a galvanised steel wire, which in its turn is supported from the posts. The advantages of this arrangement are as follows: (1) The copper trolley wire may be suspended without any sagging, by making the short suspending wires between it and the upper steel wire of different lengths; (2) the poles may be erected further apart, because the strain of each span now comes upon a steel wire instead of upon a copper wire; and (3) the use of the two wires gives a smaller resistance to current passing from the feeding point to the train, and so the feeding points may be fewer.

Multiple Unit Control. The principle of and the necessity for multiple unit control has already been stated. The control apparatus consists essentially of a small controller on the driver's platform by means of which small currents are sent to each motor-coach to actuate the larger gear installed there for the distribution of the heavy currents taken by the motors themselves. The master controller can be supplied with current from the line; but the Westinghouse Co. in their system supply a set of accumulators for only 14 volts to work the master controller circuit, it being claimed that otherwise no current is available to connect the motor switches into the braking position. As to the manner of operation of the large motor switches, this is done either by solenoids working through master controllers or by air pressure, the valves of the air pistons being worked by current from the master controller.

A further improvement has recently been introduced, and in this the rate of cutting out resistance [see page 1933] is beyond the control of the motorman. The master controller contains only one series and only one parallel notch, and having moved on to one of the notches, the closing of a switch for removing resistance is performed automatically by the motor controller as soon as the current falls to a certain prearranged value. In this way a uniform acceleration is obtained, and no waste of current takes place.

Continued from page 1992

CUTLERY AND TOOL DEALERS

The selling of cutlery and tools is a department of retail trading which is usually associated with the business of a general ironmonger. But in these days several branches of the complex trade of the ironmonger are becoming, more than formerly, specialised and dissociated from the parent tree upon which they have been wont to grow. No pruning from the ironmongery business is more likely to take independent root and become a healthy shrub than that of selling tools and cutlery. No apology is needed for considering tools and cutlery together. In the nature of the merchandise, the sources of supply, the terms of trading, and the manner of keeping stock, they are closely allied. The selling of cutlery alone would scarcely prove remunerative, although the selling of tools only might well be so ; but the man who sets up business as a tool merchant would be foolish if he did not consider that cutlery also came within his proper sphere.

Personal Qualities. The retailer of tools and cutlery must have an intimate knowledge of the wares he offers. No class of customers is more difficult to please than that of artisans who have occasion to purchase the implements of their handicrafts. Details which seem to the unsophisticated spectator unimportant to the point of triviality are, to the workman, vital to good work and essential to his acceptance. This consideration is the main reason for the possibility of successful trading by the small man of the proper type in face of all the competition which capital and organisation can pit against him. The dealer who will listen to all the objections of the exacting purchaser, who will appreciate his point of view if he cannot accept all his criticisms as reasonable, and who can exhibit a practical acquaintance with the use of tools, is always preferred by the artisan tool buyer to the ironmonger's assistant whose knowledge of tools is not deeper than that gained by unpacking and pricing them. Thus, the smart workman, with business capacity, who ventures into the field of shopkeeping as a dealer in workman's tools need seldom fear the issue provided he select a district where workmen frequent the shopping thoroughfares, and if there are not too many of his own kind already exploiting the same trade.

Locality. The provincial village is not the place where such a venture may be attempted. Men do not eat tools, and there must be a large population upon which to draw for support. It is also obvious that an industrial and not an agricultural centre offers scope for tool selling. The choice of a shop need cause the prospective tool-seller less concern than other retailers who are in quest of business premises. The tool shop need not be pretentious, nor need it be in the fashionable thoroughfares where shops, even little larger in size than decent matchboxes, command ransom rents. Fortunes have been made, and will continue to be made, in modest quarters with low ceilings. Workmen, indeed, usually avoid the large, pretentious business palaces in favour of the small tool shop, whose proprietor wears the black apron himself, and discusses the merits of the latest combination plane with the carpenter customer. The place must be dry—dry as a bone. That is imperative ; otherwise rust will play havoc with the finest stock of tools Sheffield can produce, entailing a world of attention to maintain it in saleable condition.

Stock. Tools are expensive stock. Much value may be put into very little space ; but the dealer may buy most of it in quarter-dozen lots of an article, or even one-third of this quantity, and by displaying nearly all he holds, disguise the poverty of it. A little skill in the selection and arrangement of his shop fittings will enable him to do this successfully.

The tool merchant cannot set up his sign and make a good show unless he spends from £300 to £400 in stock. Even then he must buy small and often. One thing favours him. His trade will be entirely cash, unless he be very unwise, so that he need not have capital sunk in book debts. He thus suffers little loss through bad debts.

Many circumstances must guide him in the selection of his stock. He must judge what proportion of his trade is likely to be with amateurs or ordinary householders, and what proportion he may expect from workmen. Better goods can nearly always be sold to artisans. That is not to say that the profits are larger, but that the man whose business it is to handle a tool every working hour of the day demands quality before anything else, and knows that he must pay for quality. The amateur, on the other hand, unless he be the exception, considers a German saw at 3s. 6d. as good for his purpose as a good Hallamshire tool at double the price. And the German article may even carry the larger specific margin of profit.

Thus, there are two distinct classes of tools that must be kept—good tools for judges of good tools, and cheap tools for the buyers of cheap tools.

Carpenters' tools will form the most important part of the stock of almost any tool merchant. The carpenter must purchase his own tools, but ironworkers, except in exceptional cases, have their tools provided by their employers. Thus the bulk of the trade in ironworking tools does not reach the user through the hands of the small merchant, but goes direct from the large city factor, or from the manufacturer himself.

Where to Buy. In most cases it is wise to seek direct relations with the Sheffield manufacturer. He may factor half the goods which he catalogues, but as good terms may be had from him as from the actual maker, who very often does not deal with the retailer at all. A fair proportion of the tools sold, even by Sheffield manufacturers, are foreign tools. It may be accepted as a generalism that American tools are nearly always good, and compare with the best English makes, sometimes showing decided superiority, but that German tools, except for the articles embraced in the class known as Lancashire tools, are suited only for the second-class trader. In tools, the name "American" is usually a recommendation, while an acknowledgment that the article is "made in Germany" is enough to make the wise man select something with a different parentage.

The proportion of German tools stocked will depend, therefore, upon the volume of second quality tools that are to be sold. The dealer had better place his initial order, even for German tools, with a Sheffield or Birmingham house, although, a little later, he will find it economical to open relations with the German manufacturer through his English representative, whose headquarters are usually in London. German goods of this class offer the factor the opportunity of rather large profits, and, naturally, the retail merchant wishes to avoid the employment of unnecessary intermediaries who enhance the price of the goods. He will, however, find it impossible to import direct from America. The British representation of American manufacturers is usually in the hands of one or other of the large British factoring houses, behind whose back the retailer can seldom get.

The Value of a Name. Brand counts for much in the tool trade, and local taste decides what brand is in favour in each particular district. In one district, for instance, it may be essential to the acceptance of a saw by the local carpenters that it bear the name of Sorby, while in other parts of the country the name of Sorby may count for naught, and the legend "Spear and Jackson" or "Disston" be insisted on. This local preference prevails through almost every department of the edge-tool trade, and the beginner must make himself familiar with local preferences if he would avoid the purchase of slow or unsaleable stock.

Profits. There is no uniformity of discount in the tool trade. Trade discounts from net prices may run from 15 to 80 per cent. At the lower rate of discount the particular article would be sold at more than list price, and in the latter case at something less than half list price. The usual discount from, say, flat bastard files is 60 to 65 per cent. off Sheffield list, and a common selling price is from 40 to 50 per cent. from the same list. The dealer, of course, will refrain from initiating the public into the practice of calculating prices by discount in this manner.

The Sheffield terms are usually 2½ per cent. cash discount at one month or journey account, although some firms allow 5 per cent. The larger discount should always be taken advantage of, when prompt payments will secure it.

Shop Fittings. Care in stock-keeping must be observed if the stock is to be maintained in good saleable condition, and the shop fittings should be designed with this object in view. Rust is the great enemy of the tool and cutlery merchant, and prevention of rust is better than its cure. Indeed, cure is impossible. Rust, once allowed to take hold of a stock of tools, cannot be expelled. In every case rust impairs the selling value, although not always the utility. A hammer or a plasterer's trowel is just as serviceable even if it be rusty, but edge tools become seriously injured by rust. All tools should be carefully kept from humidity. Even the papers in which they are wrapped should be greased or at least pepper dry.

Many trades are best prosecuted by making a limited window display. A few specimens may do better service than many. The trade in tools is not one of these. The window should be filled with exposed goods, but the window enclosure should always be air-tight. This precaution not only preserves the stock better, but it diminishes the frequency of window dressing—an important consideration when many small articles have to be handled.

In the matter of shop fittings, we in this country are far behind the tool retailers in the United States, where they have been improved to make the merchandise visible to the customer, ready to hand, and excellent in arrangement. A few of the best examples of American shop-fittings are described and illustrated in the article on Ironmongers in this course.

The principle of some of these fittings can be applied to every class of hand tools the merchant has to carry. A few tool shops in Great Britain have been fitted with such fixtures, but the number is much smaller than it ought to be.

Cutlery. The cutlery department is relatively more profitable than that of tools. It will form the smaller proportion of the stock value, and will not demand so much room for warehousing and display. Proportionally, cheap cutlery pays better than the better qualities.

In some classes of cutlery the stock will be almost exclusively of English manufacture. Table cutlery will be entirely of Sheffield production. American plated table cutlery has made feeble attempts to find a lodgment on the English market, but its qualities have met the cool reception they deserve. Pocket-knives, except the cheap qualities, will also be English, but the lower grades—especially carded goods if they be stocked—will be German. English scissors are unexcelled for quality, but American scissor makers supply shaped handle scissors at prices which Sheffield cannot touch at equal price, and they will therefore be patronised for such goods. German scissors may be purchased of fair quality and sold at good long profits.

Razors need not be foreign, although the best German razors are quite equal in value and quality to the best Sheffield instruments. America makes some good shaving implements in the form of safety razors which should be sold and pushed.

Cutlery Brands. Reputation counts for much in cutlery, and the public demand goods bearing the names of makers of repute. The merchant must therefore find what marks are held in the highest esteem, and purchase accordingly. As public opinion varies in different districts, experience in one part of the country is no guide to the requirements of another part. One district, for instance, may demand the name of Rodgers, and another that of Butler.

But the retailer will strive to evade unnecessary selling of well-known brands, and try to build up a reputation of his own. There are many makers of sterling qualities who are prepared to stamp the goods with the shopkeeper's own name and mark, and every blade so marked is an advertisement for the merchant as long as it remains in use. The latter will, however, be foolish if he have any but thoroughly reliable goods stamped thus.

Sets of Cutlery. Recently there has sprung up a trade in cutlery sets. Such sets have always been sold in cabinets, but lately assortments of table cutlery have been offered in cheaper qualities than formerly. The origin of the trade is to be found in the practice of some of the large instalment-payment houses working through householder agents, and those houses have done a fair trade in such goods. But the small merchant should be careful how he stocks these sets. Except for marriage and other presents the demand for them is strictly limited. The lady who requires a few knives and forks seldom has occasion for the other items in the outfit, and even if she has, she usually finds the arbitrary assortment offered not to her liking.

Selling. As the purchasers to whom the tool seller appeals are chiefly of the artisan class, who have to do their buying during the evenings, he cannot afford to put up his shutters in the early evening as many kindred tradesmen can. His hours must, perforce, be longer.

Marking prices of displayed stock in plain figures is desirable. An annual sale is usually a good "draw." It attracts the public, it clears off deteriorating stock—seldom at less than cost prices—and cheap stock may often be bought specially for such a sale. We have seen the corner of a window piled high with many grosses of cheap knives and forks cleared off in a few evenings at good profits.

Profits. The retailer of tools and cutlery may look for an average profit of 33⅓ per cent. on selling prices. Some tools which are sold at lower margin may easily be balanced by other articles with which the public are less familiar, and the average may thereby be maintained. Working expenses should come to between 10 and 15 per cent. of the turnover, and the difference between this proportion and the gross profit shows a satisfactory net result. The stock value of an established business ought to be turned over twice a year, but the beginner, by purchasing often and in small quantities, ought to reach a turnover equal in a year to three times the value of his stock.

CYCLE DEALERS

The history of the cycle trade is a history of vicissitudes, and a few brief sentences regarding the swift changes which have altered its conditions will assist in promoting an understanding of the present problems which confront anyone who would enter its ranks.

The invention of the pedal-driven bicycle created the trade which, during the 'seventies, struggled along by the sufferance of daring spirits willing to risk neck and limb upon a lofty, insecure perch. Cycling was a sport, and cycle retailers were recruited almost exclusively from the sporting class. The introduction of the chain-driven "safety" in the 'eighties widened the trade, as did again the pneumatic tyre some years later, but did not alter the class of men who were the distributing agents.

Skill and strength above the average in causing a pair of bicycle cranks to revolve may be an admirable quality, but it is not necessarily accompanied by business acumen. Thus the men who were engaged in the cycle trade were often void of commercial instinct, lacked commercial experience whatever. They had far better have remained at the vice, pick, or pen, which they had learned how to handle with more or less satisfaction and profit. Most of them were carried off their feet by the few fat seasons when Society decided that to cycle was to be fashionable. The depression caused by Society's change of mind, and by over-production, with the consequent diminution of profits, drew very many of the cycle dealers into the slough of bankruptcy, and many more perilously near it. The weeding out by the operation of relentless economic laws has helped to establish the cycle retailing trade upon a firmer basis than formerly. It has emerged from its years of trial in somewhat chastened mood. The spirit of speculation has been succeeded by expenditure of effort in the circumscribed paths of business routine, and while the cycle agent of to-day may not be able to make money as quickly as he could a decade ago, the road which he travels is much safer.

The Man. The first quality of the cycle dealer must be the mechanical instinct. Not every mechanic or engineer has this mechanical instinct, and many men in other walks of life than those mechanical possess it in a pronounced degree. We have seen a cycle repairer who had carefully overhauled an expensive bicycle, and who had passed it to his customer, claiming that it was thoroughly repaired and in perfect adjustment. The customer spun both wheels, glanced along the frame from the rear, put his hand on one of the pedals for two seconds, taking in several details the while with his eye—the whole inspection having occupied less than a minute. Then he said: "The front wheel is not quite true, the adjustment of the back wheel is too loose, the frame is slightly twisted to the right, the chain is too tight, and you have put the pad shoes of the rim brake reversed from the proper position, so that they will be pulled out the first time the brake is applied."

In this case the mechanic was sadly deficient in the mechanical instinct, while the customer, who was a member of one of the learned professions, had it in conspicuous measure. This mechanical instinct may be acquired, but hardly. It seems to be largely intuitive. The reason for the need for this faculty is apparent. He who lacks it may endanger the safety, if not the lives, of his customers.

Stock. The cheapening of the cycle has made it possible to put in a good stock at about half the price which a similar stock would have cost a few years ago. Also, the practical standardisation of pattern makes it less risky to carry stock over to another season. The diamond frame seems to have marked finality in general cycle design, and it is a fairly safe prophecy that it will never be departed from. Innovations, such as diagonal frames, serve to furnish copy for the advertisements of the firms who design them, and give the scribes of the cycle press something to write about ; but the purchasing public stick to the diamond frame with a persistency that registers good judgment.

Inventive ingenuity exercised in cycle construction now finds scope in multiple gears. A few seasons ago it was free wheels and rim brakes, and the last word of importance seemed to have been said of tyres when the patent application of the endless wire cover was filed.

The selection of stock is not difficult. The standard patterns of any good maker may be accepted with the confidence that they embody the most saleable points, and any deviation from standard pattern usually impairs the all-round chances of disposal.

Prices and Profits. The agency system is all but universal in the cycle trade. Makers grant the exclusive district agency to one retailer, confining their sales in that district to their official agent. This entails mutual obligations. It becomes the duty of the agent to support the maker as well as that of the maker to support the agent. Many agents hold more agencies than they can handle properly, thereby failing to do justice to any one of them.

The agent must remember that cheap cycles are the best sellers, and ought to be cautious in the purchase of expensive machines. The public have come to appreciate the fact that thoroughly reliable cycles at low prices are obtainable, and have generally ceased to credit the claims of the difference in price necessarily standing for difference in quality.

The Cheap Cycle. There has, however, been a retreat from the excessively cheap cycles which manufacturers, under the lead of one large firm, put on the market two seasons ago (at the end of 1904), and between £7 and £8 is now the cheapest model to which makers in the front rank affix their transfers. A machine at this price usually yields to the agent a profit of £2, which represents 33⅓ per cent. on cost price. This may be taken as the rate of profit all over. Many makers now restrict the price at which their cycles may be sold, and this measure has rather cut the stings of the "catalogue agents" throughout the country—men with no stocks, who sold bicycles from catalogues, and who were usually content with a profit of only a few shillings on a machine. To attempt to compete against such men is ruinous for the agent with a business establishment to maintain.

There is no uniformity in cash discounts given by cycle manufacturers. Nearly all are glad to give good terms for prompt payment—most 5 per cent., some only 3¾ per cent. The common monthly terms are 2½ per cent. discount.

In the early days of the cycle trade makers were wont to send cycles to agents upon sale or return conditions. The cycle boom stopped this practice while it lasted, but it has been creeping in again lately. Not many makers do it, and almost none of the first rank. Naturally, the terms under such a condition are not so favourable as when the goods are bought outright. The whole system is bad, and ought to be discouraged.

Motor Cycles. Motor cycles are worth selling. The profits are seldom less than £10 a machine, and £15 upon the better ones. The agent who sells a few motor bicycles in a season has done good business. The makers ask for payment of one-third of the price of a motor cycle with the order and the entire balance upon receipt of invoice, and such terms are supposed to be the rule. But the rule is honoured more in the breach than in the observance—at least in dealing with agents of substance—and there is no good reason why a man of standing should be required to purchase under such one-sided conditions.

In purchasing stock care must be taken not to buy too many ladies' cycles, as their sale has gone down considerably. Tandems and tricycles should not be stocked at all, but sold from catalogues upon occasion.

Capital. In a provincial town it is possible to start as a cycle agent with a capital of £200. It is common, but unwise to do so on less. The £200 will not go far, and the larger the excess above this figure the more probable will success be.

The instalment system of trading is a common feature of the cycle trade. It is risky, and it locks up much capital. But if care be taken to refuse instalment terms to all but those whose record turns out upon inquiry to be above reproach, there is no reason why the trade should not be prosecuted. The prices of machines sold upon instalment or hire-purchase should be not less than 20 per cent. higher than cash prices, and payments should be fixed so that the last instalment shall have been made not later than twelve months after delivery of the machine. As large a first instalment as possible should be secured.

Those whose capital will not permit them to embark on instalment business will find that many of the manufacturers are willing to shoulder the burden of responsibility and to pay the agent the cash profit immediately upon delivery of the machine. Some independent financial firms even do this for the retailer, paying the agent the cash price at once and pocketing the excess as profit. It pays the agent to do the business himself when he can, always selecting his customers.

Accessories. The best paying part of the cycle merchant's business is the selling of accessories. All are not equally profitable, but with a little trouble the dealer can encourage the more profitable of them and discourage the others. Articles widely advertised at cut prices should, of course, be sold as little as possible. The agent is also well advised if he stock accessories of a different make to those sold by his neighbours. Some things, such as a few of the Lucas specialities, he must keep, but he may have the bulk of his accessory stock different from that sold by his competitors, and by this device he may secure much longer prices. The public can seldom judge quality, but they can compare the prices charged by different tradesmen for identical articles.

The stock of accessories will include lamps, bells, wrenches, toe-clips, pedals, brakes, brake fittings, handle grips, inner tubes, a few tyres of standard size, carbide of calcium for gas lamps, inflators and connections, saddles and tool bags, oil cans, oils for burning and lubricating, and repair outfits. There is little outside of this list. The days of fads in accessories have gone with the passing of the society cyclist, and the cycle agent can afford to ignore anything except " bread and cheese " lines.

Profits on Accessories. The profits on cycle accessories are usually about 50 per cent. on cost price, and on special articles double this rate is often possible if the practice recommended above be followed. On certain well-known articles the makers insist that certain minimum prices must be maintained. This practice prevails in the Lucas "cyclealities," for instance, but price maintenance is not so common as it ought to be, so that the large cutting houses do serious injury to the small dealer. The duty of the latter to support firms who seek to preserve the retailer's profit is plain.

Hiring Cycles. The hiring of cycles is a department of the business which has had its day. Many hundreds, perhaps thousands of cycle agents have surrendered this branch after long and costly experience. There is smaller occasion than formerly for cylists to hire cycles. When a good bicycle can be purchased for, say, £6 to £8, the man who would pay the cycle agent's charge for hire, unless in exceptional circumstances, is more than foolish. Hirers of cycles are usually the most careless of the cycling public, and it is often impossible to secure payment for damage to machines hired. The cycle agent has no use for hirers by the hour. They give more trouble than profit. The only kind of hiring which may be done with expectation of reasonable return is that for the season, or for at least a month, the charge for which is usually about £2. If the machine be well cared for by the hirer, and it be on hire for, say, four months during a season, its cost price has been almost or quite recovered, and, as it stands, it represents the profit of its own hire for the year. Above all, it does not pay to let on hire cycles of second-class quality. The best are always the cheapest for this purpose. It matters nothing if they are last year's models, or even those of the year before, but they must be of sterling quality.

Repairing. The cycle merchant who does not repair cycles neglects the most remunerative part of the business. Nothing helps the selling of cycles like the ability to repair them. Buyers like to purchase new mounts from the man who has kept their old machines in repair. If his repair work has been satisfactory, he is properly held to be a good judge of what a cycle ought to be, and his advice regarding the new machine is usually asked and frequently taken.

The Workshop. The equipment of the cycle agent's workshop is not expensive. The essential tools are a brazing forge and blowpipe, a wheel-truing frame, a vertical drilling machine, an erecting stand, a small hand spoke-screwing machine, some tools such as pliers, wrenches, files, soldering iron, dies and taps, an assortment of spokes, nuts, bolts, cones, pedal pins, and a few less important items. The sum of £20 will purchase the whole outfit, although, if another £10 note can be devoted to this department, so much the better. The brazing forge assumes that a gas service is available. If not, a brazing apparatus with oil fuel must be purchased. The drilling machine will be driven by hand or foot power, but as the business develops a small gas or oil engine, a turning lathe, and a buffing machine may be installed.

An enamelling stove is almost a necessity. Let the man build it himself. It is attended with no difficulty, and it can thus be installed at half the price it would cost to purchase and erect it. The enamelling stove should not be too small. The gas for a small stove costs almost as much as that for a large one, and the former will not permit of exceptional work, such, for instance, as the stove enamelling of a tandem frame.

Plating Plant. Only a very large cycle business can support an electro-plating plant, and the cycle agent is seldom wise to instal one. The cost of doing so is about £100. Good workers for plating are difficult to get, demand high wages, and many of them are notoriously unsteady. He who embarks upon this department will not have far to look for his troubles. Plating must be well done to secure acceptance, and it can be well done only when the baths are kept in regular and continual employment, and after long experience of the work.

Manufacturing Cycles. It was formerly the practice of cycle agents with workshop facilities to build cycles from cycle fittings purchased from the makers of such goods, during the winter months. The practice still prevails to some extent. Two reasons stood sponsor for its wisdom. It enabled the agent to pose as a maker, although he was a maker by courtesy rather than in fact; and many prominent cycle manufacturing businesses were begun in this manner. The public have a liking to treat direct with a *maker*, imagining that they save thereby an intermediary profit. The second reason was that it provided work for the workshop staff during the "off season," and enabled the employer to retain the services of good men season after season by giving them constant employment. Even if the cost of manufacturing cycles were as high as the price of similar machines purchased from Coventry or Birmingham, there was economic profit in "assembling" cycles, as manufacture by retailers has often been called. But specialisation of manufacture and the heavy falls in the prices of complete cycles during recent years have made it impossible that the small local man can prosecute this branch of his business with profit. He can now purchase cycles far more cheaply than he can make them, and the attendant advantages of manufacture are not great enough to outbalance the higher price. It has, therefore, come about that the agent can no longer manufacture with advantage, and he ought to seek other outlets for his efforts during the months when cyclists refrain from troubling him.

The Need for Side Lines. A few years ago, when the profits of merchanting cycles were large, and before every other shoemaker and greengrocer was a cycle agent, the summer trade in cycles served to support the deadweight of the quiet winter months. These halcyon days have passed never to return, and it is now recognised that selling cycles alone is not a promising road to fortune. Profits per machine are now only half what they were, or even less, and there are many more individuals offering their services to the cycle-buying public; hence, to dispose of the same number of cycles per season as formerly yields less than half the net profit. Retailers, whose main business has lain in cycle-selling, have tried many different branches to eke out an income. The best side lines are naturally those which are in demand during the late autumn and winter months, when cycles are not wanted. This makes the selling of incandescent and other gas fittings particularly suitable for exploitation by the cycle agent. A few years ago this fact was recognised by the directors of one of the principal gas-mantle making companies, one of whom had on his wheel carried off many of the laurels of the road and racing path, and the cycle trade were encouraged to stock and push incandescent gas fittings. Those who did so made good money as the result, and the experiment led them into other branches of business. It is not yet too late in the day for others to follow suit, as the demand for such things is permanent and large, and their sale is very profitable. Mantles can be sold well at 50 per cent. profit on cost price, and the cheapest varieties are not the least lucrative.

Electric Fittings. Electric fittings are other things which may well assist the cycle dealer's annual trading account. The selling of electric fittings leads to the fitting of electric bells, electric lights, and private telephones, and although it is generally supposed by the uninitiated that there is something mysteriously technical in electric work, it is not so. Textbooks upon the subject of electric fitting are numerous, and the wholesale houses who supply the accessories are always pleased to advise customers when difficulties are encountered. In both the selling and the working departments electric work is profitable. No doubt competition by many municipal authorities makes this department a little unpromising in many towns, and municipal trading is on the increase, but there are very few places where a venture into the field of electric work will not assist the business of a cycle dealer. [See Electric Dealers.]

Other Side Lines. Baby carriages, sewing machines, domestic laundry-machines, guns and ammunition, fishing tackle, toys, and general sporting goods are often sold by the cycle dealer. Particulars of stock, capital, and probable profits in each of these departments will be found in other articles in this course. Many of them are in the height of their season when the trade in cycles is at its busiest, so that the pressure is increased at an inopportune time, but this circumstance cannot be avoided; and as competition becomes more keen, and drives to adventure into other branches, the cycle merchant, if he be wise, will try to exploit that for which his district seems the best suited.

The Cycle Show. The Stanley Cycle Show still lives, although the great competing exhibition has died a natural death. The practical uniformity of design which cycles have now reached makes less necessary than formerly a visit to the Cycle Show, but it is instructive still, and a visit is essential for the cycle retailer who would keep abreast of the times in cycle construction and in the novelties which each season brings forth. The Stanley Cycle Show is held each year in November at the Agricultural Hall, Islington, London. It runs for eight days, from the Friday when it opens until the evening of Saturday on the following week. Provincial visitors can usually secure special cheap fares, arranged to cover a few days' visit.

YARN MANUFACTURE

Thinning the Sliver. The Drawing of Cotton, Wool, Flax, Hemp, and Jute. Details of Machines and the Processes in Manufacture

Continued from page 2009

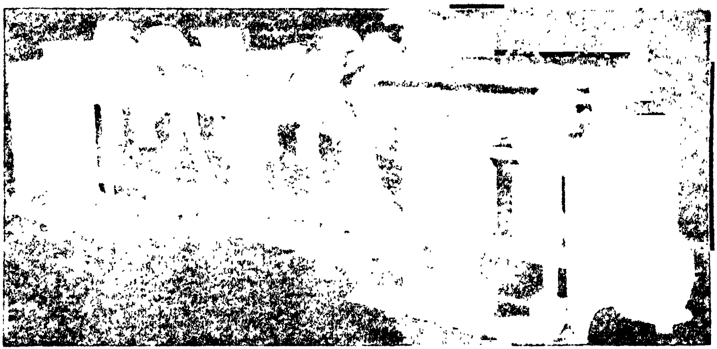
By W. S. MURPHY

BY the various methods and machines studied up to this point we are able to produce from any textile fibre the soft, thick rope technically named the sliver. Each trade has its special ways and means, but the object of all is the same. To cotton, woollen, worsted, waste silk, ramie, flax, hemp, and jute workers alike the sliver is the indispensable beginning of yarn. The only maker of fabrics exempt is the felt manufacturer; he does not need the sliver because he does not use threads. Neither does the sliver trouble the woollen cloth manufacturer very long, but for a different reason. Inquiry into this matter may yield us important knowledge.

Thinning the Threads. The woollen sliver has been taken direct from the carding engine, and formed on the condenser into a thick thread, which is finally to be spun on the mule. When it comes off the condenser, the woollen yarn has some of the defects of the sliver. It is rather loose and fluffy, and the fibres are all felted together. This will do fairly well for a thick thread, and is bound to make a very soft, woolly cloth such as the woollen manufacturer professes to make; but for a fine, light cloth, or hosiery yarn, it would never do at all. If thinning out, elongating, and compacting the sliver into a thread were our only object, then every textile worker would use a form of condenser, and discard half the spinning machinery at present in operation. But a very different thread is required for worsteds, carpets, hosiery, calico, zeyphers, muslins, lace, silk, yarns and cloths, linens, damasks, canvas, and even ropes. The general requirements are these: (1) Uniformity throughout the whole of the yarn being made; (2) a thread composed of fibres drawn out to the utmost length and laid parallel; (3) a given length of thread to a given weight. It may be truly said that such have been the aims of the carder, spreader, and comber; but it is one thing to have aims and another to accomplish them. On the carding engine the fibres may lie even and yet be doubled; to obtain continuity of sliver in spreader and combing machine the fibres have been overlapped; parallelism has not anywhere been fully assured. For these reasons the drawing frames are called into requisition. So important did Arkwright deem this operation that when defective yarns were brought to him by manufacturers seeking his advice, his first question always was: "Do you mind your drawings?"

Cotton Drawing Frames. The cotton drawing frame exhibits better than any other the fundamental principles of the operation, and it may therefore be studied first.

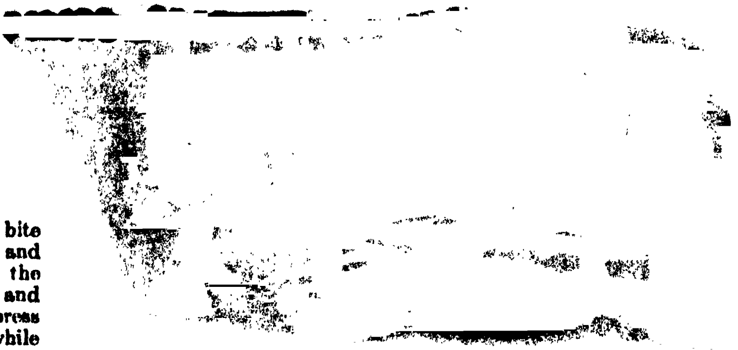
In the factory the frames stand ranked in rows, one scarcely divisible from the other; but these so complex and formidable looking machines are merely aggregations of one simple drawing apparatus. Taking one single section of the drawing frame, we find it consists of four pairs of rollers, several guide holes, guide plate, and driving gear. The bottom rollers of each pair are fluted sections of rollers extending the whole length of the frame, the spindles fixed in toothed wheels working on the drive. The top rollers are single, clad with leather or smooth felt, and set in holders from which depend weights to give them the necessary pressure. On the old drawing frames, wooden guards, lined on the under side with flannel, act as clearers to the top rollers; but in the newer frames, which we illustrate [26] the clearers are rollers revolving beside both top and bottom rollers. The guide plate has upon it curved grooves tapering to a point, for conducting the slivers to the rollers, and upon it works a wire apparatus, which acts upon the drive of the frame. As they pass, the slivers keep this wire in position, but when a sliver breaks or becomes entangled the wire falls and stops the machine.



76. COTTON DRAWING FRAME (Platt Bros. Ltd., Oldham)

Functions of Drawing Frames. The drawing frame is a product of the highest genius, and it is therefore simple and marvellously efficient; the slight mechanism performs several functions at one time. It is this complexity of function which makes the drawing frame rather difficult to understand. The machine combines several slivers into one, lengthens them, and draws the fibres composing them straight. As our habit is, let us watch the machine at work, and then discuss the performance.

Six sliver cans are set behind the section of the drawing frame we elect to study, and the ends are led through the guide holes on to the guide plate, where they are united and drawn in between the first pair of rollers. By the guide holes the slivers, which have a tendency to lump and cling in folds, are kept single. The edges of the flutes of the first under roller bite upon the soft ropes and draw them in under the weighted roller above, and between them they press the slivers into unity, while letting them out to the next pair of rollers in the form of a thick rope. Our second pair of rollers are running at a higher speed than the first, and draw out the sliver; the third pair has a higher velocity, and the fourth pair a higher speed still.



77. FLAX DRAWING FRAME (Combe, Barbour & Co., Belfast)

The Value of Speeds in the Process. The ratios of speed between the various rollers must now be observed. Say that the first pair of rollers are running at the rate of 60 ft. per minute, the second pair must not be run at a too high speed, or the sliver will be broken; but they must exercise a drawing force, and at the same time feed the next pair with the sliver. Let the speed of the second pair be 80 ft., the third pair 120 ft., and the fourth pair 240 ft. per minute. We have thus a gradation which brings the speed of the last rollers up to four times the speed of the first rollers. In practice the gradations vary; but our main point is that there is gradation, and that the speed of the last rollers is generally from two to six times quicker than the speed of the first. The effect in the former case is to produce a sliver one-third heavier than any one of the original slivers, but firmer in consistency, and with the component fibres straighter.

Adjustment of Rollers to Suit the Cotton. Not only have we to consider the ratios of speed, but we must also observe the spaces between the rollers. This is determined by the length of the fibres. A cotton averaging 2 in. length of staple would be nipped and broken if the rollers only sat three-fourths of an inch apart; on the other hand, a short-stapled cotton sliver would be parted and rendered irregular if the rollers were placed too far apart. The grip of the fluted rollers is no make-believe, no mere passing-on movement, but a firm hold meant to give a pull. Were it otherwise, the chief purpose of the drawing frame—viz., the straightening out of the fibres—would not be fulfilled. But the ends of the fibre at no time lie evenly together; the one fibre overlaps the other, even after we have done our utmost to bring them parallel. This is comparatively true; therefore the spaces between the rollers should be rather longer than the average length of the staple than shorter.

A good many other points might be profitably discussed. For example, hard, wiry cotton should be subjected to harder drawing than soft, flexible fibres. But our course of study is too general to permit the consideration of such details.

Our drawn sliver is next combined with other five or seven similarly drawn, and put through another drawing; this is again repeated. By this doubling and redoubling the slivers are brought thoroughly to uniformity. In spinning very fine counts, we have as many as six drawings, in the following ratios:

$$\frac{8}{1} \qquad \frac{4}{1} \qquad \frac{7}{1} \qquad \frac{6}{1} \qquad \frac{6}{1}$$

Multiply together the numerators, which indicate the number of slivers united at each drawing, and you have a total of 48,384 doublings. This is surely enough to delete all difference, and yet, as we shall see, it is not the last doubling.

Wool Drawing. If, in the multitude of counsellors there is wisdom, it is also certain that in diversity of advice and practice the learner is confused. Nowhere does the need for scientific classification and system appear more prominently than here. Attenuation of the sliver appears a definite enough operation, and yet it is not accurately defined in textile practice. What the cotton worker calls *slubbing*, the worsted man calls *drawing*; the jute and linen manufacturers give the term *roving* to the operation, which is only a part of drawing to the worsted worker and slubbing to the cotton spinner.

If this were all, some excuse might be offered. Different industries develop on different lines, and each one has a right to its own system. But the worsted industry has no uniformity within itself. Some run the slivers through one drawing frame, and at the second wind the drawings on to bobbins; others use bobbins at the fourth drawing. In a process so continuous and regularly graded as yarn manufacture, it is necessary to mark clearly and distinctly the points of departure, the moment when the method of working changes, or when a new instrument comes into play. We hold strongly that the moment a bobbin, with its gearing of flyers, comes into play drawing, pure and simple, has ceased and spinning has commenced. To bring in at the end of drawing, as a kind of after thought, an important principle like that of the bobbin and flyer is to invite carelessness towards a vital process.

Details of the Process. Whatever system of nomenclature or working may be adopted, the first drawing after the sliver has been taken from the combing machine is done on the gill box, which is nothing more than a finer model of the one we studied in the process preparatory to the combing machine. That there may be no mistake, we shall recapitulate briefly the working of the machine. As many slivers as it has been resolved to combine are brought to the fore end of the frame. Here we encounter a variation in practice of small importance, but to be noted. Some manufacturers feed the drawing gills straight from the cans, but others form the slivers into balls; alternatively, the sliver is balled on the combing machine, a practice coming more and more into favour. Instead of the moving lattice, our feeding apparatus is a set of pulleys, which combine the slivers and send them directly into the first of two pairs of fluted rollers which act as feed rollers. When the sliver issues from the feed rollers, it is seized by the faller combs and carried on to the drawing rollers, which are smooth but otherwise similar to the rollers on the cotton drawing frame, the upper roller being borne down on the lower by weights or springs. Thence the slivers are coiled into cans again.

The drawing is effected in the following way. The gills, or faller combs, drawing more quickly than the feed rollers supply, pull out the sliver; the drawing rollers revolving four, five, or six times more quickly than the front rollers, attenuate the sliver still further. By the combing of the gills and the drawing of the rollers the fibres are straightened, drawn, and laid parallel; by the doubling the slivers are solidified; by repeated doublings we obtain uniformity of thread.

Flax and Hemp Drawing. The drawing frame of the linen manufacturer differs in no essential particular from that of the worsted worker; but he has his own way of using it. When the slivers came off the spreader we saw that they were weighed and the weight marked on the cans, and now the use of that practice becomes evident. Before we have done drawing, we ought to possess as many thick threads as we require, all of one weight and length. By the bell at the end of the spreader we have made sure that the lengths of the slivers are equal; but the weights are still rather irregular.

In the flax drawing frame we require to consider the combs collectively; it is not enough to watch one range of combs. Take the first or "set" frame, as it is named. On this frame [77] we have, say, six combs on each bar, which will form six drawn slivers. As we start by doubling the slivers derived from the spread-board, a set will be twelve cans. The aggregate weight of the slivers of these cans must be the

78. DRAWING FRAMES PREPARING HEMP FOR

weight of the combined slivers. If one sliver is 7 yd. per lb. and another is 9 yd. per lb., the two combined will give 8 yd. per lb., if undrawn. But our drawing lengthens the sliver four times, and the result is a sliver 32 yd. per lb. In actual practice the calculations are more complex, but the principle is the same. On the second drawing frame the slivers from each set are again doubled, according to the principle of combining different to obtain equal weights. The same rule is followed on the third, and, when necessary, the fourth, drawing frames, so that at the end we have a range of slivers, or slubbings, all of equal weight to length, and straightened in constituent fibres.

Variations in Practice. Some variations in practice and common mistakes in working may here be noted. For very fine linen yarns the slivers from the set frame are kept apart, and doubled on the next frame; but hemp fibres and flax for heavier yarns have the slivers doubled again at the back of the machine, or, it may be, the whole set may be combined into one and coiled into one can. We have not yet been able to adopt the automatic stop motion of the cotton drawing frame, for a variety of reasons too minute to be detailed at present. In consequence, the failure of one of a pair of slivers is no uncommon occurrence. *Singling*, as the fault is called, may occur in spite of close attention. Perhaps a part of one of the slivers is too thick to pass with its neighbour under the pressure roller, and sticks, while the other passes on. The feeding looks all right, for the ends of the pair are in the machine, though only one is going forward. If the other gets started again before the attendant's suspicions are aroused, the singling will pass undetected till a few stages further on. When an accident may happen without fault on the part of anyone, it must be evident that many occur through preventible causes. Fig. 78 illustrates a corner of the drawing department in a hemp mill.

The Jute Sliver. The drawing of the jute sliver might be studied fully on the flax-drawing frames. But there are some differences which must not be passed over. The first drawing frame of the jute sliver is much larger than that used for flax; the rollers are heavier, and the gills are stronger. We can hardly say that this is because jute is a harsher fibre, but rather think it is because of the longer fibres, which require more room and a greater leverage.

Jute frames are run in sets of two, three, or four carriages. The best work is got from the double frames — that is, frames of two carriages. Four combs on each bar of the two carriages, and a double sliver to each comb, makes a set of 16 cans to the frame. If each single sliver weighs 10 yd. to 1 lb., the double sliver will give 5 yd. to the lb. Given that the draft of the drawing is 6 to 1, the sliver delivered should weigh 30 yd. to 1 lb. But it is considered good practice, with a view to reducing the inequalities of the slivers, to lead them in pairs over the guide plate into the delivery rollers, and so produce a sliver 15 yd. to the lb. These slivers are taken to the second drawing frame, there to be doubled and passed through finer combs, in preparation for the next process.

Various Slivers. The slivers of waste silk, ramie, and other fibres, scarcely require special study in this stage. Most commonly the longer fibres are drawn on the gill frames, and the shorter fibres are treated like cotton. No new principle or method is involved, though it would be rash to say that no adjustment of the machines is required. But the latter is a practical problem, which can be dealt with only in regard to a particular sliver or set of slivers. The machines best suited for dealing with waste silk and ramie will be more easily understood in the next stage of our study.

A STUDY OF SOUND

Nature of Sound. The Echo. Sound Waves. Noise. Pitch. Harmony. The Scale. Resonance and Vibration. The Human Voice

By Dr. C. W. SALEEBY

FOR convenience we shall use the word *sound* to indicate the external fact which gives rise in us to the sensations of sound; but meanwhile we must recognise that if there were no ears to hear there would be nothing such as we understand by sound. Apart from the hearing subject, all nature is silent; just as, apart from the seeing subject, all nature is in darkness. One kind of wave-motion, falling upon one kind of nervous structure, produces light; another kind of wave-motion, falling upon another kind of nervous structure, produces sound.

Our first assertion, then, is that sound is a wave-motion. In familiar instances, as in the case of a bell, we are aware that the body which emits the sound is itself, as we observe when we touch it, in a state of vibration. And we can easily convince ourselves by experiment that the essential consequence of such vibrations is to produce disturbances in the medium surrounding the vibrating body. Commonly, that medium is air, but it may be any other substance that possesses elasticity. The essential part played by the air in ordinary cases of the transmission of sound may readily be shown by sounding a bell within an air pump, and then gradually reducing the quantity of air surrounding the bell. When a certain rarity of the air is reached, the sound of the bell ceases, since there no longer remains sufficient air surrounding it to transmit its vibrations.

The Speed of Sound. Every kind of wave requires a certain amount of time for its transmission. This is true of the waves in the ether, which constitute radiant heat and light and electricity. These all travel at one and the same unchangeable speed. As everyone is aware who has watched cricket or firing from any distance, the speed of these ethereal waves is far greater than that of sound. One sees the bat hit the ball, or the puff of smoke appearing, appreciably before one hears the corresponding sound. The speed of sound can readily be calculated, and, unlike the speed of ethereal vibrations, is found to vary according to the state and properties of the medium which transmits it. The speed does not vary markedly, however, with the pitch of the sound, which we shall shortly study, nor yet with its loudness—facts which are fortunate for the musician.

All sounds travel through air at a speed of rather more than 1,100 ft. per second, the speed increasing somewhat with the temperature of the air. The reason of this is found in the fact that such a rise of temperature increases the elasticity of the air, and it is upon this factor that the speed of sound in any medium depends. The speed of sound in other media than gases has also been studied, as also the relative ease with which such media transmit it. We know that the earth will transmit sound more efficiently than the air above it; this every boy knows who has read of the exploits of the Red Indians and the ease with which they acquaint themselves with the approach of their enemies by putting their ears to the ground. In general, sound passes much more rapidly through solids than through liquids, and through liquids than through gases, including, of course, the air. Thus, sound travels through iron about seventeen times as fast as through air.

The Intensity of Sound. The intensity of sound varies according to a law with which we must now be familiar, since it holds true for radiant heat, for light, and for gravitation. The law is that *its intensity varies inversely as the square of the distance.* This is familiarly known as the *law of inverse squares*, and is true of wave-motions in general. But the intensity of sound varies also with another factor which has not to be reckoned with in the case of ethereal wave-motions; and that is the density of the medium which transmits it. We know, for instance, how clearly sounds are heard on a frosty night, the reason being that the air is then more dense; while a famous Alpine traveller mentions that the report of a pistol at a great elevation appeared no louder than would that of a small cracker at a lower level.

Just as other wave-motions are reflected, as we saw in the case of radiant heat, so are those which we interpret as sound. The laws of such reflection are the same as those that regulate the reflection of light; and, indeed, are the same as those which (ideally) determine the reflection of a billiard ball from a cushion. The angle of incidence is equal to the angle of reflection, and, we must add in the case of sound, the planes of incidence and of reflection coincide. These laws are equally true for the reflection of light and radiant heat.

Everyone who has ever heard an echo is aware of the reflection of sound. Echoes sometimes offer serious practical problems, since they may seriously interfere with the utility of a hall for music or public speaking. In order to correct this defect it is necessary to break up in every possible way all the sound-waves except those which actually travel directly from speaker or performer to the audience. Wires and tapestries, and, indeed, the bodies of the audience themselves, are often found to be of value.

Use of an Echo. But the principle of the echo may also be utilised in a rather surprising way. If the sound be reflected from more than one surface there will be a series of reflections, or echoes, which will remarkably modify the ordinary facts of its transmission. A familiar and conspicuous instance is furnished by the whispering gallery of St. Paul's Cathedral. Similarly, sound may be reflected from smooth sheets of ice, as in the case of two Arctic explorers, who conversed comfortably at a distance of a mile and a quarter. The principle of repeated reflection is adopted in the ear trumpet, the speaking trumpet or megaphone, and in all kinds of speaking-tubes. The most striking natural instances of echoes are furnished by peals of thunder.

Refraction of Sound. Just as light waves, as we shall afterwards see, are bent or refracted on passing from one medium to another, so also are sound waves. In the case of light and radiant heat, we have to remember that the wave is passing through one and the same medium all the time; but in the case of sound the wave is actually transmitted from, let us say, the air of one room to the wall of another, and so to the air of the next. But in such cases the direction in which the new wave travels is different from the previous one. This change of direction is indicated by the term *refraction*, and it follows the same laws for sound as for light, under which they will be discussed. Just as light—in virtue of refraction—may be brought to a focus by a convex lens, so also may sound by the employment of some medium which will refract it. A balloon filled with carbonic acid gas, for instance, will bring to a focus at a definite point on one side of it the sound of the ticking of a watch placed on the other side of it. If the balloon be made to swing from side to side, as in the case of an experiment of Lord Rayleigh's, the demonstration is still more striking.

Nature of Sound Waves. We have already noticed one fundamental distinction between the waves of sound and those of light—*viz.*, that the former are waves in a material medium (which may be gaseous, liquid or solid), while the latter are waves in the ether. But another most important distinction is that these ethereal waves or vibrations are at right angles to the line in which they advance. They are described as transverse vibrations. But the waves of sound are longitudinal vibrations. The particles of air, or whatever the medium may be, travel to and fro in the line in which the whole wave is advancing.

Now, a most important distinction between these two waves—transverse and longitudinal—is that the latter, unlike the former, bring the particles of the medium alternately nearer to, and farther from, one another than they are when undisturbed. Such waves are thus waves of alternate condensations and rarefactions. Perhaps one of the best ways in which to obtain an idea of such waves is to think of a row of billiard balls in contact with one another; the ball at one end being struck by another ball rolling up against it. The balls, being elastic, like all media which transmit sound, are alternately [illegible] and recover [illegible], with the ultimate result that the ball at the end of the row is shot forward by itself. In just such a manner must we [illegible] the particles of air to behave when [illegible] sound.

Noise. But there are sounds and sounds, as everyone knows, and though opinions differ as to the precise point where the line should be drawn, there are two great classes of sounds between which our ears detect so marked a difference that there must surely be some objective difference, equally definite, between them. Sounds we may divide into noises on the one hand, and musical notes on the other. What is the difference between them? This question can be clearly and positively answered. The vibrations which we interpret as noise are irregular, while those which we interpret as musical notes are regular. In observing this fact, we make a most important contribution to psychology. The psychologist asks why one sound is pleasing and another unpleasing? As physicists, we reply that, while ignorant as to the manner in which hearing is effected, we know the pleasing sound to be determined by regular stimulation of the nervous structures by which we hear, while unpleasing sounds, those which have not the musical quality, are determined by irregular stimulation. We need pay no further attention to noises of any kind, but must now devote ourselves to the study of musical notes—the fashion in which they are produced, and their relations to one another.

Pitch. The most striking respect in which musical notes differ from one another is in pitch, and it is easy to ascertain by what this is determined. It depends simply upon the number of shocks upon the ear per second. A tuning-fork, for instance, can be made to record its vibrations upon a piece of smoked paper passing in front of it, and we find that the pitch of the fork depends upon the rate at which its prongs vibrate. For any particular tuning-fork this rate is constant. As we listen, we hear the sound gradually die away; but the wavy line upon the smoked paper shows us that the number of vibrations per second does not vary; while our ears tell us, in point of fact, that the pitch remains constant even while the loudness diminishes.

The matter of *loudness* is so simple that we may dismiss it here. It depends merely upon the size of the waves, their extent, or, to use the technical phrase, their *amplitude*. The behaviour of the ear, however, somewhat complicates this statement, since Helmholtz, the great German physician, physicist, and philosopher, observed that the notes differing in pitch differ also in loudness, even where the amplitude of vibration is constant, the higher note always exhibiting the greater intensity. This is simply to say that, other things being equal, our ears are more sensitive to high than to low tones; but, in the case of any given note or tone, its loudness depends simply upon the amplitude of the vibrations which constitute it. So much for loudness. The essential fact of pitch we have already [illegible] to be the rate of vibration. Various instruments have been devised for proving this assertion, and also for elucidating the facts of harmony. There is, for instance, what is called the toothed wheel [illegible] of Savart; but that has now been superseded in practice by another device.

The Siren. This is the name of an apparatus by which a continuous flow of air through a tube is arrested and permitted at regular intervals by means of a revolving disc, near the edge of which are a number of holes at equal distances from each other. These holes come in succession opposite the end of the tube, and permit the air to escape. In a more complicated form of the same instrument there is an arrangement by which the speed at which the disc rotates can be readily measured.

When we experiment with such a siren, we find that the note which it produces rises or falls according as we increase or diminish the speed at which the disc rotates. But it also gives us much further information. In the first place, it gives us the limits of hearing for any individual—limits which are precisely comparable with those of sight. When the number of puffs per second is 10, let us say, individual puffs may be heard, but there is no note produced. As the speed of the disc increases, however, a note is heard, perhaps when the puffs reach the figure of 16 per second. The first note heard has, of course, an extremely low pitch, but as the number of puffs per second increases the pitch rises, until at last it becomes extremely shrill, and finally is lost altogether. The number of vibrations beyond which no further sound is heard may be 30,000 per second or 50,000 or 70,000. The figure varies with different individuals, and is also affected in any individual by the occurrence of various kinds of deafness. The upper limit of hearing, for instance, may be very much reduced in cases of what is called *nerve-deafness*, where the disorder is due not to the conducting apparatus, but to the nervous centres themselves. Thus the siren may be of considerable medical importance. It is very probable that sounds too shrill for most or for all human ears may be perfectly audible for some of the lower animals.

The Harmony of the Siren. In order to study harmony by means of the siren, Dove, of Berlin, has modified the instrument, piercing four concentric sets of holes in the disc, the number of holes having, for instance, such a ratio as 8, 10, 12, 16. He calls this the *many-voiced siren*, and can cut off any particular circle of holes at will, thus making the instrument speak with any combination of its voices. It is then found that if the eight and sixteen-holed circles be left open, two tones are heard, one an octave above the other. If the speed of rotation of the disc be accelerated or reduced, the tones are proportionally sharpened or flattened, but the one always remains the octave of the other, proving conclusively that the relation between a note and its octave depends upon the fact that the speed of vibration is exactly twice as fast in the one as in the other. Now, the ratio of 8, 10, 12, and 16 is the ratio of 4, 5, 6, and 8, and if all the circles of holes be left open, that is the ratio between the four notes which are produced. These are the notes of what musicians call the *common chord* or *fundamental chord* C E G C′. If the first and third series of holes be left open, we find that the note having the ratio of 6 to 4 or 3 to 2 is a fifth higher than the lower note. The G on the piano thus has half as many vibrations again per second as has the C below it, the ratio being that of 6 to 4 or 3 to 2. Similarly, we find other musical intervals established by sounding other combinations of the circles of holes, and it is an easy matter to establish the ratios of all the notes in, for instance, the ordinary major scale of C. Thus:

$$C : D : E : F : G : A : B : C'$$

$$1 : \tfrac{9}{8} : \tfrac{5}{4} : \tfrac{4}{3} : \tfrac{3}{2} : \tfrac{5}{3} : \tfrac{15}{8} : 2$$

$$(\text{or, } 24 : 27 : 30 : 32 : 36 : 40 : 45 : 48)$$

The Scale. The most important fact about such a scale is the constancy in the ratio between its notes. In fact, we must state, as follows, the fundamental law of musical harmony. *The notes employed in music always correspond to certain definite and invariable ratios between the vibration numbers of the notes; and these ratios are of a very simple kind, being restricted to the various permutations of the first four prime numbers, 1, 2, 3, 5, and their powers.* This fact is the whole essence of music, not only of harmony but of melody also. All the notes of any tune must lie in a definite scale, the nature of which is determined by the strictest mathematical considerations. Music is thus a variety of applied mathematics. If a note be sounded which does not possess one of these due simple ratios to the other notes of the scale, we say that it is out of tune—*i.e.*, it is either *flat* or *sharp*. The note may have pleasant enough quality in itself, but it has no relation to the rest of the notes of the piece. It simply cannot occur in such a place. This fact is quite distinct from all questions of discord. Almost any discord is permissible in its place in modern music, but all the notes so sounded have, at least, their regular places in the scale, whereas a note which is "out of tune" has no such place. The various notes of the scale quoted above constitute what is technically known as the *natural* or *diatonic* scale.

The intervals between successive notes upon this scale are either major or minor tones or semitones, the third and the seventh belonging to the latter class. If we insert an additional note between each pair of notes whose interval is either a major or a minor tone, we obtain a sequence of twelve notes, the intervals between each successive two of which are much more nearly equal than those of the notes in the diatonic scale. This more complicated scale is known as the *chromatic* scale. The distinction between the older music and the music which is most prominently represented by Wagner may most simply be stated by saying that the older music is founded upon the diatonic and the newer upon the chromatic scale.

Stretched Strings. The facts which can be so easily proved by the siren can equally well be demonstrated by several other means. Notes of varying pitch may be produced, for instance, by the vibration of stretched strings.

Certain conditions determine the note which is produced by any given string, these being its length, its mass, and its tension. The term *mass* covers two factors which may vary independently—the thickness of the string and its density. The simplest of these factors to understand is the length of the string. If a string, as in a violin—its tension being kept invariable—has its length altered, its fundamental note (we shall afterwards explain the meaning of the word fundamental) will rise in pitch in exact proportion to its diminished length. In this fashion, the diatonic scale can be played on one string of the violin, by stopping at intervals corresponding to the notes required.

Tension and Pitch. The relation of the tension of a string to its pitch is rather more complicated. Other things being equal, the note is proportional to the square root of the tension—that is to say, if the tension be multiplied by four, the pitch of the note is multiplied by two—it is raised an octave. Again, the note of a string varies inversely as the square root of its density, and inversely as the square root of the weight of any given length of the string. There is no simpler arrangement for studying these facts in the case of strings than the monochord, which was known to the Greeks and carefully studied by them. This is simply a single string stretched between two fixed points over a sounding-board. Between the ends of the string is a movable bridge, by means of which the vibrating length of string can be modified. For instance, if the movable bridge be inserted half-way along the string, the result is a note an octave higher than when the bridge was absent, and so on. So far as we have gone we find that the facts agree entirely when we turn to the notes produced by pipes instead of strings. Other things being equal, a pipe of eight feet in length will produce a note an octave higher than a pipe sixteen feet in length.

Fundamentals and Over-tones. But we find a great deal more complexity in, for instance, the vibration of a stretched string than has hitherto been indicated. The string, it is true, is vibrating as a whole, but it is also vibrating in segments. The same is true of a column of air in an organ pipe. The note produced by the vibration of a string as a whole is known as its fundamental note or tone. The notes produced by its simultaneous vibration in parts are known as *over-tones* or *harmonics* or *upper partial* tones.

These over-tones are of immense interest and importance from every point of view. We have already noted one or two characters in which one musical tone or note differs from another—characters such as pitch and loudness. But there is another character, at least of equal interest, which is quite independent of both of these, and that is the quality or *timbre* of the note. Various words have been used for expressing this quality. Sometimes we employ in English the word *clang-tint*, a translation of a German term. Any two tuning-forks sounding notes of the same pitch and loudness are absolutely indistinguishable from one another. The reason of this is that the note produced by a tuning-fork is a simple tone containing only one fundamental note without any harmonics or over-tones.

How Notes and Tones are Identified. This fact, then, leads us to understand how it is that we are able instantly to distinguish identical notes, or what purport to be identical notes, according as whether they are produced by a piano, a violin, a clarionet, the voice of one friend or the voice of another. We say these notes purport to be identical, and, indeed, their fundamental tone is identical. The differences which enable us readily to distinguish them so are entirely dependent upon the number, character, intensity, and intensity relatively to one another, of the various over-tones which accompany the fundamental note in every case. If these be few, the tone is thin and lacking in beauty; if they be very numerous and prominent, the tone may be very heavy; and sometimes, as in a very rich and resonant bass voice, the identity of the fundamental tone is actually obscured. The finest tone is that which includes the largest number of over-tones, or harmonics, that form a fine harmony with the fundamental tone. If the over-tones form an unpleasant chord with the fundamental tone, then the voice or violin, or whatever the instrument may be, is held to be unattractive.

Resonators. Everyone knows how a sound produced by any means is reinforced under certain conditions. Illustrations are furnished by a watch lying respectively on cotton-wool or on a hard table, and by a tuning-fork held in the air or having its stem firmly placed upon a table. The string of a piano produces extraordinarily little sound when struck unless it be aided by a sounding-board. If the belly of a violin be removed for experimental purposes and the instrument then played, it is impossible to get any fine tone out of it. The tone is, indeed, thin and offensive. Indeed, every kind of musical instrument is provided with some device or other in order to reinforce the sound which it produces. Such devices are known as resonators, and they are of extreme importance in music of all kinds, including vocal music. The manner in which a resonator acts is by increasing the amount of air which is thrown into vibration.

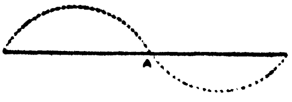
Science of Resonators. When, for instance, the stem of the sounded tuning-fork is placed upon a table, the table itself vibrates at the same rate as the fork; and consequently a very much larger amount of air is set in motion. The rule with resonators is that there are certain tones which they best reinforce. A series of resonators can be made, indeed, such that each responds to a given note and to that alone; or, at any rate, if to other notes, only to those of very nearly the same pitch. The selective action of resonators can readily be shown by holding a sounding tuning-fork over a tall cylindrical vessel containing water. The sound is found to be greatly reinforced only when the water in the tube stands at a certain level. This experiment furnishes the proof of a most important fact. Let us suppose that a compound tone is being sounded. The proportion and relative value of its over-tones can be almost indefinitely modified by the use of various resonators which pick out and reinforce various over-tones or combinations of over-tones. The immense musical importance of adapting one's resonators so as to reinforce certain selected over-tones will be discussed later.

Harmonics of the String. Let us now return to our stretched string, or monochord. So far it has merely taught us that its note varies according to the length of it that is allowed to vibrate. Now, if, instead of merely plucking the string with the finger, we throw it into what is called forced vibration by means of a violin bow, we discover that more harmonics are produced. Only the very highly trained ear can actually detect them; but everyone is able at least to recognise that a much finer and richer tone is produced by bowing the string than by plucking it. The difference is not a question of loudness, and the note is the same in both cases; it plainly depends upon the presence of over-tones. It is, indeed, found that the string is vibrating not only as a whole, thus producing its fundamental tone, but also in two equal halves, thus producing an upper partial, or over-tone, an octave higher, and also in other proportions, corresponding to the interval which is called the twelfth, to the double octave, and so on.

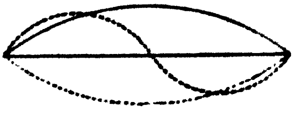
It is the presence of all these additional tones, happily blended with the fundamental tone, that accounts for the superior quality of the sound now produced. Each of the strings of a fine piano acts in precisely the same way, and there is a simple and interesting fashion in which this can be proved. Hold down with the fingers a series of notes on the piano, such as C in the bass clef, the C above that, and also the E, G, and B flat above it; now strike very firmly the low C below the bass clef, and let the note go. Immediately you hear, if the piano be a good instrument and in tune, a soft chord consisting of the notes which you are holding down. (The reason why one has to hold them down is to prevent their vibrations from being damped, as they would otherwise be.) The explanation is very simple. The low tone which was struck contained a number of upper partials; the string was vibrating not only as a whole, but also in segments corresponding to the various over-tones. How do we know this? The only statement that needs to be made for the complete understanding of the experiment is a statement of the fact which is called *sympathetic vibration*, at which we have already hinted in describing the selective action of resonators.

Sympathetic Vibration. The upper strings in our experiment, being left free to vibrate by having their dampers removed, have responded each to the over-tone identical with its own fundamental tone, in just the same fashion as a resonator of a given size and shape responds to a given over-tone in a clang or compound note. The occurrence of sympathetic vibration is not difficult to understand. We must imagine that the case is not dissimilar to the pushing of a child on a swing; a series of taps given at the right moment will soon produce a very decided vibration. In the case of the very best pianos, sympathetic vibration is a very large factor in explaining the quality of their tone, since, whenever the loud pedal is down, all the higher strings that correspond to the over-tones of any lower note that may be sounding are thrown into vibration. For this purpose it is necessary that the piano be perfectly in tune, and the owner of a fine piano but only a moderately fine ear, may know that his instrument needs tuning, less because any defect can be definitely observed than because its tone appears to be rather less rich and resonant than he has observed it to be immediately after tuning.

Nodes. If we take the simplest case of an over-tone, the production of a note an octave above the fundamental tone, we may imagine—and, indeed, may see—the string to be vibrating in a fashion which is represented by the accompanying diagram. At the point A we have what is called a *node*; the segments of string on each side of it are vibrating in opposite directions, and are technically known as ventral segments. This is the simplest case but one, the simplest case obviously being that in which the string has but one ventral segment, while its fixed extremities constitute its only nodes. But, indeed, a musical string is susceptible of an infinite variety of modes of vibration corresponding to different numbers of subdivisions into ventral segments. It is the general rule that the over-tones tend to become fainter as one passes upwards. The higher the over-tone the larger is the number of ventral segments of the string, and the less is the amplitude of their vibrations.



A second figure indicates the state of affairs when a string is giving forth both its fundamental and its first over-tone. It is, of course, evident that no part of the string can be in two places at the same time, as the diagram would at first sight appear to indicate. But, in reality, the motion of the string in such a case is complex, being the resultant of two factors, one corresponding to the fundamental and the other to the over-tone. The diagram expresses in merely ideal fashion the shape of the vibration that corresponds to each of these. The extreme complexity of the motion of the string when the number of over-tones is very large may easily be imagined.



Tuning of Resonators. Helmholtz made many interesting experiments with resonators, and devised a large instrument consisting of a whole series of resonators arranged in a definite order. Any one of such tuned resonators may be used in order to demonstrate, even to an unmusical ear, the corresponding over-tone in a compound note. Each of them is a hollow sphere, with two opposite openings, the smaller of which is applied to the ear. If now the compound tone be sounded, the resonator will immediately demonstrate the occurrence of its corresponding over-tone by greatly reinforcing it. These resonators may be arranged in such a position as to affect flames placed opposite them. When one sings opposite such an arrangement, the movement of the flames (which may be readily made visible by means of revolving mirrors) tells one precisely which over-tones are contained in the note one is singing.

Vibrating Plates. What is true of strings is true of other vibrating bodies, such as plates. The physicist Chladni made a study of this subject by taking square plates, clamping them in the centre, and sprinkling very fine sand upon them. If now the edge of such a plate be bowed, it will vibrate in a particular fashion; and this will vary if the finger be placed upon the plate at various points and accordingly as the position of the bow is altered. The plate has its nodes just as the string has, their position varying with these varying circumstances, and the sand naturally tends to be thrown upon whatever may happen to be the nodes or nodal lines of the plate. Hence there may be produced an endless number of sand patterns, which are everywhere known as Chladni's figures.

Pipes. The principles we have already learnt are applicable not only to stringed instruments but also to wind instruments, such as an organ-pipe or a flute. The column of air in such an instrument is of a certain length, and is capable of vibrating at a certain speed. That we already saw in the case of the column of air above the level of the water in the cylindrical glass vessel which we used when studying the principles of resonators. The differences between various types of wind instruments are extremely interesting, especially to the musician, mainly because each of these types has its own characteristic capacity for the production of over-tones. For instance, what is called a stopped organ-pipe is capable of giving only the odd over-tones—those whose frequencies are three or five times, for instance, that of the fundamental tone. Obviously, the quality of a note produced by such a stopped pipe must be quite different from that given by the open pipe, which is able to yield the complete series of over-tones.

The Human Voice. But the only kind of musical instrument which we have space to discuss here is the human voice—the oldest and most interesting of all. Essentially it is produced in the voice-box, or *larynx*, which is developmentally equivalent to one of the gill arches of the fish. The various cartilages of which it consists are all devoted to the service of the *vocal cords*, which are made of fine elastic tissue, and are practically stretched strings. In front they are attached close together, quite close to the projection which we call Adam's apple. Passing backwards, they slightly diverge; but the larynx is so constructed that they can be quite closely apposed, so that only a tiny chink is left between them. This the singer or speaker does, and then, by means of a forced expiration, drives a column of air against the resisting cords, which are thereby thrown into vibration. The rate of the vibration or the pitch of the note produced must depend, our study of stretched strings has already shown, upon the tension, length, and mass of the cords.

A man's larynx is larger than a woman's; his cords are longer and heavier, and therefore his voice is of lower pitch.

Causes of a Good Voice. The only factor over which we have control is the tension of the cords. If a dissected larynx be caused to emit a note, it is found to be very thin and unpleasant, being what teachers of singing call the "naked tone." But in the case of even the finest singer, no tone is actually *produced* anywhere save in the vocal cords. All the over-tones which make his voice so beautiful are produced by the partial vibration of his vocal cords. What enables him to produce such fine tone is his possession of resonators which are either naturally fitted to reinforce the most desirable over-tones, or else are capable of modification at his will for this purpose.

Voices undoubtedly differ from one another naturally in respect of their quality, the shape of the unchangeable resonators being—in some people—fortunately precisely adapted for purposes of singing; but, in addition, voices vary widely because of the varying skill with which the modifiable resonators are employed. We all of us have skill enough to modify our resonators so as to produce the various vowel tones, and the singer's skill is only an advance upon this.

The Man of Many Voices. When the teacher tells the pupil how to "place" the voice, what is meant is simply that the muscles of the tongue, lips, and throat are to be so co-ordinated that the best possible resonance is ensured, picking out and reinforcing to the utmost the most valuable of the over-tones in the laryngeal note. But there is a much higher art than this, and one known to only few singers—the art of modifying the vocal colour or quality for various purposes. Plainly, different qualities of voice are required for imprecation, love-making, and defiance. The most accomplished of living singers, M. Victor Maurel, is really the possessor of half a dozen voices. His art consists in his amazing control of all his modifiable resonators, so that while sounding one and the same laryngeal note, he is able, by variously selecting and reinforcing its various over-tones, to endow it at one time with a sensuous, at another time with a martial, at another time with a devotional quality, and so on. Why various clang-tints should possess such varying significance is not for the physicist to say.

WORKSHOP PRACTICE

The Scope of Engineering. Its Theory and Practice. The Several Departments. Castings, Patterns, and Cores

Continued from page [illegible]

By JOSEPH G. HORNER

THERE are few, if any, of the professions or manufactures which are so many-sided or so exacting in their technical demands as mechanical engineering. The practice of it involves so much of science and theory, handicraft and machine operation, of general knowledge so wide, and specialisation so minute, that a successful engineer must never cease to be a student and a worker too. The early years of training are in but a slight degree preparatory to the work that comes after, the bare foundation on which the superstructure of life's long practice is reared.

The Vastness of the Scope. The work of the engineer is in evidence all the world over. He designs and builds the tireless engines that run 200 miles without a stop, or which propel the big liners with the power of 30,000 horses, or drive the machines of our mammoth factories. Machines numbering thousands of distinct types, beautiful machines of marvellous precision employed in a hundred separate industries, are turned out of the engineering workshops of Europe and America in countless numbers. The bridging of the estuary of the Forth, of the Thames by the Tower, of the Zambesi, of the Hudson River at New York, of the broad rivers of India, Australia, and the United States, is the work of the engineer's hand. So, at the other extreme, is the making of the typewriters, the cash registers, the sewing-machines, and the small arms; and the systems and methods by which these mechanisms are produced in vast numbers are fully as marvellous and fascinating as are those by which vastly more imposing engines, machinery, and structures are built up. The principles and methods which underlie them all are similar, only differently applied. So, too, the materials used are identical; and thus it is that all engineering practice, no matter how diverse, is linked by common features, so that the man of broad technical training can, if necessary, soon acquire precise knowledge in any of the great departments between which it is specialised.

Let us see now in brief what is involved in the study of materials, designs, and methods employed in the practice of mechanical engineering.

Materials of the Engineer. There are not many materials, natural or artificial, which the engineer does not in some way or another press into the service of man. But the principal ones are the metals and alloys, timbers, and concretes. The metals take first place, and these are chiefly iron and its alloys, copper, and the alloys which it forms with tin and other metals. Superficially the objection may be made that this is metallurgy, and not engineering. But the engineer must make himself familiar with the physical characteristics and behaviour of the common metals and alloys if he is to avoid committing blunders in design. The failure of structures and mechanisms is the heavy price which has often been exacted as the penalty of ignorance, or neglect of these matters. Neither can the question of the absolute strength of these materials be considered alone, but the engineer must become familiar with the many faults which they are liable to develop during the course of manufacture, and the knowledge can be gathered only by much experience in practical duties. Their endurance or weakness under different conditions of stress, strain, and fatigue; under the action of heat, cold, moisture, or dryness, climatic or otherwise; their greater or less adaptability to various kinds of service have to be understood. An engineer, in short, must possess as intimate an acquaintance with all the materials he has to use in their numerous grades, weaknesses, and faults, as the agriculturist with his soils, or the doctor with anatomy, or the naturalist with his microscope.

The Disposition of Materials. Yet this is but the beginning of knowledge, for when we have our wealth of materials suitably selected, we must be able to dispose of or arrange them in both the strongest and cheapest manner. For these materials are all costly, and therefore it becomes of the first importance to economise them to the utmost. This necessity explains broadly the reasons for the outlines given to most structures and framings; the iron, steel, or alloy being arranged in the particular fashion which affords the maximum of strength with the minimum of material. Included in this general problem is the direction or disposition of material which corresponds best with the direction and intensity of stresses. Cast iron, for instance, should not be subjected to tensile stresses; while wrought iron and mild steel appear to best advantage in such cases.

And here, in the work of design, a vast amount is comprehended. It involves a working knowledge both of statics and dynamics—of bodies at rest, and of those in motion. It is most essential, too, to distinguish between dead and live loads; or in other words quiescent loads and those which are constantly changing in nature and intensity, since the latter are far more destructive to mechanisms than the former. The strength of bodies in movement introduces and involves problems of gravity, of centrifugal force, cohesion, and the effects of angular movements. Other results also follow, besides that of dynamic strength, the greatest of which is friction. If there were no friction a machine would give out as much power as it received. In an average factory about half the power delivered is used up and lost in the belting and shaft bearings before any useful work is done. Friction occurs in all slides and spindle bearings.

Ingenuity of Modern Mechanisms. Few save engineers know the hundreds of devices embodied in modern mechanisms having for their sole object the reduction of friction. Some of the best engines have their working parts wholly encased in an oil reservoir, the supply of which lasts for several months. All large engines have their moving parts lubricated automatically from cisterns, shaft bearings have many devices to facilitate the distribution of oil, many are lined with alloys of white metal which reduce friction. Further, the proportions of bearing surface are constantly being increased to lessen the pressure per unit area. By these and kindred devices the durability of moving parts is greatly prolonged.

The true engineer must also possess a working knowledge of many sciences besides those which deal with the mechanical aspects of things. An intimate acquaintance with the laws and effects of atmospheric pressure, of heat, electricity, and hydraulics is of first importance. These face him at every turn—in steam and gas engines, in steam boilers, in the electric driving of machines of most kinds, in water turbines, in pumps, and in the flow of liquids. Inorganic chemistry cannot be neglected, for it plays a vital part in steam boiler troubles, in refrigerating plants, in the reduction of the metals, and in the preparation of alloys. Organic chemistry is touched by the composition and action of the oils and fats used for lubrication. Practical geology is an aid to men who sink artesian wells, or who have to do with the equipment of mines and quarries. Mathematics, geometry, and the art of rapid sketching and drawing are all essentials to the equipment of a perfect engineer.

Theory and Practice. Yet these are but the preparatory stages in the training, only leading up to the construction of those mechanisms which are the actual embodiments of the ideals. It is here that many men are found wanting. They have theory and science at their fingers' ends, but have never made anything or taken a part in the manufacture of a mechanism, have never acquired those lessons of experience which are of enduring value in the world's work. To learn these they must "go through the shops," must work in the departments of an engineer's factory, must handle tools and machines, and assist in the building-up of machinery stage by stage.

Many Trades in One. A most interesting feature about an engineering works is that though it comprises an assemblage of various kinds of shops, it forms an organic whole. From one point of view each department seems to stand alone, yet each is actually dependent upon all the rest, and the work of the management consists largely in keeping things moving between departments in order to secure the economical production of the final mechanisms. The foundry must not be short of patterns, nor the turnery and the machine-shop be kept idly waiting for castings and forgings. Every element in a machine, whether it be a massive casting or forging, or a little bolt, has to pass through more than one set of hands in its progress to the mechanism in which it finds a home. If error is made in one shop it entails inevitable trouble in another, and therefore engineering practice differs in these respects from some other trades where a piece of work is begun and finished in one shop only. This practice in a typical works involves the following departments of activity.

Design and Drawing. In a well-conducted works, no piece of mechanism is made until its design and dimensions, with all particulars as to materials and methods of construction, have been definitely settled and embodied in suitable drawings for use in the shops. The men who do this work must combine a knowledge of theory with that of practice, for if they are deficient in the latter their design will prove either unworkable or unnecessarily expensive, an evil which does arise not infrequently. This subject is treated in Drawing for Engineers.

The Pattern Shop. The pattern shop and foundry are two distinct departments, in which the methods and materials have not the least resemblance to each other; yet they are the two most intimately related shops of any in the works. The first-named would be taken by a casual visitor for a carpenter's shop; the engineers' carpenters and pattern-makers, in fact, often work together. But beyond the feature which both trades have in common, of working in wood, there is no resemblance. The fact that the pattern has to be used in the formation of a mould for casting into renders its construction essentially different from that of a mere piece of woodwork. A carpenter could not make a pattern, simply because he does not know the methods of moulding, knowledge which the pattern-maker has to possess in addition to the technique of the carpenter.

The Foundry. The work done in the foundry is the making of moulds, and casting, or founding, of metal into the impressions produced by the patterns. But *the foundry* is an extremely comprehensive term, including numerous divisions carried on by different men in different buildings. Iron, brass, and steel castings are always kept entirely separate; so, generally, is aluminium. And within each of these are many subdivisions under the charge of specialists, as green sand moulding, work in loam, core making; or, again, hand work and machine work, with others yet more minute, in which one class and size of casting only is done, year in, year out, as engine cylinders, pumps, railway chairs, brake blocks, and so on.

The Smithy. In the smithy, forged work alone is produced, but here also by different methods, as at the anvil alone by hand, or under power hammers, operated either by steam, belting, water, or compressed air. These correspond with two great subdivisions, that of the anvil smith, and the stamper; the first named a craftsman, the second very often a comparatively unskilled man, who nevertheless may turn out twenty, forty, fifty times more products than the skilled smith working by handicraft alone.

The Boiler Shop. The boiler-making shop and the plating departments are two great and important shops, which, though generally kept distinct, have much in common, since they both use plates of steel and iron, and rolled sections of the same materials, in the form of angles, channels, tees, etc.; and they both adopt similar methods of union—that of rivets and of welds. In some respects, too, their methods resemble those of the smithy, but the crafts are always kept distinct, and carried on by different sets of men.

In none of those departments would the casual observer see much that he would recognise as engineering, save, perhaps, the manufacture of steam-boilers. And those are, in fact, the preparatory shops only, whence the rough-cast and forged work is supplied to the engineers' turners and machinists, who take it in hand and remove the rough exterior with cutting tools of various kinds, so that the fitters and assemblers may receive it in suitable forms and of correct dimensions to be built up into mechanisms. To many these last departments stand as the visible embodiment of engineering. Many factories have no other departments than these, adopting the policy of ordering their castings and forged work out. These shops have, as regards their methods of operation, little in common with those we have noted. Machine tools, more or less massive, predominate; there is little hand work done, and that little lessens constantly in volume, invaded more and more by machines. These turn, plane, shape, mill and grind the metal smoothly to very precise dimensions, generally within a thousandth part of an inch, or less in fine work. The operations done here, marvellous to the lay mind, are not less marvellous to those who live and move among them and conduct the shops. In no department have such great advances been made in recent years as in these, whether regarded from the point of view of gross output, of fine precision, or of beauty of mechanism—much of which, also, is automatic work.

Erecting and Assembling Shops. In the erecting and assembling shops the prepared units are built up into the complete machine. The difference between them is that in the erecting shops much hand work is done, none in the other. This, as we shall see, is a very important distinction in the economy of production.

These do not exhaust the departments which are found in large representative engineering works. Coppersmiths' and tinmen's work are present in many—as in locomotive and marine shops, in pump makers' and brewers' engineering establishments. Heavy carpentry is done in crane shops, in locomotive shops, and in those who do work for civil engineers. Many engineering firms now make their own electrical apparatus for motor driving and for lighting, and there is then a wiring department. Painting and polishing shops, too, are often a part of the equipment of a big factory.

An important section sometimes is the testing department, which may include testing of raw materials as well as of finished products. Every motor, machine, and mechanism made to specifications must be subjected to tests of some kind, and the nature of those, of course, varies much with the character of the work—that for a steam boiler, for example, being necessarily of a very different kind from that of a machine or a bridge.

We have taken a very concise survey of the ground which will be covered in detail in this series. The vastness of the field must be our justification for brevity and for statements of principles and cardinal practice without exhaustive detail.

To those who desire to become engineers, the vast extent of the knowledge which has to be acquired may seem staggering. But plodding industry will accomplish much.

The Fascination of Work. Yet there is no alternative to incessant work. Even the conscientious worker may not succeed, but the idler must fail. The true engineer finds his recreation in his work. There is a fascination in it which increases with years. In its many-sidedness lies much of its charm, and the broad-minded man of wide experience sees more than he who specialises round one branch. He feels something akin to the thrill of romance when contemplating a structure like the Forth Bridge, or the Tower Bridge, the stately movements of massive engines, the tireless movements of a machine tool, the forging of a white-hot mass under hammer or press, the roar of a Bessemer converter, or the towering blast furnace.

Custom cannot stale the infinite variety of engineering practice. It looms larger in the great world as the years roll on and the continents become opened to civilisation. But though its practice ever varies, the principles on which it all is built remain eternal and unchanged.

CASTINGS & THEIR PATTERNS

It is intended in this section to consider the work of the pattern-maker and moulder together instead of approaching them as isolated trades. The pattern is regarded from the point of view of its mould, as the means by which the casting is obtained, for the pattern is temporary, the casting permanent; only in this way can correct views be gathered.

Those who are familiar only with work done in stone, timber, and solid materials, will imagine the art of moulding and founding in sand to be one of the most curious in existence. But for the fact that it is so dirty and grimy a trade, it would take a much higher rank in popular estimation than it does. We do not forget that many of the early mediæval founders were also great designers, architects, painters, sculptors, and that they idolised and idealised the art of the moulder and caster in bronze.

If we except the very small proportion of moulds made in plaster and in metal (chilled moulds), all founders' work is prepared in sand—loose, powdery, friable—the poorest material, apparently, to withstand the inrush of molten metal, the high specific gravity of which is only disguised by its molten, fluid condition; for liquid iron is seven times heavier than water. And yet this sand will endure either the invasion of tons upon tons of molten iron or steel, or the few pounds of brass melted in a crucible. It is in the preparation, manipulation, and support afforded to the sand that the secret lies.

Moulding Material. Little difficulty need be experienced in understanding why the founder must employ this material in preparing his moulds. Think of almost any substance but sand, and the necessary conditions will be absent. The material must be obviously non-inflammable, which condition excludes wood or wax. It must be capable of being moulded into a thousand diverse forms, which excludes rigid metals—except for chill moulding, to be noticed presently. It must be very porous, to permit of the escape of gases generated during casting. It must cohere firmly, and not be acted on chemically by molten metal in such a way that the essential properties just noted should be changed. Lastly, it must be very abundant in nature, and cheap. Sand is the only substance which fulfils the whole of these conditions, which explains why all moulding and casting, with some very slight exceptions, is done in this substance.

The Moulding-box. But, though there is considerable coherence in sand when moistened with water, that alone is not sufficient to sustain the materials in moulds without extraneous aids. Hence we have the moulding-boxes, or flasks, within which the sand is rammed, and retained during making and casting. The differences in these boxes will be illustrated in another part of this course. Nor is the support of the boxes alone sufficient in all cases, since in most moulds there are many very weak sections or tongues of sand that are neither self-sustaining nor strong enough to withstand the rush and pressure of metal. Such weak portions have to be stiffened by the adventitious aids of "lifters" or "gaggers," rods, and nails—the internal skeletons, as the moulding-boxes fulfil the function of external skeletons.

When we go a stage further, and attempt to construct actual moulds, the discovery is soon made that all sands are not alike, and that there are certain properties that must be possessed by different sands, and mixtures of the same, for different classes of work, which are designated by various terms that denote their characteristics. Highly siliceous, heat-resisting sands occur in many districts, and to these are added coal dust, or, in some cases, horse manure, as follows.

Moulders designate sand as *strong* or *weak*, terms which distinguish respectively the material of greater from that of lesser consistence. Within these extremes there are numerous grades of each. Horse manure enters into the composition of all strong sands, ill-digested hay affording a good binding material, which also, when burnt out by the heat of the molten metal, assists in the *venting* of the sand. Strong, close, heavy, clayey sand has the disadvantage of being less porous than the weaker sands, and therefore it requires more venting, both with the vent wire and horse manure, than the other.

At these extremes the components of sand mixtures are composed of clayey sands, and of fine sharp sands. The first are often of a yellow colour, the second red.

A Practical Test. A practical test of the difference in quality is to squeeze a handful. If it retain the shape imparted, it is suitable for general moulding; if too heavy, and decidedly clayey, it should have a finer sand mixed with it; if it fall to pieces on the removal of the fingers, it is too *open*, and needs to have a stiffer clayey sand mixed with it.

Actually in foundries only a small proportion of new sand is used in moulds, the old or "black sand" on the floor forming the largest body of the mould, or *box filling*, and the new sand being mixed for *facing* the moulds only, to a thickness varying from an inch to two or three inches. The stronger the sand is required, the less old sand can be used for intermixing.

Strong clayey sand requires another ingredient—coal dust—in large proportions, to counteract its closeness of texture and render it better able to permit of the discharge of the gases generated by casting. This has the effect of rendering the mould more open, because, being burnt out at the time of casting, it leaves the sand to that extent porous.

The stronger sands are used in those classes of work where the mould is subject to great pressure of metal, and to prolonged heat; the weaker for the light casts, where there is little pressure and little mass, so that cooling takes place quickly.

Kinds of Sand. The difference between *green sand* and *dried sand* corresponds to a certain extent with the *weak* and *strong* sands respectively. But many green-sand moulds are made in strong sand, though no dried moulds can be made with weak sand. "Green sand" denotes any mixture, weak or strong, that is *not dried*; "dried sand" is a particular mixture of strong sand, containing old and new sand, horse manure, ground loam, and moistened with clay water.

Cores are the internal parts of moulds. They are made of various kinds of sands, similarly to moulds, ranging thus from fine red or yellow sands to mixtures of dried sands, loam, and horse manure, with other sands. But *core sand* denotes a strong sand, which has to be dried.

Whether sands are weak or strong, green or dried, it is essential that they shall be able to resist the pressure of metal without distortion or fracture, and that they shall offer no obstacle to the escape of the gas generated by casting. We now propose to discuss the method of ramming and supporting the sand.

But first a reference is necessary to the other materials of moulds just mentioned. These, a very small class, may be briefly disposed of.

in the jewellery trades, and occasionally for small brass work. Its advantage is that several casts can be made from one matrix. But it is limited to such cases, and has no place in the general engineer's foundry.

Chill, or chilled moulds are used in cases where special hardness is required on the surface only of a casting, all the casting body remaining soft. Its utilities are confined to a few articles, such as some trolley wheels, chilled on the "tread," or periphery; rolls for working on iron and steel plates; ploughshares hardened at the points and on one face; some machine slides; and the bores of some axle boxes. The *chilling* is accomplished by pouring the metal against a cold iron "chill," which produces a steely face. Excepting on the face thus chilled, all the remainder is ordinary metal cast in sand.

Ramming. We come to the methods of *ramming*. In all moulds, except some which are very shallow, ramming is essential to the proper consolidation of the sand around the patterns. Those exceptions occur chiefly in such work as making foundry lifters or gaggers, some rough and shallow kinds of fire-bars, etc. But in all ordinary work, whether deep or shallow, the sand must be rammed around the pattern.

Another fact is that no mould can be produced which will fulfil the conditions just named unless the whole of the sand is thus rammed in detail. It is not sufficient to throw in the whole boxful of sand, trample it down, flat-ram, and strickle it off. Bit by bit every inch of the sand must be consolidated with the rammers, and the nearer to the pattern it lies, and the more slender its projecting portions, the greater must be the care exercised in ramming it. All ramming must begin in corners, around flanges, bosses, prints, before the main body of the sand is filled in. The flat rammer is not used in doing this work, but the "pegging" rammers, two forms of which are shown in 1 and 2, or else—as is often the case in very small moulds—a bit of round rod ⅜in. or ½in. diameter, is employed to press home the sand. Only as much sand is thrown in as can be rammed properly. It may be a handful only, or a few shovelfuls, depending on the mould.

The Force of Ramming. Little by little the sand which lies immediately next the pattern is rammed thus in detail, using facing sand first, taking care not to bruise the pattern by allowing the rammer to come in contact with it. As the work proceeds, the facing is backed up by the old sand from the floor for box filling. This is also rammed in detail, but so much care is not necessary here as in working the facing sand. It has simply to afford backing, or support, to the sand that is next the pattern. In very small moulds no such distinction need be made, but one kind of sand would be used throughout.

When the box part is filled up to a height of, say, an inch above the joint face, the flat rammer [3] is employed to finish the whole to an equal consistence on the top, and the strickle and trowel level the joint face.

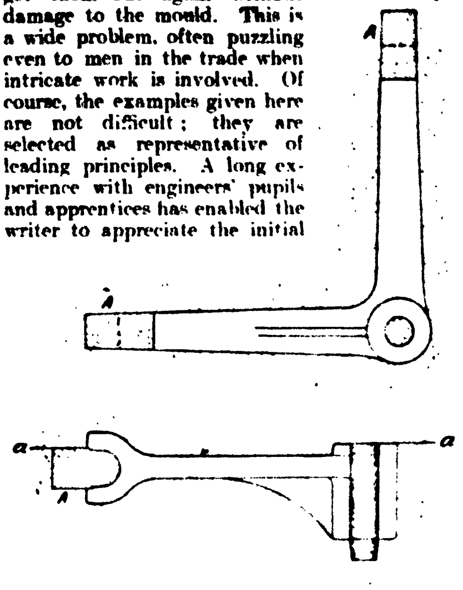
The force which is put into the ramming varies. Taking extremes, light, soft ramming results in castings covered with lumps, the imperfectly rammed sand yielding locally to the pressure of the metal. On the other hand, heavy, hard ramming is productive of "scabbing," the sand flaking off owing to the bubbling of the metal against a surface too hard to permit of the complete escape of gases. But these results can be and are modified by the nature of the sand mixture used, by the extent of the venting done, and by the location of the rammed part. Thus, a well-dried mould will endure without risk hard ramming that could not be put into a damp mould. And the more moisture there is in a mould, the more risk is there of swelling, or scabbing, occurring through light or hard ramming respectively. This is the reason why many green sand masses are "skin-dried" only on the outside. Again, much harder ramming can be done if the vent wire is freely used than if it is sparingly employed.

The location of the rammed part is of great importance in determining the degree of hardness or softness of the ramming. The bottom and the top of a mould are those which are subject to greatest pressure and most liable to scab. These should be rammed harder than the sides, and vented most. Frequently, in fact, a stronger sand is used for the top than for the sides. Sometimes the top is dried, while the sides are green. Sometimes loam cake is rammed in those portions of the bottom of a deep mould against which the metal beats or falls during the pouring.

Venting. The term *venting* signifies piercing the sand, during intervals of ramming, with innumerable fine holes, produced by a vent wire [4], ranging from one-sixteenth to a quarter of an inch in diameter. Through these vent-holes the gases escape at the time of casting and immediately following thereon. The vents, therefore, act as safety valves to moulds which would otherwise become blown up, broken, and damaged, which happens in some degree when the venting is insufficient. *A*, in 4, is a strip of wood held down on the mould joint to prevent the sand from becoming pulled up on the withdrawal of the vent wire, *B*.

Many sections of the sand require support, as previously mentioned, other than that due to the consistency of the moistened and rammed material. Nails, rods, and lifters are the means employed. It is not enough to lay these in the mould; they must have something to take hold of or be supported on—as lifters hung from the bars of boxes, and rods and nails which overhang, receiving their support in the main body of the sand. Such adjuncts are carried in any direction where they are wanted in moulds, and being dipped in clay water, the sand sticks around them, and is held in place. These will be illustrated in another section, dealing with the divisions of the moulder's work.

Difficulties. Having thus dealt with the general methods of ramming, we must now regard the subject from another point of view. Various castings and patterns are shown in the illustrations which are given in this section, with the methods of dealing with them in order to obtain moulds of the same shapes. Obviously, though it is easy to enclose the patterns in sand, properly rammed, it is necessary to know how to get them out again without damage to the mould. This is a wide problem, often puzzling even to men in the trade when intricate work is involved. Of course, the examples given here are not difficult; they are selected as representative of leading principles. A long experience with engineers' pupils and apprentices has enabled the writer to appreciate the initial difficulties experienced by these, in regard to methods of producing the different forms of moulds required for the infinite varieties of castings made. These difficulties are of a different character from those which exist in the work of the machine shop, or smithy, or boiler shop. They involve the productions of forms which exist first only on drawings, more or less intricate, and which have to be made by methods that often permit of several alternatives; all practical perhaps, but not all economical, or mechanically desirable.



17. MOULD FOR NO. 15

Often the pupil or apprentice will see that very slight, and apparently unimportant variations in form involve a different method of making, that different men will arrive at the same result by the adoption of dissimilar methods, that there are often great differences made, if a few only, or if large numbers of castings are required; and sometimes it happens that after a pattern has been made to mould in one particular way, the moulder will get it altered to mould in another. All these are puzzles to the beginner, and they serve to encircle the foundry craft with an air of mystery, for which there is no real objective. It is not so difficult when a man has grasped the principles thoroughly, and had some experience, to settle a suitable method of making any mould whatever, even though he has never seen anything precisely like it before.

Some Problems and Answers. Beyond the fact that the function of patterns and cores is to form impressions into which metal has to be poured, the mind of the pupil assumes a state of chaos. What determines, for instance, the relations of a pattern to the top and bottom portions of a mould? Why are cores inserted in some cases and not in others? Why are some portions cored out, and others left to deliver themselves from the pattern? Why are some pieces affixed loosely? These questions will find solution in the illustrations which follow in this course.

Fig. 5 is the simplest thing possible, a plain washer plate. Its pattern is seen in 6. This is moulded with the flat face uppermost, in a plane with the joint *a-a* of the top and bottom boxes [7]. The reason is that if moulded with the bevelled edges uppermost the moulder's sand joint would occupy more time in making. The hole is formed with a separate dried core, *b*, inserted in the impression made by the print *b* in 6, because it is easier to core cleanly than to allow the hole to deliver from a hole in the pattern. But, if so delivered, which is often done, about one-eighth of an inch of "taper" would have to be imparted to the sides, and then the hole could not be cast parallel. The upper part of 7 shows how the opened mould appears in plan, with the core inserted, ready to be covered with the top box of the mould.

Crane Base. Fig. 8 gives views of a baseplate for a wharf crane. In plan it has the shape of a cross. It is moulded with the vertical ribbing downwards, because less damage is inflicted on a mould by withdrawing the pattern out of the sand than there would be if, the ribs being uppermost, the sand were pulled up away from them. This is a very important practical detail, and it explains why, when deep ribs must for various reasons come sometimes in the top, they are left loosely attached to the pattern. Then they remain embedded in the sand of the top box, while the latter is being lifted, and when it has been turned over, the ribs are pulled out just as they would be from the bottom portion of a mould.

The holes *A*, for the central post, and for the foundation bolts, *a a a a* [8], are cored, for self-delivery would be impracticable. Fig. 9 shows the pattern in plan, looking on the ribbed face, with the core prints lettered similarly to the holes in 8. Fig. 10 is a cross section through the pattern just delivered from its mould below, and 11, upper Fig., is the open mould—*i.e.*, not covered with its top box, the jointing of which is in the plane *b-b*, 11, lower Fig.; and both showing the cores in place, lettered similarly to the holes and core prints in the figures preceding.

THE MYSTERY OF THE MIND

Mind and Energy. Consciousness. Working of the Nervous System. How Many Senses Have We? Co-operation of the Senses

Group 3

PSYCHOLOGY

2

Continued from page [illegible]

By Dr. C. W. SALEEBY

OUR studies have prepared us, in some measure at least, for a right consideration of the mind. Throughout the whole course on Physics we were constantly discussing a something called *energy*. We saw that it is an indestructible entity or mode of being or object which cannot be created but which can be transformed without ceasing. We saw that light and heat or radiant energy, electricity and magnetism, energy of motion, energy of chemical combination, and even matter itself, must all be regarded as various mutually convertible forms of this one something called *energy*.

In studying the facts of living matter, readers of the SELF-EDUCATOR have also learnt that the heat of the body, its various movements and activity, are derived from the energy contained in the food. They have learnt that the law of the conservation of energy, asserted by physicists of, let us say, a falling stone, knows no exception within the living body, whether of a plant, a lower animal, or a man. The more complete our study of the physical sciences, the more thoroughly we blend physics, chemistry, and biology into a consistent and coherent body of knowledge, the more strongly are we imbued with the conviction that energy is the one reality, uncreateable, indestructible.

Mind and Energy. Thus, when the student of Physics turns to the consideration of the *mind*, he is extremely apt to take it for granted that here is just another form of energy, a trifle more subtle, perhaps, than those forms he has been dealing with (though some of these are subtle enough), but nevertheless necessary to be identified with them in the last analysis. Some such view of mind is probably more widely held at the present day by thinking people than is any other view, and appears to be much more securely based than at any previous time. A very popular form of it states that the ultimate reality is motion: mind itself, of course, being thus a form of motion, or, to use other language, a form of kinetic energy. The law of the conservation and endless transformation of energy is now not only familiar to all who have any acquaintance whatever with the sciences, but it is established on a base so broad and sure that it can never be shaken. Hence, it is difficult to resist the temptation to assume lightly that mind also must be a form of energy. The assertion that mind is a form of matter is too obviously ludicrous to be credited; but if we substitute the term energy, suggesting something immaterial, impalpable, elusive, the metaphor or analogy is so good that we are apt to regard it as more than a metaphor, therein being deceived by language, as men have been ever since words were invented.

Can We Measure Consciousness? Now, let us observe two cardinal objections to the doctrine that mind is a form of energy. We are bound, in the first place, to accept the doctrine of the conservation of energy, and hence, on this theory we must believe in the conservation of mind. Other forms of energy are never created or lost, but merely transformed; they can all be resolved into one another; they all tend to become converted into heat or kinetic energy, and they are all subject to precise quantitative measurement. Every one who has electric light in his house is familiar with the phrase *unit of electrical energy*, or *electrical unit*, a term which expresses the fact that energy is a thing which can be measured or weighed, or, so to speak, chopped off in lengths. Were this not possible, plainly we could not have arrived at the truth of the conservation of energy. If we could not measure it, we should never know whether it did not occasionally come into existence out of nothingness, or, on the other hand, undergo occasional annihilation. Now, if mind is a form of energy, the law of the conservation of energy must be shown to be applicable to it. No one has ever *made* even an attempt to do so. The moment the task is contemplated, it is seen to be impossible. How, in the first place, are we to measure mind or consciousness? What unit *of it* can be conceived? What scale like a temperature scale? There is none, nor is there the smallest possibility that any can ever be framed. Very few psychologists have yet come to realise the significance of such a phrase as the *intensity of consciousness*.

The Wise Man and the Fool. In the second place, there are demonstrable and indisputable facts which clearly prove that mind is not subject to the law of the conservation of energy; indeed, an accurate equivalent for the *conservation of energy* might be the *conservation of not-mind*. It is, indeed, true that the brain depends for its working upon the constant supply to it of food materials. It is true, also, that the heat produced by the burning up of these food materials in the brain precisely obeys the law of the conservation of energy. Yet in the course of such burning up of a given quantity of food materials, the brain of a Newton may conceive the law of universal gravitation, while the brain of a fool conceives merely a piece of folly. Indeed there is no reason for supposing that the brain of a Newton may not, on occasion, be the means of production of great mental achievements during the course of the oxidation of much less food material than may be required by another brain which is producing nothing of value.

Mind and "Not-Mind." Furthermore, the food materials employed might have been oxidised elsewhere than in the brain at all, and in either case would have produced exactly the same amount of heat energy. Whatever the circumstances, the law of the conservation of energy is strictly observed ; yet in the last case we have supposed, the transformation of energy is accompanied by no mental product whatever. If, then, the transformation of a given amount of potential chemical energy into kinetic energy may, in one instance, be accompanied by no mental products, and in other instances be accompanied by mental products varying in value from nothing at all to a value which no language can express, it is surely evident that the law of the conservation of energy is ludicrously inapplicable to the facts of mind. Universally, invariably, and rigidly true elsewhere, it is simply irrelevant when we come to deal with mind. We would insist upon this fact ; for, in the first place it absolutely disposes of the *popular but uncritical and wholly false doctrine* that mind is a form of energy ; and in the second place it furnishes the most striking of all proofs, in the judgment of the present writer, of the immeasurable gap, the incalculable difference, between mind and not-mind. In our opinion, the law of the conservation of energy is precisely equivalent to a law of the conservation of not-mind. It is unquestionably the greatest exact generalisation in the physical sciences, but it has no place or applicability in the science of mind.

And, finally, let us note a last objection to the doctrine—a doctrine which is, in reality, a new variety of materialism—that mind is a form of energy, like heat or motion. The objection consists of a criticism which would never occur to the physicist, but which inevitably occurs to the psychologist. For when we come to analyse this idea of energy, what do we find ? Surely we find that it is, like all our other ideas, a product, in a sense, of the mind, and dependent upon the nature of the mind itself. But, obviously, it is wholly illogical and indeed childish to assert that the mind, to which we owe the idea of energy, is itself merely a form of that energy of which we have no idea or knowledge, save in virtue of the activity of the mind itself.

Mind is not a Physical Thing. This wild notion is, indeed, absolutely parallel to the notion of Huxley, that consciousness is what he called an *epiphenomenon*—a sort of accidental and wholly unnecessary by-product of the physical activities of the brain. For Huxley, and, indeed, all who hold the view that mind is a form of energy, believe all external things (the brain included) to be *phenomena*—that is to say, appearances or things appearing to someone. That is all very well, but it does not do thereafter to regard the someone to whom the phenomena appear—*viz.*, the perceiving mind—as itself a secondary phenomenon or epiphenomenon.

What a ridiculous theory is this which regards the mind, to which all other things appear and by which all other things are known, as itself no more than an appearance—and an appearance of quite second-rate importance—being, indeed, a sort of accident : not even a phenomenon, but merely an epi-phenomenon ; not even a product, but merely a chance by-product. So much for the most widely held and most indefensible of those physical views of mind which have gained such currency in consequence of the spread of the knowledge of the physical sciences without a corresponding spread of knowledge of the mental sciences. There is no mental philosopher, nor probably ever was, that regards mind as a physical thing. The doctrine in all its various forms owes its currency to physical philosophers like Huxley and Clifford and the German materialists, who have dogmatised about psychology without any previous training in the subject, and especially without any conception whatever of that vastly important branch of inquiry which is known as *epistemology*, or the theory of the knowing process.

We cannot spare more space at present for the philosophical aspect of our subject, which is, however, supremely important, and could not be wholly ignored. Let us turn to its least philosophical and most purely scientific aspect.

The Business of the Nervous System. The reader is already acquainted with the main facts of the nervous system. He is aware that it consists of a central portion—the brain and its continuation, the spinal cord—and of an outlying portion composed of innumerable nerves. If we examine the history of the developing individual—that is to say, if we call in the science of *embryology* to our aid—we discover the extremely significant fact that the whole of the nervous apparatus, without exception, has been developed from the surface of the organism. Historically, thus, the nervous system is evidently what we know it to be for other reasons—primarily and essentially a means of recognising what is outside us. Locke knew nothing whatever about embryology ; the science did not exist in his day, but it has provided us with the most striking and significant confirmation of his view that the origin of all our ideas is to be found in sensation. For this new science demonstrates that the nervous system in its development is, so to speak, a product of the skin, a product of the exterior of the body—that part of the body which is next the external world, and which directly receives influences from it.

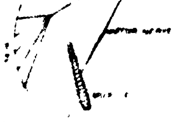
Plainly, this fact is in precise accordance with the view of Locke. Embryologists have proved by direct observation that the external layer of the developing embryo gives off a certain portion of itself in the form of a groove, later separated from the surface altogether and converted into a canal. This canal, lined by cells derived from the skin, ultimately becomes the central canal of the central nervous system, and the cells around it develop into the brain and spinal cord. Thus, perhaps, the first important fact for the psychologist to note concerning the nervous system is that the details of its history afford a most signal confirmation of the doctrine that sensation is the primary fact of mind.

The Avenues of Sensation. But the purely anatomical and physiological study of the nervous system throws even more light for the psychologist upon this very point. The reader is already aware that the nervous system consists, in brief, of nerve cells and nerve fibres. Now what do we find to be the cardinal fact of their arrangement? It is that—to reduce the vast complexity to a simple scheme—the nervous system consists of an immense multitude of what are called *reflex arcs*, closely interconnected with one another. Now the scheme of a reflex arc is simply this: (1) a nerve fibre running from the surface of the body to the centre; (2) a cell which receives the sensation thus conveyed; and (3) another nerve fibre running outwards from the cell to a muscle, which tends to contract—this being the ultimate consequence of the passage of the sensation along the centre-seeking nerve. This contrasted pair of nerve fibres, together with a nerve cell, constitute the simplest possible representation of a reflex arc. All the nerves that run centrewards are called centripetal (that is, centre-seeking), or afferent or *sensory*; while those running outwards from the central nervous system to its servants, the muscles, are called centrifugal or efferent or *motor*. The simplest conceivable nervous system consists of just one such reflex arc as we have described. The nervous system of man consists of millions of such arcs all joined up with each other, so that one afferent impulse may give rise to an efferent impulse in one or another of thousands of efferent nerves; while, on the other hand, one and the same efferent nerve may be excited in consequence of a sensation incoming through any one or any set of thousands of afferent nerves.

Everything Has Sensation. It has already been briefly noted that the French thinker Descartes must be credited with the first clear understanding of reflex action. To-day this subject constitutes one of the most important in the whole realm of psychology, not only on account of its own interest, but because of its all-important bearings upon the whole subject of will. The description of a reflex arc already given makes plain the meaning of a reflex action; but instead of considering one such reflex arc, let us consider the nervous system of man. What we find is that the reflex arcs of the human nervous system are arranged in an ascending order of control, so that—in a fashion it would take a volume to discuss properly—the higher levels of the nervous system are able to control and determine the behaviour of the lower levels. Furthermore, the whole series of occurrences in these lower levels of the nervous system is almost entirely unknown to our consciousness. Hence it is extremely common to describe reflex action as action which is independent of sensation. Now the physiologist may let pass such a phrase, but the psychologist certainly cannot. The psychologist is assured that away down in these little-understood regions of the nervous system sensations of sorts certainly occur. It is impossible to regard any reflex action as independent of sensation. Sensations cannot be denied even to the simplest living cell that has no nervous system at all. No one can question the occurrence of sensation in the lowest organisms who has watched through the microscope a conflict between a white-blood cell and a microbe.

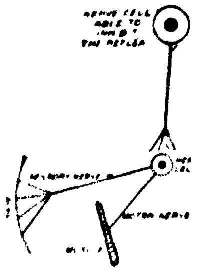
Self-control of the Nervous System. On the contrary, we must define reflex action as action which is independent of the will. We must drop altogether the old distinction between a *reflex* act and a *sensori-motor* act. We must regard all reflexes as in reality *sensation reflexes*; and the two great classes of acts which we must distinguish are the *sensation-reflexes* and *voluntary acts*. We are now able to understand the significance of what has been said regarding the control exercised by the various levels of the nervous system upon the levels beneath them. This control has the technical name of *inhibition*—one of the most important terms, since it expresses one of the most important ideas, in the whole of psychology. In virtue of this power the higher levels of the nervous system, and especially the highest level of all, are able to control the lower levels—that is to say, the lower reflex arcs—in such a way as to arrest completely the performance of reflex actions which would otherwise take place. Indeed, we may regard self-control—that is to say, the self-control of the organism as a whole—as the most important function of the higher levels of the nervous system.

Is Movement Unconscious? Reflex action is simple enough to understand; we can readily figure to ourselves the passage of nervous energy inwards along a nerve, the termination of which has been stimulated by, for instance, a ray of light. Then we can conceive how this nervous energy is transformed in the nerve cell and passes outwards again to a muscle, which moves in consequence. That, essentially, is just what happens when we close our eyelids in consequence of our vision of something which threatens the safety of the eye. But suppose we take the case of the boy who is able to keep his eyes wide open in spite of the tendency to close them when another boy makes the action of striking him in the face. It is incalculably more difficult to understand what happens in such a case; but, at least, we can draw a diagram which clearly indicates the state of affairs and which, though so simple, does really correspond to the actually observed facts of the anatomy of the nervous system (see 1). In 1 we have a simple reflex arc, the afferent, centripetal, or sensory impulse from the skin being transmuted in the nerve cell into an efferent, centrifugal, or motor impulse, which throws a muscle into responsive or reflex action. In 2, however, we see the same reflex arc under the rule of a nerve



1. SIMPLE REFLEX ARC

cell lying at a higher level in the nervous system, which is enabled, by means of its nerve fibre, to inhibit the reflex, or allow it to proceed, according to circumstances.



2. REFLEX ARC WITH INHIBITION

Now there are two opposed views, both of extreme interest, which are held as to the interpretation of these facts. The older view is that advanced by Herbert Spencer in his pioneer study of the evolution of the mind. For convenience, we may express it in a much more extreme form than he ever held. In this extreme form, the theory would be that all movement is originally unconscious and reflex, and that the will has been evolved from reflex action and from the gradual control of reflex action by the remarkable faculty of inhibition.

Voluntary Actions Become Automatic. On the other hand, there is the theory which has been advanced by Spencer's successors, and notably by Prof. Wundt, that all movement is originally voluntary and purposeful—even the simplest movements of a microbe, for instance. Wundt maintains that, as the animal world has evolved upwards, the conscious and deliberate factor in the large majority of movements has disappeared, and they have become reflex. Thus, for him, will is not evolved from reflex action, but reflex action from willed or volitional action. Both Spencer and Wundt insist upon the remarkable fact with which we are all so familiar, that actions which were formerly under the immediate and continuous control of the will constantly tend, when practised, to become reflex, involuntary, automatic and unconscious. This is true of walking, for instance, of learning to play any game of muscular skill, and, indeed, it is true of nine-tenths of all the actions which we perform.

The controversy is far too long and too difficult to be pursued here. Enough, if the reader notes the existence of this difference of opinion amongst psychologists as to the historical relation between reflex and voluntary action. Every reader who cares to think about the subject at all will be able to evolve for himself many arguments, some of which will tell on one side and some on the other. If space availed, it might be shown, we think, that with a little modification the opposing views can be reconciled.

Sensation and the Senses. We are all familiar with the five senses—the five gateways of knowledge—and, unfortunately for the progress of psychology, we are apt to think that there are no more. But even confining ourselves to external sensation alone, we very soon discover that, in the first place, certain animals appear to possess senses unknown to us, and in the second place, that our own senses need analysing. Take, for instance, the so-called sense of touch: we actually include, under one term, a whole series of senses, each of which has its own special kind of sense organ, which are definitely known to be conveyed in special and independent paths of their own along the spinal cord. The word *touch* should really be applied to the *sense of resistance*. In addition to this, there is the sense of *pain*, which takes a nervous path of its own; the sense of heat, and the sense of cold. These last two are quite distinct from one another. Our skin, indeed, is covered with "hot and cold spots," of which the first appreciate a rise in temperature, while the second appreciate a fall in temperature.

Our Many Senses. But, in addition, we have a number of internal sensations which are of the utmost importance. There is, for instance, the so-called muscular sensation, which informs us of the position of our limbs and the various parts of our body in space. This, however, appears to arise less in the muscles than in the joints, the skin, and the structures called tendons, by which the muscles are attached to the bones. Without the muscular sensation it is absolutely impossible to do any muscular act of any complexity at all. It is, for instance, quite impossible to stand, let alone walk. Closely allied to this—in, at any rate, its value for us—is the *sense of equilibrium* or equilibration. The function of this is to enable us to preserve our equilibrium, and it has a special characteristic end-organ of its own, known as the semicircular canals, three of which lie in the three axes of a cube or the three dimensions of space, near the internal ear on each side of the head.

By way of showing how imperfect was our knowledge of psychology when we used to talk of the five senses, it may be noted that it is absurd to speak, as we do, of the *auditory nerve*, as if it were the nerve of hearing alone. It has scarcely yet been fully appreciated that the organ of hearing and the organ of equilibration, the internal ear and the semicircular canals, though so close together, are yet two independent organs of two independent senses, each having its own independent nerve fibres. The auditory nerve, so called, is thus really two distinct nerves—the nerve of hearing and the nerve of equilibration; and of this there can be no doubt when we find, on tracing the nerve fibres to their ultimate destination in the brain, that the fibres of one sense soon part company from those of the other, and the two sets run to two very different parts of the brain, so remote, indeed, that they have scarcely any connection with one another.

Briefly alluding to other internal senses, such as the sense of hunger and the sense of thirst, we must note the existence of an enormous group of slight and vague, but important, sensations which reach us from our internal organs.

The Sense of "Feeling Fit." The phrase that best describes the whole mass of vague and barely recognised sensation which reaches us from our internal organs is undoubtedly *organic sensation*. In health, the total result of this group of sensations upon consciousness is usually described as the *organic sense of well-being*.

This sense of "feeling fit" or "in good form" may be regarded as, on the whole, the most valuable sign of health that exists. In a very large number of diseased conditions, the organic sense of well-being, which is, at bottom, the most important factor of all in the happiness of every man and woman, is abolished; or, worse still, is replaced by an organic sense of ill-being which is more or less familiar to all of us and which is the most radical and essential character of that whole group of diseases of the mind which are usually classed under the name of *melancholia*.

Perhaps the due recognition of the importance of organic sensation is as important as any of the discoveries of physiological psychology. For it provides us with the key to the understanding of many of the mental symptoms of various diseases; a recognition of it is essential to the student of insanity, and it is of immense importance in understanding what we may call the normal mind, and especially the varieties of emotional character, of temperament, and of mental energy.

"Seeing by Memory." In so brief a course as this, it is necessary to deal with the whole subject of sensation very concisely, but before we leave it, we may at least describe in outline what is perhaps the most important instance of the building-up of our sensations into complex ideas. Kant, as we have seen, regarded our idea of space as a "form of the mind," inherent in its constitution, and not given in experience; but now we know very differently. By a series of observations and experiments, we have been able to prove that our idea of space is built up from a large number of indications furnished by many and various senses. There is, perhaps in the first instance, the sense of vision. When we look out of one eye we perceive things in two dimensions of space only, *breadth* and *height*; we see them on the flat. The reader will certainly and rightly question this statement; he will say that when looking out of one eye he does not see things on the flat; but we now have to remember that all the sensations of adult life are complicated by memory and experience. These it is which give us the impression of depth and perspective, even when looking out of one eye, though it is undoubtedly the case that the image which is planted on the retina has only two dimensions, and that external objects would appear to be all in one plane to an eye which had not been instructed by past experience.

How We Realise Space. In what is called binocular vision, however—that is to say, vision with two eyes at once—we receive two views of one object, which differ in, literally, their point of view; they are taken at slightly different angles. Our combination and comparison of the two images thus formed gives us the impression of *depth* in addition to the impressions of breadth and height for which one eye alone would suffice. Vision is thus certainly an important factor in the formation of our ideas of space, but it is doubtful whether other factors are not of greater importance. Great value must be attached to our sensations of movement, reaching us from the joints, muscles, and skin, whereby we become acquainted with the position of the various parts of our own person in space, and which undoubtedly contribute towards the gradual formation of the idea which to the adult's mind seems so obvious. And of no less importance is the organ of equilibration, the six semicircular canals, three on each side of the head, which are arranged in the three dimensions of space.

Movements of the head, in any direction or combination of directions, are unfailingly registered in health by means of a corresponding movement of the fluid in one, two, or three pairs of these canals—such movement stimulating the ends of the nerves of equilibration, and being appreciated probably by the cerebellum or hind brain. Hence it happens that after long rotation in one direction—as, for instance, in waltzing—we acquire a giddiness that can be relieved by "reversing," which reverses the direction of movement or pressure of the fluids in the horizontal pair of semicircular canals.

In the lowest vertebrate animals we do not find these canals at all; they are not present, for instance, in the fish; they occur in birds, however, and the physiologist Flourens was able to prove, by observations on the pigeon, how close is the connection between each pair of semicircular canals and movements of the head in the corresponding direction. Observations in what is called "Ménière's disease"—the chief symptom of which is giddiness, and which is due to disease of these semi-circular canals—have shown that the giddiness which ensues from disorder of these canals corresponds to the direction of the particular canal or canals which *may be affected*. If these, for instance, be the horizontal canals, it is the movement of shaking the head, or movement in the horizontal plane, that upsets the equilibrium of the patient.

What is Space? Some years ago the argument was advanced by the present writer that the number and arrangement of the semicircular canals may be regarded as a proof, or at any rate a fact tending to prove, that our idea of the tri-dimensional character of space is a true one. The philosophers known as idealists, for instance, deny that any real validity can be attributed to our belief in the tri-dimensional character of space; while the mathematicians have invented what they call *hyperspace*, and can construct theories or solve problems concerning space of four dimensions or of *n* dimensions.

Now, it is certainly *no argument in favour* of the actuality of our tri-dimensional notion of space that the organ of equilibration consists of three canals at right angles to each other. Indeed, our opponents may say that we believe space to be tri-dimensional simply because we happen to have a tri-dimensional arrangement for appreciating it. But evolutionary considerations, we believe, raise another question, and it is this: If space be not really tri-dimensional, why should there have been evolved within our heads a tri-dimensional arrangement for appreciating our position in it? Surely the evolutionist's answer to this question would appear to be that the fittest type of organ of equilibration survives; that the fittest or most useful type of such an organ would be one that most truly acquainted its possessor with the fact; and thus that the tri-dimensional character of the organ of equilibration is most satisfactorily to be explained on the ground that space *is* tri-dimensional, and so favoured the evolution of an organ having this character.

But whatever the truth on this matter may be, it is, of course, quite idle any longer to speak of space as a *form of the mind*. On the contrary, we have to recognise that our idea of space is a gradual and complicated acquirement, dependent upon the long and co-ordinated experience of many different senses. Whether the idea is in true correspondence with external reality, we cannot indeed say; and though that is a question of even greater interest, it is, at any rate, a very great advance to have achieved an understanding of the idea of space, such as was entirely impossible for the psychologist who died scarcely more than a century ago.

Our Senses Help Us to Stand. Finally, we must note that the success of equilibration—that is to say, of preserving our balance—and also that success in all those arts and games and technical procedures, such as threading a needle or building a Forth bridge, which depend upon an accurate estimation of space—that such success is conditioned, not by any form of the mind, but entirely by a due co-ordination of all the senses that are involved. It was stated above that the fact of balancing ourselves is accomplished by means of the semicircular canals—that is to say, by the organ of equilibration. But it is of great significance to observe that the indications of this organ alone are quite inadequate for all our practical purposes, just because our idea of space depends upon so many other indications beside those which it furnishes. The nerves of the soles of the feet, for instance, are of great value in helping us to balance ourselves when standing. If these nerves are thrown out of action—as by painting the soles with a strong solution of cocaine or some other local anaesthetic—the art of standing erect is made much more difficult. Our eyes are also of great use in helping us to preserve our equilibrium. In the lamentably common nervous disease known as *locomotor ataxia*, the spinal cord is so affected that sensations cannot properly travel from the soles of the feet or from the muscles, joints, and skin, which are involved in the act of standing. In very severe cases, the eyes cannot save the situation; but in much less severe cases the patient may be able to stand erect with his feet placed close together, so long as his eyes are open. When he shuts them, however, the task of preserving the bodily balance is found to be too much for the unaided organ of equilibration, and the patient sways and falls.

Co-operation of all the Senses. One other *term* which should be familiar to every student of psychology must be discussed in this connection. Not one of the purposes for which we employ any of our muscles could be accomplished if we were not able to combine various muscular groups for particular movements and, very often, to control the movements of those groups by setting in action, though much less powerfully, other groups of muscles which tend to oppose them. In bending the arm slowly, for instance, it is not the case that the action depends solely upon the contraction of the biceps muscle. There is also acting, all the time, the muscle on the back of the arm which is known as the triceps, the unopposed action of which would be to extend the arm. If it were not for co-ordination our lives would be impossible. The power of acquiring this amazing art, which is exhibited in every voluntary action and in very nearly every reflex action, depends upon the combination and co-operation of all the senses, chiefly and most essentially for the establishment of an accurate and constant and invariable idea of space.

A Great Discovery. The term *co-ordination* is commonly used by psychologists of actions or movements, but it should just as properly be applied to sensations. It is by means of the co-ordination of an extraordinary number and variety of sensations that we obtain the idea of space, which without co-ordinated movement would be impossible. The co-ordination of motion depends upon the co-ordination of sensation, and too much emphasis cannot be laid upon the complete reversal of Kant's doctrine regarding this, which is, perhaps, the most important of all ideas. That which Kant thought to be a form of the mind, prior to all experience, conditioning all experience and interpreting all experience for us; that which he thought to be a simple and indivisible form of knowledge, is now known to have the most complex and varied origin in the co-ordination of the indications of senses having their localities as far apart as the eyes and the soles of the feet. This great discovery is, perhaps, the most precious fruit of the recent union of psychology and physiology.

THE VIOLIN

The Demands of the Instrument. Names of the Parts. Buying a Fiddle. The Strings and Bow. Tuning. Time. Exercises

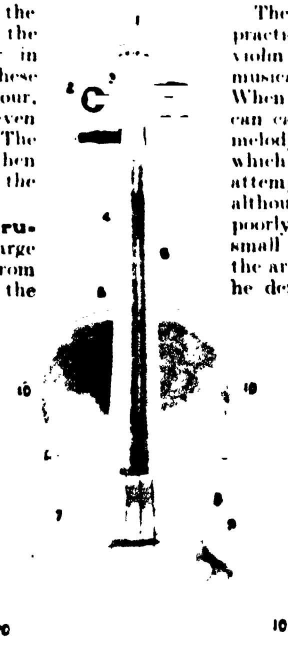
Continued from page [illegible]

By ALGERNON ROSE

THE precursor of the violin was the viol of the Middle Ages. As early as 1200 the word "violin" is mentioned in the legendary life of St. Christopher. It is an abbreviation of the Italian violino, the latter implying the diminutive of the great violone, or double bass. There were four chief patterns of viols. The smallest of these, termed the treble, or discant viol, was superseded by the Italian violin. The next size interpreted a deeper part. It was known then, as now, by the name of viola. Thus, our tenor violin is the only instrument of the group of fiddles retaining to-day the name borne by its predecessor in mediaeval times. Certain of these tenor viols, like the viol d'amour, had seven fingerboard and seven additional strings underneath. The latter, vibrating in sympathy when those above were bowed, gave the instrument a peculiar quality.

Construction of the Instrument. The violin, whether of large or small pattern, is differentiated from all other musical instruments by the strings being set into vibration through the friction of rosined hair. In the old rota, and, later, the hurdy-gurdy, this was effected by means of a wheel instead of a bow. In the violin we have a survival of the fitter method.

Votaries of the violin point to the fact that, whereas other instruments are always being modified or improved in some way, during the past three hundred years the fiddle has undergone no change in construction. Considering that sensitive musicians are somewhat given to fault-finding, and that thousands of them have not only been entirely satisfied with the instrument, but have shown an intense love for it during that long period, the beginner may well regard it with reverence. Apart from this, since violin evening classes have been instituted by the London County Council, it is evident that we are on the eve of a popular development in violin playing. Although a temporary check may have been put on pianoforte teaching, owing to the spread of mechanical players, there is little likelihood of the inventor encroaching on the preserves of the violinist.



1. THE INSTRUMENT

Practice. The importance of the violin cannot be overestimated. It is the chief, or leader, of the group of bowed instruments which forms the basis and body of the material constituting the modern orchestra. The greatest of the composers, therefore, have made a careful study of the violin and its kindred. At the same time, although indispensable for the achievement of collective effects in a concert-room, there is no other orchestral instrument which can show such a roll of honour of world-famous solo players.

The instrument demands industrious practice. The fact that to excel on the violin is at first uphill work makes a musical hero of the successful student. When he presently discovers that he can captivate his hearers by a simple melody, after the mastery of studies which appeared impossible when first attempted, he has his reward. Thus, although violinists, as a body, may be poorly paid, the instrument itself in no small measure mentally compensates the artist by the ever-growing pleasure he derives from his close association with it.

The Parts. The pianist may win a scholarship at a chartered institution without knowing why the bent side of a grand is on the right instead of the left of the keyboard, or without being able to describe the difference between a hammer-butt and a balance-rail. But the fiddler prides himself on understanding every detail of the anatomy of the violin. As a consequence he looks after his instrument more intelligently. He is able to comprehend its many moods—for a fiddle can catch cold like a human being. If properly cared for, it recompenses the player by the extra pleasure it gives.

The student should now turn to 1; the numbers attached refer to the different parts.

The *Scroll*, or *Head* (1). Its base forms the *Peg-box*. This bears the strain of the four strings, approximating to 68 lb., but the total pull of a heavily-strung fiddle has been known to reach 80 lb. The weight of the scroll also gives as much equipoise to the instrument as the extra heaviness at the stock of a rifle makes that weapon more easy to handle. The *carved ends* at either side of the cheek are called *volutes*, an architectural term denoting the spirals in Ionic and Corinthian capitals.

The *Tuning-peg* (2). It is bored in the shank with a *String-hole*. If the peg be too firm, ease it by rubbing it with a little dry soap.

The *Peg-hole* (3) is bored through both cheeks of the peg-box. The lowest hole bears the heaviest string, the next the lightest, the one above the second heaviest, and the top hole the second lightest. In this manner the strain is distributed evenly.

The *Neck* (4). This is covered in front with the ebony *Fingerboard* (6). No matter how good the tone of the *body* of the instrument may be, if the neck is not well proportioned and the fingerboard fixed at the proper angle, the cleverest player cannot make the fiddle sound to advantage.

The *Shoulder* (5). The shoulder is the part under the base of the neck. It supports the hand of the player when fingering in an upper register.

The *Belly* (10), carved in an arched or bulged-out manner, is pierced by two sound-holes (7 and 8). These, on account of their shape, are called *f holes*. The belly, being of silver pine, the most elastic of known woods, acts as a resonator, and amplifies the initial tone which comes from the strings down through the *Bridge* (9). So as to get the pulsations of the strings swinging through its two feet over the whole soundboard and the body of the instrument, it is important that the bridge should be of the right height and material. Hard beech is most satisfactory. On the top of the bridge are four *chimbs*. If these nicks get too deep, the strings, when tuned up, will rise in jerks instead of stretching smoothly. The inlaid lines, of black wood between fine strips of white plane-tree round the margin of the belly, are known as the *purfling*, which, by binding the fibres together at the border, preserve the edges of the instrument.

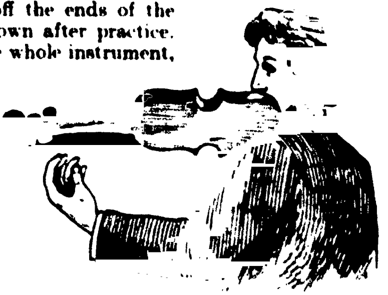
The "Body." The belly is connected by curved *sides*, of a carefully calculated depth, with the *back*. These three parts form the *body*, which is so graduated internally as to enclose a mass of air necessary to produce 512 vibrations per second. Jammed between the belly and the back is the *soundpost*. Without this little rod, the violin lacks its sustaining qualities. By uniting the opposite sides, the soundpost permits the circuit of vibration to complete itself, and enables the sound-waves to act and react on each other freely. Another great nerve in the fiddle under the belly is the *bass-bar*. This extends from the left foot of the bridge in a slightly slanting direction. To explain the influence of this bar, it may be mentioned that every piece of wood has a definite tone when struck, if one has the ability to hear it. The great fiddle-maker, Stradivarius, on completing a belly of sonorous pine, found that it emitted the note C. After cutting the *f* holes, the pitch was lowered half a tone to B. Thereupon, he accelerated the vibrations by adding a bass-bar. This raised the sound to D. He then reduced the thickness of the bar until the belly responded with the note he wanted, C. But if the belly sounded C he tuned the pitch of his backs to D, always a tone higher.

For the *Tailpiece* (11), glass, ivory, and various metals have all been tried, but plain ebony is best. It will be noted that between the edge of the tailpiece and the bridge there is a space of about 1¾ in. where the strings are not played upon. The length of this un-bowed portion is mathematically calculated. It has a great influence on the character of the tone. Although the bowing is done below the bridge, when the long segment of the string there is set into vibration, the unused remainder of the strings reinforces the sounds by emitting what are called overtones, which add to the brilliancy of the notes. These sympathetic upper partials may not be perceptible to ordinary ears. If a piece of heavy felt is wrapped over the strings from the tailpiece almost as far as the bridge, the difference in quality can be proved. At the broad end of the tailpiece are four slots, or eyes, to receive the ends of the strings. The outline then diminishes before it terminates. The small bulb at the end is called the *saddle*. In this are a couple of holes. These receive the *loop* of thick black gut which fits round the *tail-pin*. The latter is fixed firmly into the *tail-block*. This, before being glued into its place, furnishes a spy-hole for the maker to see that all is right inside before he closes it up.

Buying a Fiddle. When choosing an instrument, do not expect to pick up a bargain for a small sum, especially at a pawnbroker's. Refrain from answering catchpenny advertisements, and disregard an old name on a label inside any instrument offered for less than two figures. In every large town a repairer of violins is to be found. Seek out such a craftsman. His tribe is invariably enthusiastic, and useful hints may be gained from him.

Because great players possess old instruments bearing famous names, it does not follow that an ancient fiddle is invariably better than a modern one. The reverse is the case if the purchase is limited to about £2. For that sum an excellent copy of a good model may be obtained from well-known London firms, such as Hill, Withers, or Hart. Unless the beginner's fingers are diminutive, it is better to get a full-sized instrument. In the former case, a three-quarter or even a half-sized instrument may be advantageous. In the latter instance, the length of the string from the bridge to the nut on the fingerboard should be approximately 13 in., and the total length of the body nearly 14 in. If the violin is required for orchestral work, choose a flatter belly than if for solo playing. A flat model has more penetration of tone. A fuller curve is calculated to produce more mellowness, or sweetness.

Strings. The same consideration applies, in a lesser degree, to the gauge of the strings used. A set of the thickest gives fulness at the expense of brilliancy, whilst the thinnest give brilliancy at the expense of fulness; moreover, the latter are more liable to break. Medium gauge is preferable. Before putting on a string, see that it has not become untwisted. Make a small loop at one end of the thinnest, or E string. Slip this through the aperture in the tailpiece. Draw the rest of the string through the loop. With the other end, thread the eye of the tuning-peg. A pair of tweezers is useful for drawing the end through the other side. The other three strings do not require a loop; a double knot suffices to keep them in their places on the tailpiece. After screwing up the pegs, cut off the ends of the strings. Do not let them down after practice. This alters the tension on the whole instrument, and when they are screwed up again they will never keep in tune.

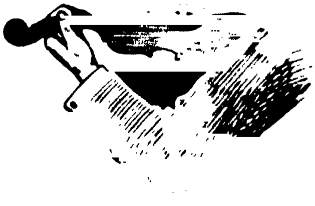


2. CHIN-AND-SHOULDER GRIP

The Bow. If a serviceable violin can be purchased for £2, a suitable bow is obtainable for 5s. or less. In selecting, be careful to get a straight, flexible and light stick. The whole should not exceed 2¼ oz. in weight. See that the screw works properly. The best hair is that from the tail of a white horse. One hundred hairs are used, and they should not cross over one another. The hair of horses is whiter and less greasy than that taken from mares. Some players nowadays affect very long bows, several inches in excess of those of the celebrated Tourte pattern. Avoid extremes. Choose a bow of medium length. Get a box of purified rosin for a few pence.

Another small item usually incurred is the purchase of a "chin-rest." Great players formerly were content to make a pad of their handkerchief. But a plain ebony chin-rest gives increased firmness when holding the instrument. Spohr's fiddle-holder was fixed immediately over the tailpiece. Nowadays, the accepted place is to the left of the tailpiece over the body of the violin. An advantage claimed for the chin-rest is that it does not damp the vibration of the belly, as is partially the case when the latter is pressed by the lower jaw.

Soundpost and Bridge. Sometimes an otherwise good fiddle may sound very dull in tone owing to the wrong position of the sound-post. This little cylinder inside the instrument, as has been explained, supports the bridge, and is placed under its right foot. The middle of the left foot of the bridge must stand exactly over the bass-bar, the position and breadth of which can be discovered by a thin hooked wire being inserted through the *f* hole. A slight adjustment of the soundpost, with what is called a soundpost setter, may greatly improve the tone.



3. KEEPING THE WRIST DOWN

Or perhaps the reason of the dulness is because the bridge is too high. The outline of the top of the bridge is regulated by the arching of the belly. It always slopes more over the E string than over the one covered with wire, so as to enable the latter to be more easily bowed. The back edge of the feet of the bridge should be in a line with the inner notches of the *f* holes.

Tuning. Each of the four strings of the violin has a different gauge. The thickest of the four is the D, although that does not give the lowest sound. The bass string, being artificially weighted with wire, is only a little thicker than the A, or second string. Copper-covered strings are less expensive than those with silver. Their tone is often as good, but their surface is more apt to corrode. When a gut string is put on the tone is sometimes false. This may be due to an error in the make, or to the fact that the string has perished. A dull or spotted appearance indicates the latter condition. Good strings are pale yellow, transparent, and glossy. In any case a false string is worthless. To keep spare strings in good condition, enclose them in an air-tight box wrapped in oil-silk. Always buy the best quality of strings. Avoid "acribelle," or silk strings; they are liable to fray, and their sound is generally undesirable.

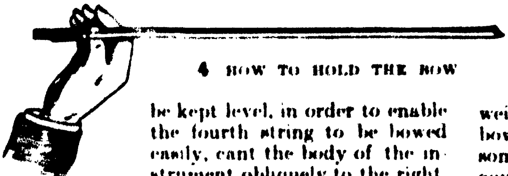
Tune the second string to A—second space, treble clef—by a tuning-fork or piano. If a piano is unavailable, sets of four pitch pipes can be obtained for a small sum. If too low in sound, screw the string up gradually. It may break if the tension is increased suddenly, or the string is wound too far. When turning the peg and twanging the string, watch the bridge. If the string pulls it forward, release the strain slightly, or the bridge may fall and break.

Tune the third string to D, a perfect fifth below A, and the fourth string to G, a perfect fifth below D. Lastly, tune the first string to E, a perfect fifth above the A of the second string. If it does not sound flat enough, a pressure of the thumb along the string should suffice to stretch it to the lower pitch without further screwing. If the pegs are loose and they run down, chalk will make them hold better. These four strings give the natural, or "open" notes of the violin.

Attitude. The first exercise is to learn to bow the four open notes properly. To do this, the beginner must hold himself and his violin correctly. He will be seen at his best—as well as at his worst—when he plays standing. Hold the body erect. Keep the feet slightly apart. Throw the weight on the left foot. Avoid assuming any position which is unnatural. Nothing looks worse than a fiddler who stoops, sticks out his elbows, or lets his instrument droop in front whilst he scrapes on it limply.

Left Hand. Hold the violin by its neck with the left hand. Lay the tail-end of the instrument upon the left collar-bone. Advance the left shoulder slightly to receive the violin. Incline the head to the left; place the chin on the chin-rest to the left of the tailpiece. The grip between chin and collar-bone should be sufficient to hold the violin horizontally without assistance of the left hand [2].

It is better at first to incline the fiddle a trifle up rather than downwards. Although the axis of the violin from the tail-pin to the scroll should be kept level, in order to enable the fourth string to be bowed easily, cant the body of the instrument obliquely to the right. Place the left hand on the neck, with the thumb to the left and the fingers over the strings. Do not let the neck drop into the hollow of the thumb. Instead, regard the thumb and first finger as a two-pronged fork. Whatever pressure is necessary should be between the ball of the thumb and the second joint of the first finger—half way up the prong. At the base of the fork, the player must keep a free space, so that "daylight" may show between the two digits [3].



4. HOW TO HOLD THE BOW

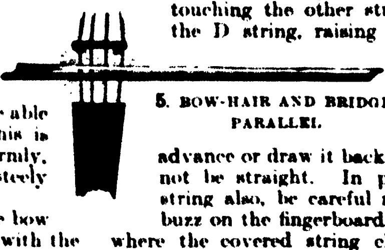
The object of this rule is to keep down the wrist as vertically as possible, well under the neck, so that, later, when the hand is shifted up the fingerboard for playing high notes, it may move freely and uniformly. The tendency of the beginner is to let the wrist advance to support the neck. This is a bad habit, and must be avoided. The instrument should not require any such assistance if held properly by the chin. The thumb acts as a rest rather than a vice when in contact with the neck.

Bend the elbow to the right, well under the centre of the instrument, without leaning it against the player's body. It constitutes a zigzag bracket, which should be free to swing laterally. Paganini, the greatest of fiddlers, crooked his elbow in such a way that it came out at the right side of his instrument. But he was a phenomenon. In violin playing, the position should be as graceful as possible. If good tone is to result, the fingers must be able to move freely and independently. This is only possible when the fiddle is held firmly, and at the same time with a certain steely flexibility.

Right Hand. Having rosined the bow thoroughly from tip to nut, take it up with the right hand [4]. Place the thumb in the hollow in front of the nut, or screw-slide. Rest the first, second, and third fingers on the back of the stick, pointing them to the screw end much in the manner that one holds a pen. The place of the first finger is at the end of the silk wrapped round the stick, which gives it a good hold. The fingers should not touch the hair. While the first finger encompasses the stick, pressure between the second finger and thumb mainly controls the bow movements. If it is necessary to keep the joints on the left fingers well up over the strings, it is equally desirable that the right wrist should be held high, while the fingers, pointing down, are kept close together on the stick of the bow. Do not project the right elbow; hold it close to the side.

Exercise on Open Notes. Place the tip of the bow on the first string midway between the bridge and the end of the fingerboard. Press the tip on the string. Play the open note E, keeping the body steady. Push the whole length of the bow slowly upwards across the string. Instead of trying to crush the tone out of the string by means of downward weight, cultivate a lateral pressure. Pass the bow along firmly, with its stick inclined somewhat to the right, as if cutting the string equally with a sharp knife. What is wanted is not vertical, but an even sidelong weight. To get this, keep the bow parallel with the bridge and at right angles to the strings until the nut is reached [5]. As the bow ascends, curve the wrist gradually more and more; make the wrist movement artistically. If the beginner has a chance of seeing Lady Hallé play, he will understand how beautifully this can be done. The action should be light rather than heavy; but whilst supple, there should be no display of weakness. As slowly, draw down the bow until the tip again reaches the string. Throughout each bow movement, the stroke should be of equal length and equal duration. Do not be discouraged if the effect is rough and squeaky; the coarseness will diminish with practice on the beginner bearing in mind to try always to cut the string figuratively by the sharpness of the bow.

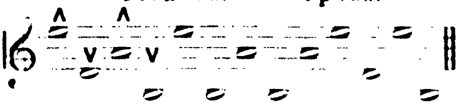
Having tried the E string, take the A. Simple as it may seem, to hold both the instrument and bow correctly requires as much self-discipline as holding a rifle in order to shoot properly. As the A string is higher than the E, begin with the nut of the bow slightly elevated, compared with its position on the first string. Do not be satisfied until the note is produced steadily without touching the other strings. Then take the D string, raising the right elbow a little; lastly, go to the G. The elbow is now more elevated; take care not to advance or draw it back, or the bowing will not be straight. In playing the fourth string also, be careful not to let the wire buzz on the fingerboard. In some fiddles, where the covered string chatters chronically under pressure of the bow, the defect has been cured by a slight hollowing of the fingerboard at its wider end, so as to give increased space for the vibrations.



5. BOW-HAIR AND BRIDGE PARALLEL

Repeat the foregoing exercise quicker, bowing four strokes to each string. A flute player, when he practises, cannot count aloud. Make use of the advantage which the violinist has in this respect. Imagine that the beginner is a recruit on parade, and is being drilled by numbers. On the word "one," pass the bow up its full length; on "two," bring it down firmly; on "three," pass it up again; and on "four," bring it down. Without break, continue the motion on the A, D, and G strings. After four more strokes on the G, return to the D, the A, and finish up on the E. Still counting, next proceed to leap from one open string to another, and then play two open notes at one time, thus:

Λ Down bow. V Up bow.



Stopping. Hitherto, the left fingers have been clear of the strings. The beginner will now begin stopping the notes. Remember, whilst doing so, to keep the left wrist down and get daylight between the thumb and the base of the first finger. Practise these preliminary exercises in front of a looking-glass, so as to contract no bad habits as regards position. See that the scroll of the violin is kept well up, that the bow does not sway from side to side, but passes parallel with the bridge, and that the movements of the arm and body are not jerked, but are made easily.

Now press down the fleshy tip of the first finger on the first string tightly, near the nut of the fingerboard, so as to form a half-tone, F, above the open note E. When the finger goes down, the violin must be kept still, and the ball of the thumb will resist the pressure. Count three. On the word "one," bow the F evenly and clearly; on "two," take off the first finger. With the down bow, play the open E. As the stopped note was less clear than the open note, try the F again with the up bow, pressing the finger well down. Continue on the second string. On this, put down the second finger; it should produce C, a third above the open note A. Count three. On the word "one," play the C; on "two," the open A; on "three," make the C sound better than it did before. Get it well in tune. Proceed to the third string. On this, put down the third finger to produce G, a fourth above the open D. As the third finger is weak, press with emphasis. Count as before. Sound with the up-bow the stopped note G, with the down bow the open D, repeating the up-bow in order to do better than before.

Advance to the fourth string. On this, put down the little finger to stop D, a fifth above the open G. Although the fourth finger is the smallest member of the hand, it is important to the violinist; being the smallest, it should receive special attention. Keeping the midget down firmly, on the word "one," sound the D with an up-bow; on "two," raise the little finger and play the open G; on "three," repeat the up-bow, getting a better result. Try the G string exercise again; then go back to the third string; put down the fourth finger with that also, and stop A, a fifth above the open D. Proceed to the second string; put down the third finger, sounding D, a fourth above the open A.

Lastly, put down the second finger on the first string, stopping G, a third above the open E. To make the motions even, it is advisable to practise with a metronome, as drummers do in the Army. If a metronome is not available, regulate the strokes of the bow to so many ticks of the clock. Avoid beating time with the foot, and do not sway the body.

Time. We have laid stress on the desirability of the student drilling himself by numbers. From the onset he should appreciate the value of playing in time. He should realise that each bar in Common Time is marked by four equidistant beats. However long or short various notes or passages played within one bar may be, the four beats should pulsate as regularly as the heart. Many amateurs who take up the fiddle as a pastime fail to cultivate this feeling. The result is that they may gain considerable facility in playing, but are as useless in an orchestra as a civilian who takes a place among a body of soldiers and cannot march in step. He throws the others out. To emphasise the first beat of the bar, it is the rule to play it with the down-bow, the down-stroke being slightly heavier than the up-stroke because of the influence of gravity. For that reason, to make the bowing equal, the player unconsciously gives a slight extra pressure with the up-bow.

COOKERY RECIPES

How to Prepare various Vegetables: Cauliflower au Gratin, Curried Mushrooms, Asparagus with Vinaigrette Sauce, Vegetable Scallops, etc.

VEGETABLES

Boiled Potatoes

INGREDIENTS. Potatoes, salt, water.

Method. Choose potatoes of about uniform size, when possible. Wash and peel them thinly, laying them in cold water as you do so. Put them in a saucepan with enough cold water to cover them, add two teaspoonfuls of salt to each quart of water and let them boil gently till they can be easily pierced with a skewer. Then drain off the water, put the pan back on the stove, shake it about occasionally until the potatoes are dry and floury. New potatoes should be put in a pan of boiling water, and beside the salt should be added a sprig or two of mint.

Boiled Cabbage

INGREDIENTS. The greens, water, salt and soda.

Method. Trim off the thickest stalks and lay the leaves in a pan of strong salted water, to draw out the insects. Next wash them carefully under the tap, put them in a pan of fast boiling water to which has been added one tablespoonful of salt and a pinch of soda to each quart of water. Boil them fast with the lid off the pan till the stalks are tender, then drain them through a colander, with the exception of Brussels sprouts, press them well.

Peas, French beans, Brussels sprouts, savoys, or broccoli are practically cooked in the same way, but for peas add a sprig of mint and a lump of sugar.

Cauliflower au Gratin

INGREDIENTS. One cauliflower, half an ounce of flour, one ounce of butter, one and a half gills of milk, two ounces of grated Parmesan cheese, salt, pepper, and a dust of nutmeg, browned crumbs.

Method. Take the cauliflower, cut off the stalk and trim off all except about four or five green leaves. Put the cauliflower to soak in cold salt water. Boil till it is tender, but not broken in boiling salt water. It will take about twenty to thirty minutes according to the size. Keep it well skimmed. Lift it out carefully, and well drain off the water. Put it on a hot dish and squeeze it lightly together with the hands and a clean cloth. This compresses it and improves the shape. The sauce should be made while the vegetable is being boiled. Melt the butter in a stewpan, stir in the flour smoothly, add the milk, and stir over the fire till it boils and thickens. Season well, and mix in one-half of the cheese. Pour the sauce all over the cauliflower; it should be thick enough to well cover it. Sprinkle the remainder of the cheese and a few browned crumbs on the top. Put it in a quick oven till the cheese is browned, or use a salamander. Serve very hot.

Jerusalem artichokes, vegetable marrow, celery, sea-kale, can all be treated in this way.

Tomatoes à la Savoy

INGREDIENTS. Six tomatoes, four tablespoonfuls of chopped cold veal, two tablespoonfuls of chopped ham, one teaspoonful of chopped parsley, salt and pepper, four tablespoonfuls of mayonnaise sauce.

Method. The tomatoes should be firm but ripe. Cut out the centre piece at the stalk end; then carefully take out some of the pulp, leaving a hollow in which to put the stuffing. Mix together the chopped veal, ham, and parsley; season it carefully, add enough mayonnaise sauce to well moisten the mixture, and fill the tomatoes with it. Place each tomato on a neatly-cut piece of fried bread. Garnish them with a little lettuce, and serve them as cold as possible.

Curried Mushrooms

INGREDIENTS. One dozen large mushrooms, one ounce of dripping, one onion, three teaspoonfuls of curry powder, one teaspoonful of curry paste, one teaspoonful of flour, one pint of stock, a little lemon juice.

Method. Peel and carefully examine the mushrooms. Melt the dripping in a pan, peel and slice the onion, and fry it a pale brown; then put in the curry powder, paste, and flour. Let these fry gently for a few minutes, then pour in the stock and stir over the fire till the sauce boils; season it carefully. Next put in the mushrooms, and let them simmer very gently for about half an hour, or till they feel tender. Put them in a hot dish, and arrange a border of nicely-boiled rice round. About four ounces of rice should be thrown into a pan of fast boiling salted water, and boiled till tender; it should then be drained off, well washed under the cold water tap to separate the grains, and dried in the oven.

Celery Fritters

INGREDIENTS. Three heads of celery, a quarter of a pound of flour, a quarter of a teaspoonful of salt, a quarter of a pint of tepid water, one tablespoonful of melted dripping, the whites of two eggs.

Method. Sieve the salt and flour into a basin, stir into it smoothly the dripping and water. Beat the whites of eggs to a very stiff froth, then add them very lightly to the batter. Wash the celery, cut off the outside sticks, cut the white sticks into pieces about four inches long. Let them cook gently in a pan of hot, salted water till they are just tender. Then drain them, and dry them gently with a cloth. Have ready a pan of deep frying fat, drop a stick of celery into the batter, then into the frying fat, and fry it a pretty brown; drain it well on paper. When all are fried, pile them up in a hot vegetable dish.

Salsify may be treated in the same way. Brussels sprouts are very good dipped in batter and fried.

Asparagus with Vinaigrette Sauce

INGREDIENTS. A bundle of asparagus three tablespoonfuls of salad oil, one tablespoonful of tarragon vinegar, half a teaspoonful of chili vinegar, one teaspoonful of chopped tarragon, one teaspoonful of chopped chervil, salt and pepper.

Method. Trim, wash and slightly scrape the asparagus, cutting the sticks the same length. Tie it in small bundles, put them in a pan of boiling salted water, and boil them gently until they are tender. Then lift them out carefully, drain them well, and arrange the heads neatly on a slice of hot buttered toast. Put all the other ingredients into a basin and mix them well together. Season this sauce carefully, pour it into a sauce-boat, and serve it with the asparagus

Stuffed Vegetable Marrow

INGREDIENTS. One small marrow, two ounces of breadcrumbs, two ounces of butter or clarified fat, four ounces of cold meat or poultry, two teaspoonfuls of chopped parsley, one teaspoonful of chopped shallot, one teaspoonful of chopped mixed herbs, two teaspoonfuls of white sauce or milk, one egg.

Method. Peel the marrow, and cut it in half lengthways. Scrape out all the seeds and soft, woolly part. Chop the meat finely, mix with it the parsley, shallot, herbs, crumbs, seasoning, and melted butter, and then beat the egg and add it also. If the mixture seems dry, add the sauce, but it may not be necessary. Fill each half of the marrow with this mixture. Put the halves together, and tie them in place with a piece of broad tape, then wrap it up in a piece of buttered paper. Put the marrow in a saucepan with water to come about three-quarters up the marrow. Let it boil gently till it feels tender when pierced by a skewer. It will probably take half an hour. Place it on a hot dish and serve with it tomato or brown sauce.

Cucumbers are excellent done in this way.

Braised Carrots

INGREDIENTS. Two bundles of young carrots, two ounces of butter, one pint of good brown stock.

Method. Peel and trim the carrots, put them in a saucepan with cold water and a pinch of salt. Bring the water to the boil, then strain it off and dry the carrots. Melt the butter in a saucepan, put in the carrots, and fry them a nice golden brown. Then add a quarter of the stock, put a piece of buttered paper over the top, then the lid, and let them braise slowly at the side of the fire for an hour or more. As the stock becomes less, add more until you have used the pint. When the carrots are done, the gravy should look nice and thick, like glaze. Put the carrots in a hot dish, and pour the gravy over. It should first be nicely seasoned, and if it seems too firm, add a little more stock to it.

Vegetable Scallops

INGREDIENTS. Four Spanish onions, one pound of tomatoes, two ounces of butter, browned crumbs, salt and pepper.

Method. Thickly butter some scallop shells, either the natural ones, or those of tin or fire-proof ware. Sprinkle them thickly with bread-crumbs. Boil the onions till soft, then cut them in thin slices; slice the tomatoes as well. In each shell put a layer of onions, then one of tomatoes, another of crumbs with a dust of salt and pepper, and so on till the shells are full. They should be slightly heaped up with the last layer of crumbs. Put a few tiny bits of butter here and there on each. Bake them in a moderate oven till they are a nice brown and hot through. They will probably take a quarter of an hour. Onions alone, or vegetable marrow make excellent scallops.

Spinach à la Carlton

INGREDIENTS. Two pounds of spinach, one pound of potatoes, two ounces of butter, one pint of tomato sauce, two ounces of dripping.

Method. Wash and peel the potatoes, then cut them in halves lengthways. Put them on a baking tin with two ounces of beef dripping; put them in the oven, and bake them till they are soft and nicely browned. Wash and pick the spinach very carefully; it should be washed in several waters, otherwise it will be gritty. Put it in a large saucepan, with half a pint of boiling water, a tablespoonful of salt, and a tiny piece of soda. Press it down well with a wooden spoon, and let it boil fast, stirring it often to prevent it sticking. Let it cook till it is soft, then drain it in a colander, pressing it well. Next either rub it through a sieve or chop it very finely. Melt the butter in a stewpan, put in the spinach and salt and pepper to taste, make it thoroughly hot, then arrange it in a bed down the centre of a hot dish. Arrange the baked potatoes in a line down the middle, the pieces overlapping one another. Pour the tomato sauce round. For the recipe, see under SAUCES

Jerusalem Artichokes à la Crème

INGREDIENTS. Two pounds or less of Jerusalem artichokes, milk and water in equal proportions to cover them. For the Sauce: One pint of milk, one small carrot, one stick of celery, one gill of cream, one bay leaf, one shallot or onion, two ounces of butter, one and a half ounces of flour, ten peppercorns, salt and pepper to taste.

Method. Cut the carrot, onion, and celery into dice. Put them in a saucepan with the milk, peppercorns and bay leaf, and let them simmer for a few minutes. Mix the flour and butter together, strain in the milk, then stir over the fire for about ten minutes. Season it, add the cream, and it is ready. Now prepare the artichokes. Well wash and peel them, dry and cut them into neat, pear-like shapes. Put them into the pan containing the milk and water and a teaspoonful of salt for each quart of liquid, and boil until quite tender for about half an hour. Then drain them, arrange them on a hot dish and pour over the sauce.

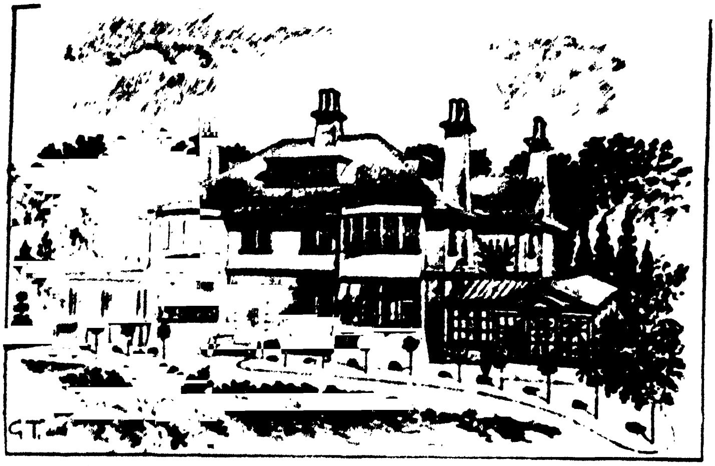
ARCHITECTURAL DESIGN

Typical Designs. Designing Elevations. Classic Renaissance. Studying and Evolving Styles. Proportions. The Five Orders of Architecture

By GASPARD TOURNIER



3. ELEVATIONS TO FIGURE 2 (Messrs Rolfe & Matthews Architects)

WE now come to the ultimate aim of all the student's endeavours, the supreme subject of architectural design. He often asks at what stage he may expect to be able to start designing for himself. This is a most important matter. He must attack it by *system* or he will waste much time and be disheartened by many humiliating failures. He must begin early, but he must not aim at palaces, nor even at cottages. He must begin with designing anatomical parts only and not wholes; and these at first must be of the simplest constructional description.

The bodies of animals have certain members common to all of them, each bearing a certain relationship to the other, such as arms, hands, eyes, ears. Similarly, buildings have common parts — rooms, corridors, walls, and windows. They vary in design, just as the limbs of animals do, but repeat elements common to all. These elements must be tackled as "designs."

For instance, let us start with designing an ordinary and quite simple wood floor and its junction to the wall [1]. Put aside all books and drawings dealing with the subject, and set down the provisions, or what would, in the case of an author, be the information to be embodied in a sentence he wishes to write, including the spelling of the words. Suppose the joists to be, say, 9 in. by 2 in. and 1 foot apart, the floor board 1¼ in. thick, the walls one brick and a half thick, the skirting

for room above to be 11 in. and the cornice for room below to be 18 in. in girth, which means that amount in length of a flexible tape laid across the mouldings, to touch and include their entire section.

A Typical Design. Then combine these details in your scaled section across the floor and you have, in a primitive way, two items of personal designing as such. These are the mouldings to the skirting and the cornice. The purpose of such mouldings is to give shaded lines to the eye to emphasise or soften edges or borders, or skeleton lines, some lines to show up strong or black by being well cut in and angular, others blending lighter above or below by curving the section of the mould. In the case of the skirting the moulding lines suggest a tapering back

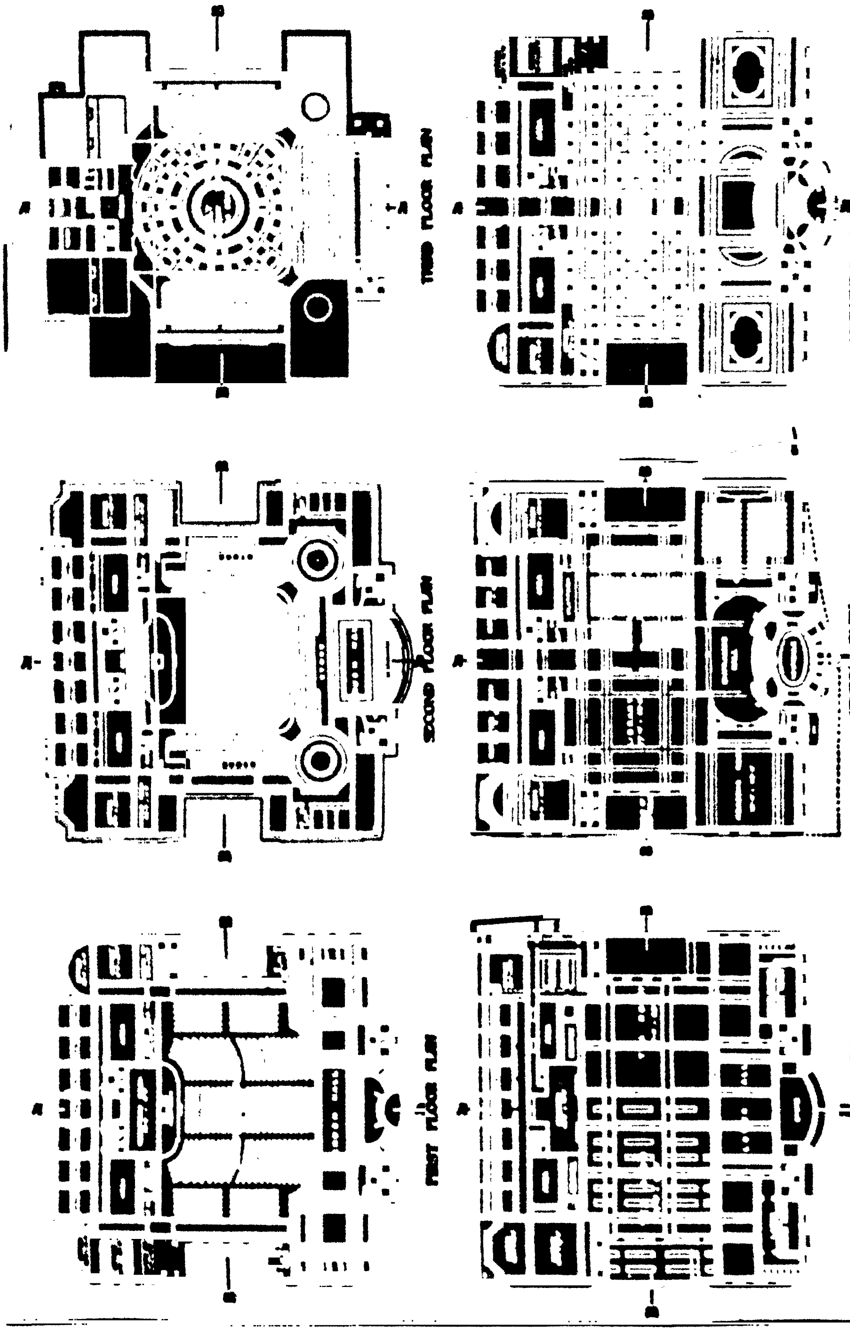
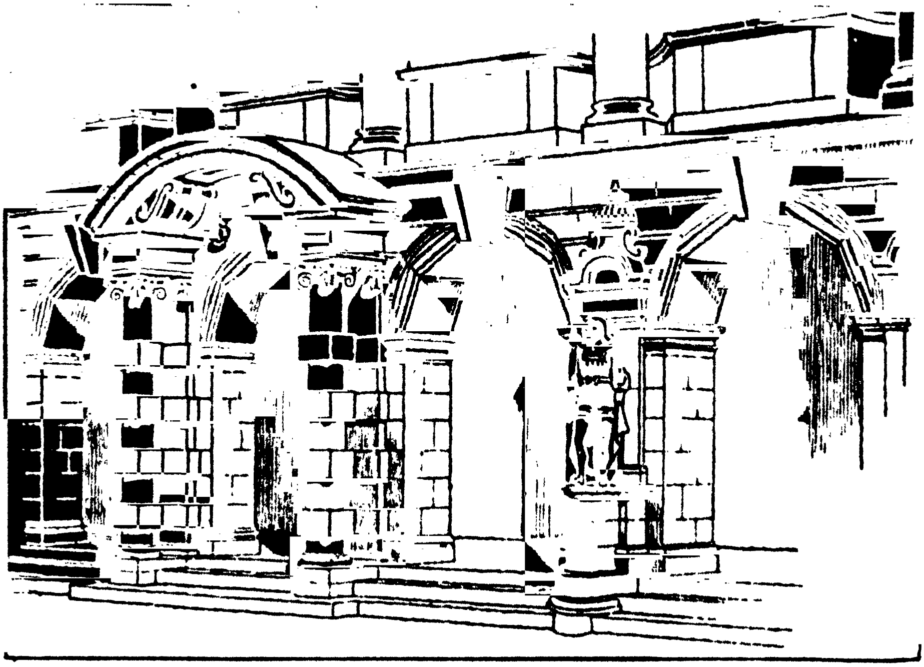
BLOCK PLANS SHOWING METHODS FOLLOWED FOR INCREASING COASTAGE FOR LIGHT BY WINGS AND COURT AREAS



7. PLANS OF PROPOSED WESLEYAN HALL AND OFFICES, WESTMINSTER

Messrs. Lanchester and Rickards, Architects. Showing a fine example of complex planning solved with lucid simplicity

towards the wall. You remember that the wider a board the more it is liable to shrink with time, so you keep within moderation by using two boards, which you join by a groove and tongue and emphasise the fact by another facial moulding, or by a simple set back as shown in this case. In the cornice to the ceiling, keeping in mind what has been said about mouldings,



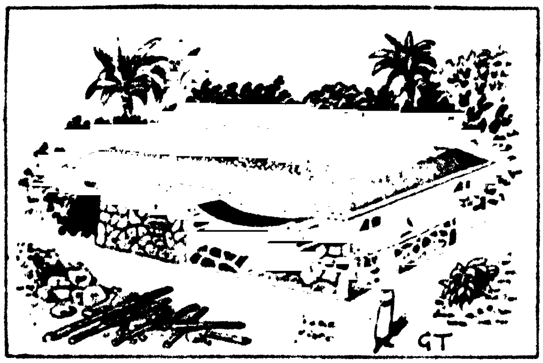
12. PART OF PROPOSED UNIVERSITY FOR SOUTH WALES
W. B. Caröe, M.A., Architect. A striking example of free adaptation in style

you probably elect to use them in the fashion of a cove to soften the transit from the vertical wall to the horizontal ceiling, which is the method in general use. But, in time, you become fastidious about cornices and their relative proportions to the rest of a room, and find many other ways of making a cornice harmonise with the character of the room.

In this way you attack all the anatomical members of a building, and it will be seen you have before you a large task which must be done concurrently with other studies. From it you will come out equipped for designing complete combinations, and you will see by it that the elevations must be governed by the plans and sections—not vice versâ, as many, at an early stage, are tempted to do. The plans and sections represent the skeleton, and the elevations, skin or clothing. If an artist designed an animal without reference to its bones, a monstrosity would result; so a good plan is always capable of having good elevations evolved from it.

11. AN INTERIOR ARCADED CORRIDOR
Referring to the difference between the legitimate and illegitimate transference of features from one style of architecture into another

A Good Plan. The merits of a plan are judged by the extent to which the position of every detail meets the requirements of the people who are to inhabit the dwelling. For instance, a drawing-room should be on the sunny side of the house, its doors not too near the fireplace so as to disturb those sitting round the fire, and a kitchen should have its windows looking northwards. The range should not be placed so that the cook has to stand with her back to the fire, etc. Corridors should not be wasteful in length or wind indirectly to rooms, and so on. The functions of each member must be grasped before trying to solve the problem of



12. TYPE OF STONE BUILDING IN THE PRIMITIVE AGES

their union. This the student at first generally thinks he can do by seeking, in books and the back numbers of the architectural publications, a plan answering the requirements of the one he is making. He then tries, by slight alterations, to preserve its points yet hide its origin. This never can be done. For instance, 2 and 3 show a country house at Tamworth designed by Messrs. Rolfe & Matthews, architects. The plans are admirably contrived to suit the site and the requirements of the client. Let the student, with tracing-paper experiment by moving the rooms about, not even disguising the original plan, and the whole will be thrown into bad planning.

This is altogether different from critically analysing the plans of others till they become digested in one's mind. Such study is very helpful; but when one plans for oneself, one must rely solely on the degree of inventive power already attained.

A good method for beginners is to draw separately to scale each room required to be incorporated in the plan, then to cut these out and use them as dominoes, moving them about till a likely combination is found.

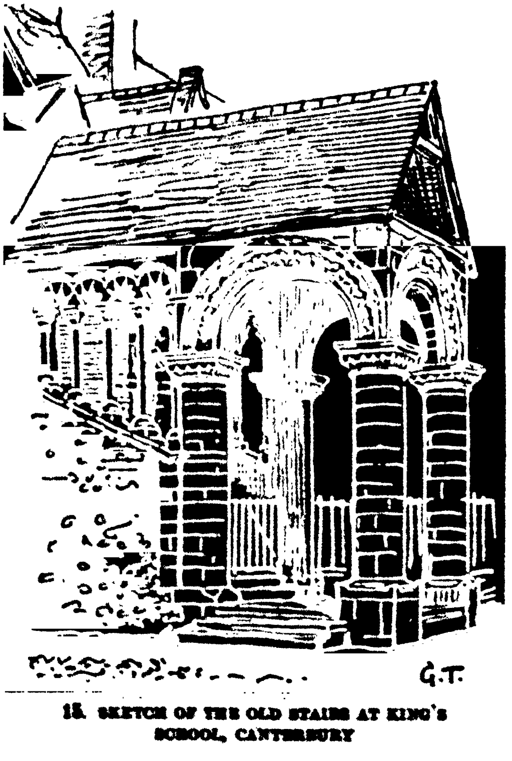
The Problem of Light. A building can get light on one or more of its sides according to the restrictions round the boundary of the site. In large structures, such as municipal buildings, colleges, etc., the amount of available light from the outer boundaries is often not enough. So the coastage for light has to be increased by various sorts of wings, as in 4 and 5, or by enclosed area courts, as in 6, or by combinations of wings and courts. In these the problem is so to work things that the strips of rooms have sequence and are connected in groups according to their uses; the corridors to them must not be twisted, but lead people direct, in a self-evident manner, from one part of the building to another.

The houses best planned are those which anyone can picture mentally on entering them. This remark applies to all buildings except sometimes Gothic churches, monasteries, and quaint family houses where the charm of mystery and surprises claim legitimate play. But these, when well done, appear on paper also to "occur" in an obviously natural way. All good plans look simple when they are done—so simple that the tyro thinks them so self-evident as to require very little ingenuity to make; but he soon finds out his mistake when he tries for himself and sees how necessary it is for him to "grow at it" slowly.

A striking example of extremely difficult planning, solved in a masterly and therefore apparently simple way, is Messrs. Lanchester & Rickards's Wesleyan Central House, recently won in a competition [7 and 8].

On a relatively cramped site there had to be fitted in features to meet several very opposite needs, yet the whole had to be treated with spacious dignity, the location of each part being obvious and direct. It is a plan for which no precedents could be consulted; unassisted invention had to do it.

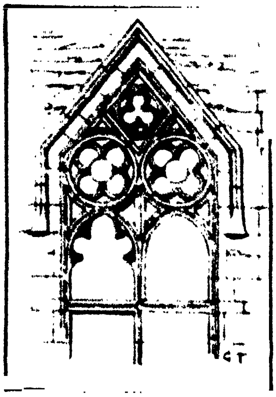
Designing Elevations. After plans come elevations, and here we come to deal with what is more generally called architecture by the outside public, though it is but one of its integral parts. The student designs his elevations and



13. SKETCH OF THE OLD STAIRS AT KING'S SCHOOL, CANTERBURY

His first attempts invariably end in his critics saying they are ugly and have no "style." He has read what the textbooks say on "style" and "beauty" in design, and usually considers he has fulfilled their directions. He therefore cannot perceive the reason his achievements do not please.

For instance, he has seen the statement urged that a utilitarian origin accounts for everything ever shaped by man, and that absolute fitness for its practical purpose gives tone. "style," and makes it beautiful. This principle is sound in germ but it is only a factor in the equation. A modern steam-locomotive is a masterpiece of fitness, in every detail, for the practical purposes attained, yet no amount of reasoning can make us think it is anything but ugly; and no one without an effort of supreme verbal gymnastics, such as Rudyard Kipling has achieved, can make poetry out of its physiognomy. Take a wooden rudder, design it with practical common-sense, and you have 9. The thing does not give pleasure to look at, and is especially offensive at the junction of the rudder with the tiller, yet the junction is theoretically correct. Compare it with that of a Dutch rudder [10], and it cannot stand the same theoretical test, yet it pleases and gives us a sense of being suitable. The fact is that in æsthetics—"the science of the beautiful"—there have to be compromises between the various elements; and these are many.



14. EXAMPLE OF THE "ANGULAR ARCH" TRANSMUTED INTO GOTHIC

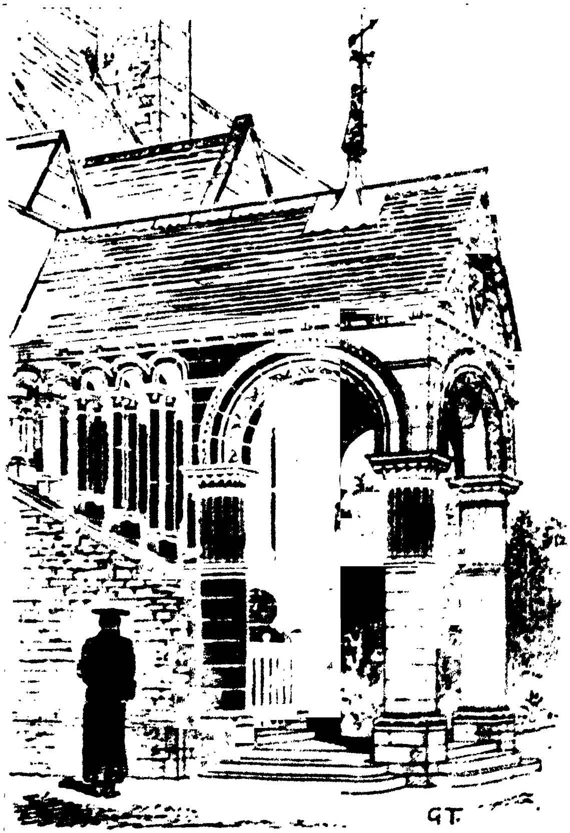
Illogical shapes sometimes please in art, and this is often due to the fact that a silly object perpetuated by one generation becomes beautiful by the memorised associations connected with it gathered in the hearts of the next generation.

Another dogma in the books is: "Copy Nature in design; if you add, it must be ugly shams and vulgarities—it is as if you 'gilded the lily.'" But man has instinctively, all through the stages of his evolution, universally shown no complete love for the way Nature has designed him. He has always been tinkering to "improve" it or hide his shape—ashamed of it.

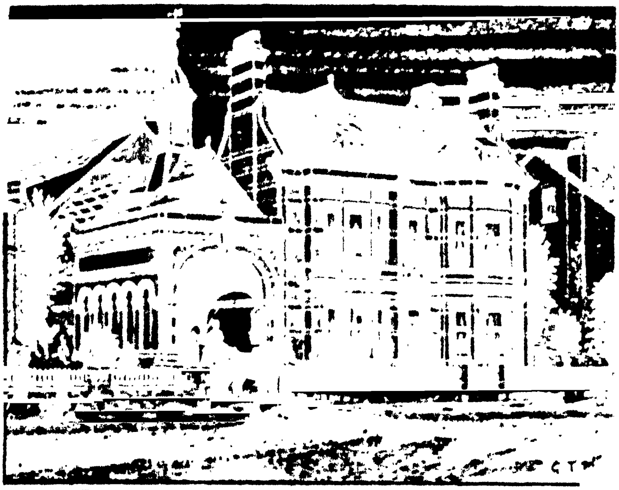
Study of Ancient Styles. Ancient fashions do, sometimes, appeal to our æsthetic feelings—such as those of the Greeks and Romans, the Egyptians and Moors, etc., when at their zenith; and it is seen that men, in seeking for what they thought beauty, stamped these experiments in "adornment" with a unity of type in race and period—a unity which persisted in their dress, utensils, and architecture. This unity is what is called a fashion, or manner, or style.

The student, having reviewed these styles, and having seen in all of them some features that look to him beautiful and others vagaries, is at first impressed with a strong desire to *invent* for himself a new style which shall embody the choicest of all of them. But a style cannot be "invented."

The delusion was very rampant in England during a part of the last century, and some of the resultant abortions are to be seen today in the buildings of that time.



16. STUDY FROM FIGURE 15
A form of exercise recommended for acquiring facility in handling the spirit of styles



17. EXAMPLE OF A BUILDING DEFICIENT IN "STYLE"

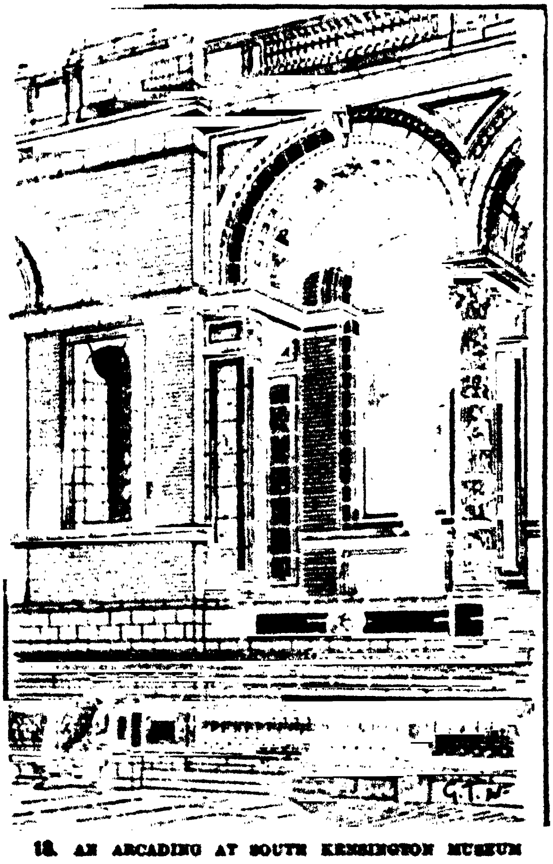
A style is a thing of growth fostered by unanimity of sentiment in a community, and the definitions of what is beautiful have varied therewith.

Having grasped what is meant by styles, and that there can be no such thing as the invention of a new one, the student must select a root style and work from it. Let that root style be that of the trend of his day, and let him put into it all the invention and individual character he has.

Classic Renaissance. The root style of to-day is Classic Renaissance, which has reached us by an evolution ripe with English associations of our past; and it has been wisely said that it is from our past that all beauty comes, whilst that which is sprung on us raw rasps us and makes us dissatisfied. But keeping to a root style does not prevent the admission of constructional or other features new to the style's origin, when these assimilate sympathetically with the root style. It is to the advantage of modern English Renaissance that this is being done in many directions. Consider, for instance, freedom in treating arches and their architraves. Fig. 11 shows an arcading which disregards tradition, but it cannot be said to jar on classic feeling or look incongruous. Among leading masters of English architecture who are more and more abandoning the rigid letter of tradition while retaining the essence of its spirit is Mr. W. D. Caröe, M.A., who has obtained many striking results. One of them is his recent design for South Wales University, where he introduces a row of angular arches [12]. The building is very large, and, seen in conjunction with the whole, the feature is a happy one. Its construction is legitimate. Its origin goes back to the time when primitive tribes first built walled houses [13]. The transmuting of a feature from one style into another has many legitimate precedents. Four of the five orders of columns and entablatures of the Roman style came thus from the Greek, and, during the Gothic revival of last century, though many of its transmutations were painfully raw, many were æsthetically legitimate, such as that shown in 14.

So, style is not bound by a schedule of features, but is a matter of essence or spirit.

Evolving a Style. A practice recommended for beginners studying style is to take an old example, or ruin, as a suggestion for a theme, and



18. AN ARCADING AT SOUTH KENSINGTON MUSEUM

Referring to the question of fixed proportions in architecture continue its evolution in the spirit of its initial style, but not its letter. Fig. 15 represents the old stairs at King's School, Canterbury. Its style is that which came to England with the Normans, and was derived from the Romans. Fig. 16 shows a free study evolved from its spirit.

Before leaving this subject it should be noted that architects sometimes, in adversely criticising a design, say it has "no style." Strictly speaking, every building has a style or fashion, however objectionable. What they mean by "no style" is that the result gives an effect which (for lack of nearer words) may be said to be sterile and incongruous, as in 17.

Proportion. Another difficulty the student meets with concerns the functions of proportion. He reads about many arithmetical ratios in the dimensions of features, such as that the height of a window should be twice its width, and that a cornice should be a certain fraction of the height of the column beneath it, etc. He tries to drag these figurings into all he does. The result disappoints him. The fact is that a feature which looks well proportioned in one position does not necessarily do so in another. Proportions must be harmonised with their surroundings. A cornice, for instance, does not primarily claim a ratio to the diameter of the column beneath it, but to conditions above it. The cornice at the South Kensington Museum [18] is below the ratio of the standard orders, but it is derived from a minor cornice, or string, brought from the side wings, and supports arches in a way which, when seen associated with the whole design, looks well proportioned. At the Bible Society's house in Queen Victoria Street there is what is technically a cornice to the pilasters [19]. This is also art of orthodox ratio; but the massive pilasters carry the eye past it, up to the higher cornice, with an effect well proportioned.

Five Orders of Architecture. The study of what is known as the Five Orders of Architecture is responsible for much over-use of arithmetical ratios. These orders are of great value in themselves as beautiful types to be well studied, but not as dogmas. On page 2036 will be found reduced copies of the fine set published by Sir William Chambers in his treatise on architecture. They are called, respectively, Tuscan, Doric, Ionic, Corinthian, and Composite. The Doric, Ionic, and Corinthian belonged to Greek architecture; the Romans transmuted them into their own style, and in time the fifth grew into existence. They became standardised to proportions based on multiples and fractions of the lower diameter of the columns. Half the diameter is called a module, and this is divided into thirty equal parts, called minutes.

THE MAN WHO THINKS

Reflection. The Necessity for it. How to Develop the Faculty. The Value of Discussion. Thinking Alone

By HAROLD BEGBIE

TO acquire information is comparatively easy; to make use of it, which is the real object of learning, is extremely difficult. Many things, as Landor tells us, which were formerly *known* as poisons are now *employed* as drugs. "Perhaps if we should meet Shakespeare," says Emerson, "we should not be conscious of any steep inferiority; no, but of a great equality—only that he possessed a strange skill of using, of classifying, his facts, which we lacked."

Cramming the Mind. The brain absorbs information as a sponge drinks water. It is possible to fill the brain with knowledge and yet find it sodden, heavy, and useless. Only by reflection upon the information we acquire can the mind make use of knowledge, and employ its facts for creative purposes. There is a digestion and an assimilation of the mind as well as of the body.

In olden days meditation was regarded as a principal exercise of the philosophical life. The prophet went into the wilderness, the ethical teacher sat with folded hands and closed eyes. To be quiet was not then synonymous with idleness. To-day—as may be seen by the questions put before young men in competitive examinations—we prize a mass of information far beyond the power to make use of it. The soldier must give proof of knowledge of mathematics and dead languages, not of his capacity to lead a regiment or conduct a campaign. The civil servant must prove that he has Homer by heart and historical dates by rote, not that he has pondered his knowledge and fitted himself for government.

It is a common remark that to meet a great man is to encounter disappointment. The great soldier proves to be an uninteresting man; the brilliant philosopher is a dull dog; the mighty financier a commonplace bore. We miss in our heroes the dash, the vivacity, the forcefulness, and power which we have accustomed ourselves to think about in their connection.

The Successful Man. But the man who succeeds in his work must, almost of necessity, prove socially uninteresting. He can never hope to possess the flourish and animation, the high spirits and the glittering ornamentations of the mediocre person who struts under the canopy of heaven as gay and light-hearted as a cockerel. His success has not been won by sudden rushes and unreasoning intuitions; his everlasting contributions to the honours and glories of humanity have not been made by impulse and impromptu. Success which has been obtained by such methods seldom stays by humanity.

Almost invariably the leaders of mankind are quiet and drab-coloured persons in the brightness of Vanity Fair. Their success has been won by a continual process of reflection, a perpetual habit of meditation, a process and a habit which cause them at all moments to be self-questioning and self-answering. They have accustomed themselves to absorb the light of the sun, not to reflect the glitter of every rush and taper. Tell a great man some fact of which he is not aware, and instead of answering you with another fact greater than your own, or instead of rushing off to narrate his new-found knowledge to the world, he will ponder it, question it, and in his own gradual fashion so absorb it as to render it useful and homogeneous with other facts already stored for eternity in the treasury of his mind.

Many men had seen an apple fall to the ground, but it was one man who deduced from that commonplace of human experience an eternal and universal law. Many men had seen the lid of a kettle dancing above the pressure of boiling water, but it was one man who built from the commonplace of life the steam-engine which has revolutionised the world.

The Habit of Meditation. Accustom yourself to reflection, and you will almost assuredly be led on to creation. It was because Charles Dickens had acquired the habit of meditating on everything he saw in boyhood that he was forced, despite an unlikely environment and an insufficient education, to create more characters on the canvas of art than any other genius of imagination. Many a man had walked the London streets at night, but it was only Dickens who so absorbed and made his own the tragedy and the comedy of the town as to create in literature a faithful and eternal picture of the scene.

The meditative man is usually the creative man. Inventors are silent men; great generals are seldom loquacious; captains of industry are not often chatterboxes. To be always retailing information is not generally to be creating knowledge.

There is an instinct of meditation which is one of the best gifts of the gods, and which is surely never to be learned; but the habit of reflection, we believe, is one that can be cultivated, and there are exercises to this end which every man, whatsoever his ambition, should of a certainty find time in his life to practise conscientiously. If a man would merely enjoy the experience of his life, it is necessary for him to acquire in some measure the habit of reflection; but if a man would succeed as an artist, as an inventor, as an artificer, as a teacher, as a discoverer, or in any of the fields of human activity, it is beyond all things essential to him that he possess in constant energy the habit of meditation.

The Habit of Reflection. The common practice of giving a child a book, and after a page or two has been read questioning its memory thereupon, is an illustration of the signal fashion in which we are thrusting reflection out of employment. One of the best exercises for acquiring the habit of meditation is the method which a wise governess employs with a child; not questioning it as to details which its memory may or may not have remembered, but rather questioning it as to the effect made upon its mind by the passage lately under its consideration. For while memory is of slow growth, the habit of reflection is instant with every hour in a child's life. Watch a child, and you will perceive it reflecting on everything that enters the field of its vision; tell it a story, and at every point, by a question or a look, it will inform you that each incident of your narrative has set the machinery of its meditation in motion. It is natural to meditate and reflect; it is only the insensate habit of cramming with the details of information which, in the case of the multitude of school children, chokes, suffocates, and finally destroys this natural faculty.

For the victim of this unscientific system of education, for the grown man who would fain recapture something of the power of this natural faculty, the path is by no means an easy one. He may even find it painful to think at all, for he will be applying his will to a department of his mental equipment which has almost atrophied. Many men confess that it is irksome, that it irritates them, to think out a problem. In such cases it is necessary to begin at the beginning of all reflection, to return honestly to the experience of a child, and cultivate the habit of wonder.

The Stimulus of Wonder. The earliest exercise of the brain in Nature's process is wonderment. A child accepts nothing without wondering how it comes to be. That a watch should tell the time does not interest it; it wonders how the wheels go round. It wonders why the stars do not fall, why the waves do not flow over the land, why the flowers have a fragrance. Facts do not interest it; the existence of the fact is always its wonder. In place, then, of accepting the daily facts of existence as a matter of course, the student must learn to let nothing escape his wonderment. He must begin with the child's mind, and wander in the field of Nature. He will soon be astonished to find that his easy-going ignorance has dulled his senses so completely as to make the great fairyland of Nature a stupid and unsuggestive place. Life will become a keener pleasure to him; his wits will waken from their slumber; he will be more and more puzzled, but always more and more delighted. So long as one accepts life as a dull and necessitous fact, existence can never stimulate the constructive faculties of the intelligence. Begin to wonder, and you begin to think.

Research. The second exercise flows naturally out from the first. Directly a mind has begun to wonder about Nature, directly it has perceived that life is a constant presentment of mystery, it becomes eager for an explanation of its problems. The mystery teases it into search after reasons. The least scholarly of men, when once they have perceived intelligently a problem in Nature, become students of knowledge. It is a healthy instinct that leads us to seek after reasons and explanations, and we must be guided by it. The habit of consulting encyclopædias is one that leads infinitely farther than to the gratification of curiosity—it leads the way to reflection, which is the beginning of creation. A man who has found a pleasure in seeking for explanations of all those phenomena which stir his wonderment is not likely to remain a seeker after facts; he will proceed to a comparison of his discoveries with men of like taste; he will think about them, turn them over in his mind, read about them, talk about them.

Discussion. The value of conversation with men of intelligence is hardly to be exaggerated. The spoken word is more impressive and suggestive than the written word; the mind is more detached in conversation, is more ready to seize upon a point, to apprehend an argument, to perceive the drift of a thesis. Moreover, it can question as it goes, and needs to skip no difficult passage. In olden days, men learned their philosophy by word of mouth, and students were *talked* into pedagogues. A good conversation is better than a treatise. Speech, it has been said, is the electricity of action. He is a wise man who seeks a *viva voce* with his intellectual superiors, and considers no day a good day in which he has not enjoyed the felicities of conversation. A man discovers in conversation exactly how much of the information he thinks he has acquired is really his own, has really been apprehended, really grasped and absorbed. Without these constant discussions, no man can truthfully determine how surely he is laying the foundations of his knowledge. And conversation is not only a test of our studies, it is a tonic to our energies. It inspires us with fresh relish for the intellectual life, and breathes into our spirit the quickening impulse of spiritual curiosity.

Privacy. Finally, we come to the environment necessary for the exercise of the faculty of reflection. It is now impossible for a man to go into the wilderness. We cannot commonly follow even Thoreau into the woods, who went there "to live deliberately, to front only the essential facts of life, and see if I could not learn what it had to teach, and not, when I came to die, discover that I had not lived."

But even more necessary than in older and quieter periods is now the opportunity for reflection. The wise student will set apart a certain time in his day when he may escape the contagion of our rushing age and be alone with his mind. He will insist upon giving himself an intellectual self-examination as severe and earnest as the spiritual self-examination enjoined by religion.

Not how he stands with God, not how his soul grows in relation to spiritual reality; but how much he honestly knows of the world about him, how truthfully he has understood his readings and his conversations, and how far he is advancing as a master of his craft. It is the experience of ages that profound reflection is difficult in an environment where distraction easily enters. The severest of chambers is necessary, and even there the ancient habit of closed eyes may be found a necessity. Few people realise, perhaps, how hard a thing it is to pursue a single line of thought without breaking away into a hundred aimless directions. It requires considerable concentration of the will-power, even in places of the greatest solitude, to follow steadily and consecutively the thread of a single thought. Only with difficulty will the student learn so to conduct his self-examination that his reflections are undistracted by valueless and wandering thoughts. Montaigne once determined, "solitarily and quietly," to wear out the remainder of his life; but he found that his spirit warred against this seclusion, begetting in his mind "chimeraes and fantisticall monsters, so orderlesse, and without any reason, one huddling upon another, that at leasure to view the foolishnesse and monstrous strangenesse of them I have begun to keep a register of them.

To sum up, the exercises for the creation of the reflective habit are: first, an intelligent response to the wonderment of Nature; second, a search for explanations and reasons; third, a cultivation of conversation with intellectual superiors; and fourth, a recognition of the sanctity of

Practical Results. Most people, says a writer, are other people. To be oneself, to be greatly individual, to be sincerely and splendidly self-conscious, one must be given to meditation. "I have more understanding than all my teachers, for their testimonies are my meditations." By continual reflection upon what we observe, and what we hear and what we see, we grow to perceive the real meaning of these things, and from this apprehension—far rarer than many imagine—we go on to creation. No man pply his education who has not digested and assimilated it as he goes along. You may know all the volumes of this present work by heart, but if you don't give a certain time of your day to discussing them, and to reflecting upon them in your own privacy, you will fail to win from your knowledge the pleasures and rewards of certain success. An engineer may rise from the lowest position to the highest, may have had a lifelong experience of all the various "shops" in a factory; but if he has not reflected upon the working of the machines, has not meditated upon the system of the operations, he will never be able to suggest an improvement in the machinery, nor ever be able to invent a new method or a new article. If we would apply our knowledge, we must certainly reflect upon it.

The Student's Bible. In one of his letters Matthew Arnold writes: "I read five pages of Greek anthology every day, looking out all the words I do not know; this is what I shall always understand by *Education*, and it does me good, and gives me great pleasure."

The student can begin his work with no better aid than a really good dictionary. He should strive to possess himself of "The Century Dictionary" and Professor Wright's marvellous "English Dialect Dictionary." The dictionary, indeed, is the Scholar's Bible. It must be always at his elbow. The habit of looking up a word is an excellent one, not only good in itself, but good in that it springs from the other habit of reflection. To see a word of which we know not the meaning ought to drive the stupidest to his dictionary; but to see a word the meaning of which we know very well but whose history we are unacquainted with ought also to send us to the dictionary. The history of words is one of the pleasantest studies in life, and the reflecting man will always be finding in his reading words which check him and puzzle him with their origin.

To take a trite but striking instance. Everybody knows what it means to say that a man is *ostracised*; but how many men know the inner, the reflective meaning of that word? A man with a smattering of Greek will say that it has something to do with an oyster shell, and leave it at that, sufficiently puzzled. The true student, the deeply reflecting man, will hunt down the word till he has found how the Greeks recorded their votes on oyster shells, and learnt from his search into the meaning of this single word something of the history of a whole people. Looking up words is a great education; and the more the habit of reflection is encouraged the more frequently will the student consult his dictionary. It is the habit of reflection, in short, which determines a man to find out a reason for everything, from a word to a law in Nature.

EIGHTEENTH CENTURY PROSE

3. In which the Review of this Period is Concluded. Notes on the Study of Style, Letter-writing, and the significance of "A Man of Letters"

Group 10
LITERATURE
15

Continued from page [illegible]

By J. A. HAMMERTON

WE have now learned enough to realise that the study of English prose must be pursued on lines different from those on which we undertook the study of English poetry; whereas poetry is universally the voice of inspiration, prose in its development departs from the sphere of literature proper. Sometimes retaining but frequently losing its claim as literature, it becomes in turn the servant of theology, the handmaid of history, the medium of science, the channel [illegible] theoretical ends.

A Parting of the Ways. At the beginning of the eighteenth century the student stands at a parting of the ways. He has to distinguish between what is prose literature and what is not. To a certain extent the answer will depend upon his own bent or "humour." But he still has to ascertain why and when and by whom particular books were written. He must learn not only the history of those books, but become acquainted with their relationships—their position in regard to the treatment by others of the subjects with which they deal—before he is able to satisfy himself as to their value. A French book of scientific, theological, historical, or philosophical importance is usually of literary importance also. The rule in France is, however, the exception in England.

Turning aside for a moment from our historical review of the literature of this period, to take stock of what we have learned thus far, we must urge the advisability of some study of the political and social developments of which particular books were either a cause or an outcome. The extent of this study will depend largely upon the student's desire to confine himself to or to range beyond the scope of "belles-lettres." By "belles-lettres" is meant literature that is [illegible] by the charm of its style or form apart from its claims as a vehicle of instruction. It has to be borne in mind in this connection that in the last result prose lives because of its power not its prettiness.

The Secret of Style. Charm and distinction of style are peculiarly characteristic of our eighteenth-century prose. The century "found English prose antiquated, amorphous, without a standard of form; it left it a finished thing, the completed body for which," as Mr. Gosse says, "subsequent ages could do no more than weave successive robes of ornament and fashion." Style, however, implies something more than precision of form. Good style is inseparable from appropriateness of diction. For example, the great writer does not approach great themes with a string of light colloquial sentences, any more than one would appear at a funeral attired in fancy dress. To appreciate style one must bring to it a knowledge of grammatical rules. But grammar is not all. Ideas are not all. The secret of style lies in the character of the man behind the writing. For this reason, while we can but admire the finished grace of a Chesterfield, Johnson, with all his heaviness, compels our affection.

this period [illegible] the clearer shall injustice of the common indictment of the age as one of shams and sentiment. Apart from the influence of Johnson, the age of Berkeley and Wesley and Whitefield cannot truthfully be described as devoid of healthy enthusiasm or activity. It was the age of our great historians. It was adorned by some of our greatest philosophers and keenest critics. If it questioned the bases of religion, it quickened both faith and good works. English writers of the period influenced Continental thought more perhaps than did the writers of any other period of our history. Eighteenth-century England, as we have already seen, discovered Shakespeare before the Germans. It standardised the essay, sowed the seeds of modern nature study and modern chemistry, gave birth to our first great novel, laid the foundations of our periodical literature, stood sponsor to the beginnings of daily journalism, and crushed the system of literary patronage. It was the age also of political economy and of public eloquence.

Chesterfield's "Letters to His Son." The eighteenth century is also rich in its letters. The correspondence of Horace Walpole has been already referred to. PHILIP DORMER STANHOPE, Fourth Earl of Chesterfield (b. 1694; d. 1773), was a statesman and wit who remembered to-day chiefly for his "Letters to His Son." Given to the world in 1774 by the son's widow, these letters were described by Johnson as displaying the morals of a courtesan and the manners of a dancing-master. They argue, nevertheless, despite their worldliness, a sincere solicitude for the welfare of the son to whom they were addressed. A great French critic, Sainte-Beuve, has said of them: "If Horace had a son I imagine that he would address him in this way, and no other." Here is a representative example of Chesterfield's style:

"Style is the dress of thoughts; and let them be ever so just, if your style is homely, coarse, and vulgar, they will appear to as much disadvantage, and be as ill-received as your person, though ever so well proportioned, would, if dressed in rags, dirt, and tatters. It is not every understanding that can judge of matter, but every ear can and does judge more or less of style; and were I either to speak or write to the public, I should prefer moderate matter, adorned with all the beauties and elegancies of style, to the strongest matter in the world, ill-worded and ill-delivered. . . . A person in the House of Commons, speaking two years ago upon naval affairs, asserted that we had then the finest navy *upon the face of the earth.* This happy mixture of blunder and vulgarism, you may easily imagine, was matter of immediate ridicule; but I can assure you that it continues so still, and will be remembered as long as he lives and speaks. Another, speaking in defence of a gentleman upon whom a censure was moved, happily said that he thought that gentleman was more *liable* to be thanked and rewarded than censured. You know, I presume, that *liable* can never be used in a good sense.

"You have with you three or four of the best English authors, Dryden, Atterbury, and Swift; read them with the utmost care, and with a particular view to their language, and they may possibly correct that curious infelicity of diction which you acquired at Westminster. . . . . Cicero says, very truly, that it is glorious to excel other men in that very article, in which men excel brutes, speech. . . . Gain the heart or you gain nothing; the eyes and the ears are the only road to the heart. Merit and knowledge will not gain hearts, though they will secure them when gained. . . . If you have not a graceful address, liberal and engaging manners, a prepossessing air, and a good degree of eloquence in speaking and writing, you will be nobody, but will have the daily mortification of seeing people with not one-tenth of your merit or knowledge, get the start of you and disgrace you both in company and in business."

Chesterfield's Style. Much might be written of the argument set forth in the foregoing extract. It is quoted for its own sake, but the passage is given also as an example of writing that is at once clear, simple, forcible, and polished. The aim of the writer is apparent throughout. The means he adopts to further that aim are direct. He describes things that are desirable and against them sets the means by which they are to be attained. The chance that ambition may not be sufficiently stimulated is provided for by the closing appeal to fear—the fear of ridicule. Lord Chesterfield uses the words "happy" and "happily" in the now obsolete sense of "accidental" and "accidentally."

Johnson's Famous Letter. By way of contrast to Chesterfield's appeal to selfish instincts may be given part of the famous letter in which Johnson repudiated the patronage which, though it was offered when his "Dictionary" was completed, was—possibly through the indiscretion of a servant—refused when that work was originally planned. Johnson's letter was written after the appearance, in a periodical called "The World," of two papers by Lord Chesterfield recommending the Dictionary to the public.

"Seven years, my Lord," wrote Johnson in 1755, "have now passed since I waited in your outward rooms, or was repulsed from your door; during which time I have been pushing on my work through difficulties, of which it is useless to complain, and have brought it at last to the verge of publication without one act of assistance, one word of encouragement, or one smile of favour. Such treatment I did not expect, for I never had a Patron before."

Johnson, it should be explained, had inscribed the "Plan" of his Dictionary to Lord Chesterfield after some intimation had reached him indicating that that nobleman was interested in the project. His letter continues:

"Is not a Patron, my Lord, one who looks with unconcern on a man struggling for life in the water, and, when he has reached ground, encumbers him with help? The notice which you have been pleased to take of my labours, had it been early, had been kind; but it has been delayed till I am indifferent, and cannot enjoy it; till I am known and do not want it. I hope it is no very cynical asperity not to confess obligations where no benefit has been received, or to be unwilling that the Publick should consider me as owing that to a Patron which Providence has enabled me to do for myself."

Lord Chesterfield, to show that his withers were unwrung, laid this letter open upon his table for others to see. Johnson, pressed for a copy of it, continually refused to give one, remarking on one occasion: "No, sir; I have hurt the dog too much already." Johnson saw through the veneer of Lord Chesterfield's bearing the shrivelling heart of a bitterly disappointed man.

Other Letter-writers. Among other letter-writers of the eighteenth century must be named the poets COWPER and GRAY. The letters of Cowper afford, perhaps, the best argument against the effectiveness of ornamental diction when it is confronted with a style that is simple and sincere. Cowper's delightful letters describe in the most natural and most charming of language the surroundings and incidents of the poet's life at Olney and Weston. Gray's letters possess the qualities of the bookman and the scholar, and represent a man who seems never to have permitted himself to appear in "dressing gown and slippers." The "Letters" of LADY MARY WORTLEY MONTAGU (b. 1689; d. 1762), describe in the simple and elegant style of an accomplished if worldly woman her experiences of travel in Europe and the Near East between 1716 and 1718. Though circulated in MS. during her lifetime they were not printed until a year after her death. The "Natural History of Selborne," by GILBERT WHITE (b. 1720; d. 1793), marks the beginning of popular Nature studies. It is composed of letters to the writer's friends, written, it is believed, at the suggestion of the Hon. DAINES BARRINGTON (b. 1727; d. 1800), who was an antiquary and a naturalist as well as a lawyer.

Thomas Pennant (b. 1726; d. 1798) was another famous naturalist and a friend of Gilbert White; his "British Zoology" and "History of Quadrupeds" were for a long time classics of their kind, while his "Tour in Scotland" had an appreciable effect in stimulating travel in that country. The letters of Humphrey Prideaux, Dean of Norwich (b. 1648; d. 1724), give many details of old Oxford life.

Various Writers of the Period. Among the divines whose work continues to be read may be named William Warburton, Bishop of Gloucester (b. 1698; d. 1779), author of a voluminous work entitled "The Divine Legation of Moses Demonstrated." Warburton was a friend of Pope, and a man who, said Dr. Johnson, "Praised me, sir, when praise was of value to me." Richard Hurd, Bishop of Worcester (b. 1720; d. 1808), was a pupil and biographer of Warburton. Dr. George Campbell (b. 1719; d. 1796) wrote a valuable "Philosophy of Rhetoric," which is remembered where the "Lectures" of Hugh Blair (b. 1718; d. 1800) are rather ungenerously ignored. William Paley (b. 1743; d. 1805) wrote lucidly on the subject of Christian evidence. His "Treatise on Natural Theology" and "View of the Evidences of Christianity" are still read; but his "Horæ Paulinæ," a defence of the genuineness of St. Paul's Epistles, is his most important work. An interesting controversy was raised by the coarse satire of "The Fable of the Bees," a work of doggerel verse and prose commentary in which Bernard de Mandeville (b. 1670; d. 1733) ridiculed humanity with none of the moral fervour, but all the savage contempt of Swift.

The butt of Mandeville's personal gibes was Lord Shaftesbury; he was attacked in turn by Bishop Berkeley (already mentioned) and William Law (b. 1687; d. 1761), whose "Serious Call to a Devout and Holy Life" influenced men so dissimilar as Johnson, Wesley, and Keble, and stands by the side of Jeremy Taylor's "Rule and Exercises of Holy Living" as one of the most impressive devotional treatises in the language. The principal Deists of the period, who denied revelation and traced their freethinking parentage to Lord Herbert of Cherbury, were Matthew Tindal (b. 1653 (?); d. 1733), John Toland (b. 1670; d. 1722), Anthony Collins (b. 1676; d. 1729), and William Wollaston (b. 1660; d. 1724). The Rev. Conyers Middleton (b. 1683; d. 1750) wrote a "Life of Cicero" (largely a plagiarism) and a remarkably rationalistic "Free Inquiry into the Miraculous Powers which were supposed to have existed in the Christian Church." His vigorous, direct style has many admirers. The "History of Civil Society," by Dr. Adam Ferguson (b. 1724; d. 1816), has been ranked as a companion to Adam Smith's "Wealth of Nations." Thomas Reid (b. 1710; d. 1796) wrote "An Inquiry into the Human Mind on the Principles of Common Sense." He had a distinguished follower in Dugald Stewart (b. 1753; d. 1828). Dr. Richard Price (b. 1723; d. 1791) was a dissenting clergyman whose approval of the French Revolution provoked a fiery retort from Burke; he is less known as a writer on morals and finance.

Other Groups of Scholars. Following David Hartley (b. 1705; d. 1757) and Abraham Tucker (b. 1705; d. 1774) in adopting the theory of the association of ideas came Joseph Priestley (b. 1733; d. 1804), who, as a controversialist as well as a writer, was distanced by Bishop Horsley (b. 1733; d. 1806), the accomplished editor of Sir Isaac Newton's works. Priestley is best remembered as the "father of modern chemistry," the author of a "History of Electricity," and as the man who discovered oxygen, but by a blind attachment to theory failed to appreciate its significance, leaving that honour to Lavoisier. Thomas Paine (b. 1737; d. 1809) wrote an influential book on "The Rights of Man," in answer to Burke, and was himself very ably answered by Gilbert Wakefield (b. 1756; d. 1801). The Greek scholarship of Richard Porson (b. 1759; d. 1808); the translation of Demosthenes by Dr. Thomas Leland (b. 1722; d. 1785); the still unapproached translation of the Koran by George Sale (b. 1697 (?); d. 1736); the version of "Plutarch's Lives" by J. and W. Langhorne (b. 1735; d. 1779, and b. 1721; d. 1772); the standard translation of Josephus's "History of the Jews," by William Whiston (b. 1667; d. 1752); the still popular version of "Gil Blas" by Tobias Smollett (b. 1721; d. 1771), whose "History of England" must also be noted; the translation of the "Satires of Horace" by the unhappy Christopher Smart (b. 1722; d. 1770); the "Don Quixote" and the "Rabelais" of Peter Anthony Motteux (b. 1660; d. 1718), who completed the work of Sir Thomas Urquhart, all testify to the learning and literary activity of the eighteenth century.

An Age of Scholarship. But this list, long as it is, and irrespective of the fact that we reserve fiction for separate consideration, is far from comprehensive. We have not yet mentioned the translations from the Sanskrit of Sir William Jones (b. 1746; d. 1794), the scholarly discourses of Sir Joshua Reynolds (b. 1723; d. 1792), the valuable "Diversions of Purley" of John Horne Tooke, the philologist (b. 1736; d. 1812); the histories and biographies of John Strype (b. 1643; d. 1737), the educational manuals of Isaac Watts (b. 1674; d. 1748), the "History of England" and "History of the Puritans down to 1689" of Daniel Neal (b. 1678; d. 1743); the sprightly "Memoirs of the Reign of George II." of John Lord Hervey (b. 1696; d. 1743), the "Dialogues of the Dead" of the first Baron Lyttelton (b. 1709; d. 1773), the colossal "Commentaries on the Laws of England" of Sir William Blackstone (b. 1723; d. 1780), the "Biblical Concordance" of Alexander Cruden (b. 1701; d. 1770), the "Anecdotes" of Joseph Spence (b. 1699; d. 1768), the "Anecdotes of Samuel Johnson" by Mrs. Thrale (b. 1741; d. 1821), the essays of Mrs. Chapone (b. 1727; d. 1801), the "Travels" of Mungo Park (b. 1771; d. 1806), or the admirable Shakespearian studies of Richard Farmer (b. 1735; d. 1797), George Steevens (b. 1736; d. 1800), Isaac Reed (b. 1742; d. 1807), Edmund Malone (b. 1741; d. 1812), and John Dennis (b. 1657; d. 1734).

Early Journalism. It is of interest to remember that "The Times," first started as "The Daily Universal Register" in 1785, came out with its present title on January 1st, 1788; that the "Gentleman's Magazine" dates from 1731; and that there was a "London Magazine" in 1732, a "Monthly Review" in 1749, a "Literary Magazine" and a "Critical Review" in 1756; while, in addition to other encyclopædias, the "Encyclopædia Britannica" appeared for the first time in 1771, in three volumes.

A Plea for General Knowledge. We have thus arrived at the end of the eighteenth century in our study of English prose, and have thought it well to maintain up to this point our historical treatment of the subject rather than to dwell at any length on the practical side of prose study or the examination of special branches of prose writing, though we have at least gleaned some useful knowledge by considering the different styles of the master-writers of the age. But presently we shall look more closely into the fabric of our English prose, now that we are coming into touch with the living and growing prose of our own time. This great distinction has to be noted between the eighteenth century and our own time: that the term "a man of letters" formerly stood—even into the middle of the Victorian Age—for one who had ranged at will in all those fields of study represented in our history of eighteenth century prose-writers: philosophy, travel, history, fiction, science, religion, etc. Unhappily, but perhaps inevitably, the nineteenth century saw a great change in the direction of "specialising," not only in the case of writers, but in that of readers. Authors now find it profitable to limit themselves to one branch of literature only; readers, with far less reason on their side, are too prone to fall into the same habit. In the eighteenth century it was accounted no discredit to a writer that he expended his energies in many different fields of thought: that he wrote histories, biographies, poems, criticisms, philosophies, stories. In our day this would be to an author's disadvantage; publishers would demand that he produce only the class of book which they could sell most rapidly. That is the author's excuse, and it is a valid one; but the reader who confines himself to only one class of reading has no excuse. The man who to-day would be well read should go for example or precedent to the "men of letters" of the eighteenth century, who regarded the whole varied field of literature as their hunting ground, and were not content to linger unduly in one particular corner of it, but to range throughout its length and breadth.

Books to Study. "A History of Eighteenth Century Literature (1660-1780)," by Edmund Gosse (Macmillan. 7s. 6d.); "The Age of Pope," by John Dennis, and "The Age of Johnson," by Thomas Seccombe (Bell. 3s. 6d. each); "English Prose Selections," edited by Sir Henry Craik, with critical introductions by various writers (Macmillan. 5 vols. 7s. 6d. and 8s. 6d. each); "Eighteenth Century Vignettes," by Austin Dobson (Chatto & Windus. 4 vols. 6s. each); "Eighteenth Century Essays on Shakespeare," by D. Nichol Smith, M.A. (MacLehose. 7s. 6d.); "The Spectator," edited by G. A. Aitken (Routledge. 6 vols. 1s. each); Boswell's "Life of Johnson" (Froude. 5s.); the late Sir Leslie Stephen's "History of English Thought in the Eighteenth Century" (new edition, 1902); "The English Utilitarians," "Hours in a Library," and "Lives" of Johnson and Swift, in the "English Men of Letters" series. The more expensive works can usually be seen at the public libraries; where the student, having mastered the outline of the period, desires to read particular works, he should first of all secure lists of the cheap and excellent reprints now being published by so many leading firms. There is no better work of its kind than the "English Prose Selections," and Mr. Gosse's book is most helpful; but Sir Leslie Stephen is the greatest authority on eighteenth century philosophy. The lighter side is safe in the hands of Mr. Austin Dobson.

THE SPINAL CORD & THE BRAIN

Shape and Functions of the Spinal Cord. Its Relation to the Nerves. The Size and the Weight of the Brain. Its Appearance

Continued from page 1944

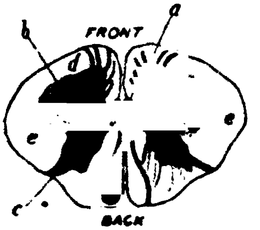
By Dr. A. T. SCHOFIELD

WE now approach the most difficult part of physiology—that borderland when it touches psychology, when body and soul, and matter and mind meet; for the central nervous system, composed of brain and spinal cord is the exquisite instrument that enables impulses of mind to be translated into movements of matter, just as a piano or organ materialises the musician's dreams into sounds of harmony. These centres, acted on by the mind and will, constitute the engine, or driving power, of the whole body, and the nerves just described are the connecting wires between those batteries of force and the machinery to be moved in the body.

The Spinal Cord. We will begin with the spinal cord, because it is the most ancient nerve structure in the body, and the brain has been developed from it. It will be seen in the section on Biology how far the spinal cord carries us back, whereas the brain proper is of much more recent origin. According to our custom so far, we begin with the structure, and then proceed to the functions of the nervous system.

The spinal cord is a flattened cylindrical band of soft material *eighteen inches long*: it is nearly one inch in diameter, and weighs about *an ounce*.

Its Shape. It is somewhat oval in shape, and one section is grey inside and white out. The cord, like the brain, is partly divided into right and left halves. All along it pairs of nerves are given off right and left, both in front and behind; and these pass out into the body between the vertebræ; while at the end the cord itself divides up into a bunch of white nerves called the *cauda equinæ*, because it is like a horse's tail.

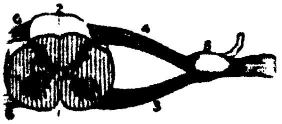


110. SECTION OF SPINAL CORD IN THE CERVICAL REGION

a Central tube b Grey matter c. Posterior sensory nerves d Anterior motor nerves e. White matter

Its Composition. The cord is really a tube, there being a small hole or foramen in the centre, running from end to end, lined with many ciliated epithelia. This tube is surrounded first by grey matter, then by white, and then by the membranes of the cord. These membranes are three in number, of the same name and similar in structure to those covering the brain; they will be fully described later on. The grey matter in the middle is somewhat in the shape of a butterfly with outstretched wings [110]. It is also like two large "commas" back to back, united by a band, in the centre of which the small tube runs. It consists of nerve cells and naked axis cylinders, and is rather pink, from the amount of blood which circulates in it, and is four times as great as in the white matter. This part of the cord consists of medullated nerves, blood-vessels, etc., all embedded in neuroglia, which is a close network of fibres. Grey matter contains four-fifths, and white matter three-fifths of water.

Its Work. The white matter gets less and less from above downwards, as the nerves composing it become fewer, while the grey matter suddenly enlarges at the spots where the nerves of the arms and legs are given off, there being here a great increase of nerve cells, owing to the great activity in the cord at these points. Only about half the spinal nerves that enter the cord pass into the brain, a large number terminating in the grey matter.



111. SECTION OF SPINAL CORD, SHOWING NERVES ON THE LEFT

1. Anterior cord 2. Posterior cord 3. Anterior motor nerves 4. Posterior sensory nerves 5. Ganglion on posterior nerve 6. Nerves on right

The spinal nerves come off in 30 pairs between the vertebræ, leaving the cord on each side by two roots, anterior and posterior. The anterior pass out in several bundles from the front of the grey matter of the cord, and are *efferent*, or *motor*, as is proved by the fact that all motion ceases in the part they supply when they are cut, while sensation persists. The posterior roots come off from the back of the grey matter in one large trunk, and shortly after they leave the cord, and before they join the anterior, they pass through a ganglion, or a swelling, composed of nerve cells on the trunk [111]. These are *afferent*, or *sensory* in character, as is proved by the part they supply losing all feeling when they are cut, while it still retains its powers of motion. The function of the ganglia has been explained in the section on Nerves to be that of nutrition.

Course of the Nerves. The course of the nerves in the cord is threefold:

The afferent, or sensory nerves, entering at the back, ascend to the brain along the posterior and lateral segments of the cord.

The efferent, or motor nerves, leaving at the front, descend from the brain along the anterior and lateral columns.

The third class, those terminating or originating in the cord, constitute, as we have said, nearly half the entire mass.

One point should be noted, and that is that both motor and sensory fibres cross to the opposite sides—the motor fibres at the top, just before they enter the cord, and the sensory at the level with the cord, where they join after passing through the ganglia.

The centres of nutriment for the motor nerves are in the brain proper—any degeneration in them extends downwards; whereas, as we have seen, the nutritive centres for the sensory nerves are in the ganglia, or the posterior roots, and any degeneration in them extends upwards.

Four Functions of the Spinal Cord.

The functions of the spinal cord are principally four in number—reflective, conductive, transferent, and trophic.

REFLEX ACTION consists in a response to a sensation, or it may be to an afferent impulse outside consciousness; it is fully described in that part of the course dealing with the brain.

CONDUCTION is the simple passing of nerve force through the cord to and from the brain.

TRANSFERENCE is the diffusion of nerve force to neighbouring nerves.

TROPHIC functions consist in the nutrition of nerves, and are well exhibited in the posterior ganglia of the spinal cord.

The Size and Weight of the Brain.

We now turn to consider the brain, which forms in adults $\frac{1}{40}$th part of the weight of the body (in babies $\frac{1}{18}$th); in elephants it is $\frac{1}{500}$th, and in whales $\frac{1}{3000}$th part. The English brain averages 48 oz., the Scotch 49, and the Irish 47 oz. An idiot's brain may weigh as little as 16 oz., while a scientific man's (Cuvier's) may weigh 64 oz. Weight of brain does not, however, always mean great intellect, for a washerwoman's healthy brain has weighed as much. At three years old the brain is $\frac{4}{5}$th of its full size; at twelve, $\frac{9}{10}$th; at fourteen it reaches it, though the development of functions may go on to forty.

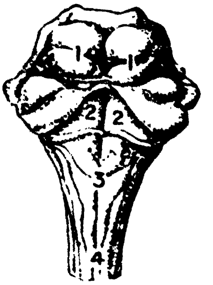
The Rhythmic Movement of the Brain.

The first thing to be observed, if part of the skull-cap could be removed during life, is that the brain inside is continually moving. It throbs like a heart. If we put a finger on the membrane, or watch it and count the beats, we find they are just the same as the pulse. This movement of the whole brain is very remarkable. We do not *feel* it ourselves, unless it be very excessive, and then we say the brain throbs, or seems too large for the head. This throbbing is caused by the numerous blood-vessels that run everywhere in the soft, yielding cerebral substance; and as all these arteries beat with the heart, they move the whole brain up and down in regular rhythm.

Turning from the brain to the inside of the skull-cap, we observe many channels and depressions grooved deeply in it, for the larger veins on the surface of the brain to run in. The brain itself cannot as yet be seen, as it has no less than three membranes, or *coverings*, over it, and the outer one is very thick and opaque It is called the *Dura Mater*.

The Outside Covering. The Dura Mater (or Hard Mother) is so called because it is a rough, hard, and unyielding covering of the brain. Its outer surface is very rough, and adheres closely to the bones of the cranium, of which it forms the periosteum, while at the margin of the great hole for the spinal cord in the occipital bone it is continued downwards to form the outer covering of the cord, being, however, only loosely attached to the vertebræ. Its inner surface is smooth and glistening. It is made of a similar material to the white of the eye. It forms also the outer sheathing of the various nerves that pass out of the brain, and inside the skull the layers separate and form fibrous tubes, which are used as veins for the return of blood from the brain. The arteries that run on its surface are very numerous, and all help to supply the brain. The Dura Mater sends a strong arched division down, like a sickle, between the two halves of both the greater and lesser brains, stretching from before backwards; and also a horizontal layer between the lesser brain below and the greater brain above [118]



113 POSTERIOR SURFACE OF MEDULLA
1. Anterior pyramid
2. Olivary body
3. Restiform body
4. Spinal cord

The Middle Covering. The Arachnoid (or Spider) membrane is so called from its delicate structure, resembling a spider's web. It is a closed and empty bag, consisting of two layers, and the brain is folded up in it. The outer layer rests against the dura mater, and the inner one against the third membrane of the brain. At the base of the brain a good deal of fluid often collects in the cavity, and thus forms part of the "water-bed," on which the brain rests. The main bulk of the fluid lies, however, *between the arachnoid and the innermost membrane*, in the space between the two. This fluid is watery, slightly saltish in taste, and is called cerebro-spinal fluid; it is very like lymph, and is the drainage of the brain.

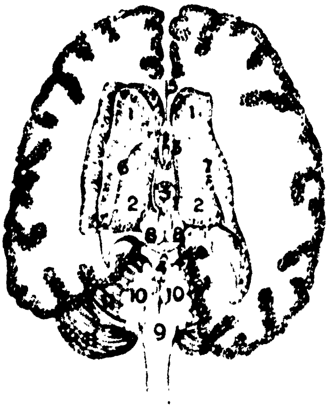
The Inside Covering. The Pia Mater (or Pious Mother), the innermost membrane of the brain, is so called because it takes such excellent care of the valuable organ—the brain—within it. It is a single layer of very fine membrane, holding together a perfect meshwork of blood-vessels that spread in all directions over the surface of the brain. It dips down between all the convolutions, and adheres closely to the brain substance beneath, though quite loosely to the Arachnoid above.

116. LAYERS OF CORTICAL GREY MATTER OF CEREBRUM

The Brain. When these three membranes are stripped off, the cerebrum, or brain, is seen beneath as a soft mass nearly 3 lb. in weight [117]. If we carefully take the brain out of its bony case, and examine it [112] minutely, we notice at once certain features. In the first place, there are two brains—the larger one, the cerebrum, in front and above; and the little one, the cerebellum, below and behind—the one as big as a melon, the other the size of a small orange. A girl's head with part of her hair done in a small knob behind very much resembles these two brains.

115 ANTERIOR SURFACE OF MEDULLA
A Pons *B* Medulla

A Woman's Brain. Brains do not, as we have shown, all weigh alike. The average is about 45 oz., the extremes ranging between 1 lb. and 4 lb. In a child three years old the brain is only ½ lb. lighter than a man's, and when it is twelve years old it is only ¼ lb.; and when fourteen, the brain has reached its full weight. After forty years of age the brain gets about an ounce lighter every ten years. The brains of women are about ¼ lb. less than those of men, not because they are lighter in proportion, but because the whole body is generally of a smaller size. The brain of the larger apes weighs under 1 lb.



114. SECTION OF BRAIN FROM ABOVE
1. Corpus striatum 2. Optic thalamus 3. Third ventricle 4. Fourth ventricle 5. Fifth ventricle 6, 7. The two lateral ventricles 8. Corpora quadrigemina 9. Posterior surface of medulla oblongata 10. Section of cerebellum 11. Exterior of left hemisphere of cerebellum

Another feature is that both brains are divided by a cleft down the middle into two halves—right and left. The two halves appear exactly alike, and are joined together by a *broad band of white matter* about the centre of the cleft called the *Corpus Callosum*.

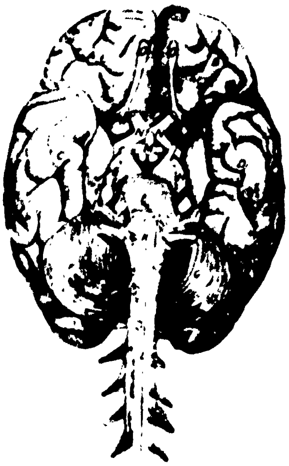
We next observe that the large brain may roughly be divided into *three regions, or parts*.

The upper part, which includes all the surface of the brain, or *cortex*, is a mass of convolutions, looking just like a number of snakes twisted together. Between the folds of these convolutions the *Pia Mater* dips down, carrying the blood-vessels. These folds are very intricate, and run in all directions. If the surface of the brain were flat, it would not be a quarter of the extent it is when folded up in convolution. The folds not only enormously increase the superficial area, but are connected closely with mind power, for the cleverer a man the deeper and more numerous they are. In a child they are comparatively few and shallow, but rapidly increase with age and education.

The mid brain is quite different. It includes all the central part and under surface of the cerebrum, and consists of masses of nerve substance—two in front are called the *Corpora Striata*, and two behind the *Optic Thalami*.

The lower brain is called the *Medulla Oblongata* [113] (or oblong marrow), and connects the large brain with the smaller brain, or cerebellum, behind and the spinal cord below. It also is partly divided in two, and contains a long, hollow space (the fourth ventricle), and several small masses of nerve matter the size of peas or beans.

There are also several other ventricles, or empty chambers, in the brain—one being as much as 4 in long—with channels leading from one to another.

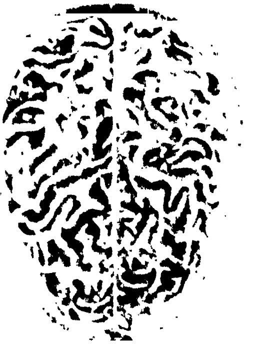


119. THE BRAIN SEEN FROM BELOW

A Right frontal lobe *B* Left frontal lobe *C* Right temporal lobe *D* Left temporal lobe *E* Pons Varolii *F* and *G* Cerebellum *H* Crus cerebri *I* Crus cerebelli *K* Medulla *L* Spinal cord *N* Optic nerves *O* Olfactory nerves

What the Brain Looks Like. If now, with a large, sharp knife, a horizontal slice is taken completely off the cortex, we get a very good view of the wavy external border of grey substance following the outlines of the convolutions, and looking just like the shaded margin that used to indicate the coast-line in all old fashioned maps.

The Empty Spaces in the Brain. If a second horizontal slice be cut right down to the connecting band of white fibres, we get a still better view. The whole of the brain so far is *quite solid* and soft, like the curd of milk, white inside, and grey round the edges. The next slice will cut through the roofs of *two* of the five caverns, or *ventricles*, of the brain [114] which have long extremities like horns, and lie on each side of the connecting band and in the centre of each hemisphere. Their peculiar shape and the rounded masses rising inside them are very curious, and their use is not fully known. The other three ventricles are in the base of the brain and medulla, and are very small. Beneath the two lateral ventricles we reach the mid brain and the four large masses of nerve matter, two—the Corpora Striata—connected with motion, and two—the Optic Thalami—with sensation. Behind these, again, are four little bodies—the *corpora quadrigemina*—like four white peas, where the nerves of sight terminate, and where the power of sight really exists, for, if these are destroyed, the person is quite blind, though the eyes may be perfect.

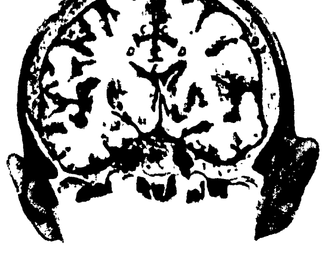


117. THE BRAIN SEEN FROM ABOVE AFTER REMOVAL OF THE SKULL-CAP

A and *B*. Left and right cerebral hemispheres *C* Great longitudinal fissure 1. Frontal lobe 2. Parietal lobe 3. Occipital lobe

The Lower Brain. Perhaps we may get a clearer grasp of the divisions of the brain if we follow them upwards from the spinal cord. When the cord reaches the brain it spreads out and flattens and divides from the back so as to be spread open like a split herring; this is the medulla, or lower brain, underneath [115]. Across its front is a broad band of fibres known as the *pons*, or bridge, which, passing upwards on each side, is connected with the little brain or cerebellum, which rests on the medulla above. Beyond this bridge of fibres the medulla divides into two great pillars—the *crura cerebri*—which pass up to the mid brain, each forming therein the two masses of grey, nervous matter we have seen—the Corpus Striatum in front, and the Optic Thalamus behind. From these masses two bands of fibres pass upwards and are folded backwards, right over the mid brain, forming eventually the two cerebral hemispheres and all the convolutions of the cortex in the upper brain.

The Five Lobes. There are five lobes in each half of the cortex—the *frontal* in front, the *parietel*, or middle lobe, separated from the former by the great *fissure of Rolando*; then the *temporal*, at the side, also separated from the first by the *fissure of Sylvius*. The *occipital* is behind, and is separated by the *parieto-occipital fissure*. In the centre is the fifth lobe, known as the *Island of Rheil*.

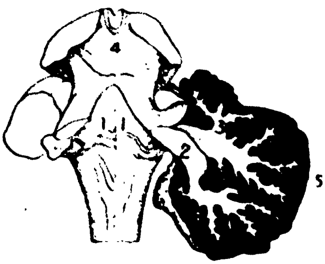


118. VERTICAL SECTION THROUGH BRAIN

A. Skull *B*. Dura mater *C*. Right and left hemispheres *D* Parietal lobes *E* Corpus callosum

About 2 in. down between the hemispheres, or slightly separating them, can be seen the broad white band of fibres that connects one side with the other

(*Corpus Callosum*). We will now look at these three divisions and the cerebellum a little more closely. If the convolutions of the cerebrum be examined in the upper brain, or cortex, they will be seen to have a grey appearance [116], and if cut, it will be seen that there are several very thin layers of grey and white matter alternately for about ¼ in., and then the inside of the convolutions and the whole cerebrum are pure white. The depressions between the convolutions are about 1 in. in depth. Although the exact shape of the convolutions varies in each individual, just like the features in the face, yet there is always a general plan followed, so that the leading elevations and depressions have all received special names [118].



120. FOURTH VENTRICLE WITH LEFT CEREBELLUM (SECTION)
1. Fourth ventricle 2. Inferior crus 3. Superior crus of the cerebellum 4. Corpora quadrigemina 5. Left cerebellum (section)

Organs of Smell and Sight. At the base of the brain and in front we see embedded in the under side of the hemispheres of the cerebrum the two nerves of smell (olfactory bulbs) as they proceed forward to the nose [119]. They consist of two large masses of grey matter that receive the impression of odours, and two large white nerves that carry the sensation on to the brain. Further back you see two larger nerves crossing each other from right to left, and running backwards into the brain. These are the two optic nerves, or nerves of sight. The reason they cross, and thus mingle together, is in order that each eye may see alike.

The medulla is somewhat pyramidal in shape, and is about 1¼ in. long, 1 in. broad, and ¾ in. thick. The cerebellum that rests upon it is 4 in. by 2¼ in. and 2 in. thick, and consists of a body and three pairs of bands, or cura, two upper ones connecting directly with the cerebrum, two forming the bridge, or *pons varolii*, and two connecting behind with the medulla direct [120]. The surface of the cerebellum is not in convolutions like the cerebrum, but is in fine vertical plates, all being grey outside and white within, the arrangement or section being in branches, like a tree.

The Nerves in the Brain. The nerves in the brain have been grouped generally into three great divisions.

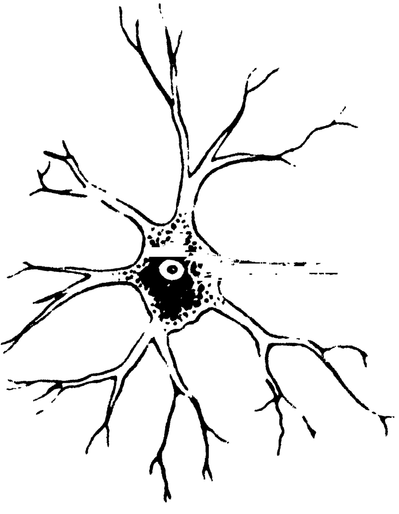
1. Those that connect every part of the cortex of the hemisphere with the great ganglia of the mid brain (corpora striata, optic thalami, and the corpora quadrigemina), both motive and sensory.

2. Those that connect every part of these ganglia with the lower brain, or medulla, and the spinal cord, both motive and sensory.

3. The peripheral nerves that leave the spinal system and form the nerves proper.

The grey matter of the brain is composed of a basic substance — *neuroglia* — and closely-packed cells of every shape and size [121], with an interlacing network of naked axis cylinders.

The white substance is one mass of medullated nerves passing to and fro in all directions.



121. BRAIN CELL
Isolated and highly magnified to show connections

How Blood Feeds the Brain. The blood supply of the brain is of a special nature. The total amount passing through the brain is not very great, but five times as much circulates in the grey matter as in the white, the former being the true centre of metabolism in the nerve cells connected with the action of mind. There is probably a controlling centre in the brain for regulating its own blood supply. If this does not act well, any sudden change in the position of the head causes dizziness, or vertigo. The arteries leading to the brain are exceedingly tortuous, thus by mechanical means lessening the force of the heart's beats; and there is a circle of arteries at the base of the brain (the *circle of Willis*) to ensure a free supply to all parts. Large lymph spaces exist round the arteries, so that when these expand they do not press on the brain substance.

The large veins are not true veins, as they contain no muscle fibre, nor valves, but are open channels, called sinuses, formed by the bone and Dura Mater, and can neither be compressed nor distended.

Besides moving with the heart the brain rises and sinks a little with respiration.

NOTE. In the title to the illustration on page 1604 the words Tibia and Fibula should be transposed.

Continued

Hence, *to obtain the product of two compound expressions we take the sum of the products formed by multiplying every term of the one expression by every term of the other.*

Example 1. Multiply $3x + 4y$ by $-x + 2y$.

The product

$$= (3x + 4y) \times (-x + 2y),$$

or, as it is usually written [Art. **2**],

$$\begin{aligned} &(3x + 4y)(-x + 2y) \\ &= (3x)(-x) + (3x)(2y) + (4y)(-x) + (4y)(2y), \\ &= -3x^2 + 6xy - 4xy + 8y^2, \\ &= -3x^2 + 2xy + 8y^2 \ \underline{Ans.} \end{aligned}$$

The work is generally arranged as follows,

$$\begin{array}{rrr} 3x & +\ 4y & \\ -\ x & +\ 2y & \\ \hline -3x^2 & -\ 4xy & \\ & +\ 6xy & +\ 8y^2 \\ \hline -3x^2 & +\ 2xy & +\ 8y^2 \ Ans. \end{array}$$

Explanation. Write the multiplier under the multiplicand. Multiply every term of the multiplicand by the first term, $-x$, of the multiplier as in Ex. 1. of Art. **26**. Next, multiply every term of the multiplicand by the second term, $+2y$, of the multiplier, writing "like" terms of the two products in the same columns. Finally, add the two lines, as in Ex. 1. Art. **15**.

28. When the multiplier and the multiplicand consist of terms containing different powers of some common letter, it will be found convenient to arrange the terms in the following way:

In each expression put the term which contains the highest power of that letter first, the term which contains the next highest power next, and so on. This is called *arranging the expression according to descending powers of that letter*. The expression $3x^3 - 2 + 4x^2 - x + 5x^4$, when arranged according to descending powers of x, becomes $5x^4 + 3x^3 + 4x^2 - x - 2$. In a similar way we may arrange an expression according to *ascending* powers of some particular letter. For example, if we arrange $y^4 - x^3y + 2xy^3 - 5$ in ascending powers of y, we obtain $-5 - x^3y + 2xy^3 + y^4$.

It should be remembered, however, that this rearrangement of the terms, before beginning the multiplication, is not absolutely *necessary*. The reason for doing so is that it saves some trouble in getting the like terms of the product into the proper columns.

Example. Multiply $3x^3 - xy^2 + 2y^3 - 4x^2y$ by $y^2 + x^2 - 2xy$.

$$\begin{array}{llllll} 3x^3 & -\ 4x^2y & -\ xy^2 & +\ 2y^3 & & \\ x^2 & -\ 2xy & +\ y^2 & & & \\ \hline 3x^5 & -\ 4x^4y & -\ x^3y^2 & +\ 2x^2y^3 & & \\ & -\ 6x^4y & +\ 8x^3y^2 & +\ 2x^2y^3 & -\ 4xy^4 & \\ & & 3x^3y^2 & -\ 4x^2y^3 & -\ xy^4 & +\ 2y^5 \\ \hline 3x^5 & -\ 10x^4y & +\ 10x^3y^2 & & -\ 5xy^4 & +\ 2y^5 \ Ans. \end{array}$$

Explanation. We have here arranged both expressions in descending powers of x. Note that by so doing we have also arranged them in ascending powers of y. We then work from left to right, multiplying first by x^2, then by $-2xy$, then by y^2, finally combining the like terms as in addition.

DIMENSIONS OF EXPRESSIONS

29. When a simple expression consists of the product of n letters, it is said to be *of n dimensions*, or, *of the nth degree*. *Numerical* factors do not affect the degree of an expression.

Thus, a^2, that is aa, is of two dimensions, or of the second degree. $5x^2yz$ is of the fourth degree, since it consists of the product of four letters, $xxyz$.

The degree of a compound expression is the degree of the term of highest dimensions contained in it. For example, $2a^3b - 4abc + c^2$ is of the fourth degree, since the term of highest dimensions, $2a^3b$, is of the fourth degree. But, in speaking of the degree of an expression, we sometimes only take one particular letter into account.

Thus, $2a^3b - 4abc + c^2$ is of the *third degree in a*. It is of the *first* degree in b, and the *second* degree in c.

An expression of the second degree is often called a *quadratic expression*.

HOMOGENEOUS EXPRESSIONS

30. *A homogeneous expression* is one in which all the terms are of the same dimensions.

$5x^7 - 3x^4y^2z + y^3z^4$ is a homogeneous expression of the seventh degree, since each term is of the seventh degree.

We have seen in Art. **27** that any term in the product of two multinomials is obtained by multiplying a term of the one multinomial by a term of the other. It is clear, then, that if each of the multinomials is homogeneous, their product will be homogeneous. For example, if every term of the multiplier is of the *second* degree, and every term of the multiplicand is of the *third* degree, then every term of the product will be of the *fifth* degree, since $2 + 3 = 5$. See the Example in Art. **28**. If every term in the product was not of the fifth degree, then we should know there was a mistake in our multiplication.

PRODUCTS BY INSPECTION

31. The student must learn to write down the product of two, or of three, such factors as $x + a$, $x + b$, $x + c$, without going through the process explained in Art. **27**.

If we do the actual multiplication we find that

$$(x + a)(x + b) = x^2 + ax + bx + ab,$$

which may be written

$$x^2 + (a + b)x + ab.$$

This result will be true whatever values a and b may have. A *general* result, such as the one just shown, is called a *formula*.

Let us now give special values to a and b. Suppose $a = 3$ and $b = -2$. Then we have

$$\begin{aligned} (x + 3)(x - 2) &= x^2 + (3 - 2)x + 3(-2) \\ &= x^2 + x - 6. \end{aligned}$$

Or, if $a = -7$ and $b = 4$, we get

$$\begin{aligned} (x - 7)(x + 4) &= x^2 + (-7 + 4)x + 4(-7), \\ &= x^2 - 3x - 28. \end{aligned}$$

We see, then, that the product of two such binomials as $x + 6$ and $x - 5$ consists of three terms, and that (i.) the first term is x^2; (ii.) the coefficient of x is the *sum*, taken with their proper signs, of the second terms of the binomials; (iii.) the third term is the *product* of the same two terms.

In the same way, by actual multiplication, we find that the product of $x + a$, $x + b$, and $x + c$ is

$$x^3 + (a + b + c)x^2 + (bc + ca + ab)x + abc.$$

Hence we can at once write down the product of three such binomials as $x + 2$, $x - 1$, $x + 4$.

Thus,

$$\begin{aligned}&(x + 2)(x - 1)(x + 4)\\ &= x^3 + (2 - 1 + 4)x^2\\ &\quad + \{2(-1) + 4(-1) + 2 . 4\}x + 2 . 4 . (-1)\\ &= x^3 + 5x^2 + 2x - 8.\end{aligned}$$

After a little practice, the second line of work can be performed mentally, so that we have nothing to write down but the actual result.

SQUARE OF A MULTINOMIAL

32. We shall now show how the square of any multinomial can be written down by inspection.

In the formula

$$(x + a)(x + b) = x^2 + (a + b)x + ab,$$

if we put $b = a$, we obtain

$$(x + a)^2 = x^2 + 2ax + a^2.$$

That is, *the square of a binomial is equal to the square of the first term, plus the square of the second, plus twice the product of the two terms.*

Example **1**. Write down the square of $2a - 3b$.

Here, we have

$$\begin{aligned}(2a)^2 &= 4a^2,\\ (-3b)^2 &= 9b^2,\\ 2(2a)(-3b) &= -12ab.\end{aligned}$$

all of which can be done mentally, so that,

$$(2a - 3b)^2 = 4a^2 - 12ab + 9b^2 \quad \underline{Ans.}$$

In the formula $(x + a)^2 = x^2 + 2ax + a^2$, suppose a is equal to $(y + z)$. Then we have

$$\begin{aligned}(x + y + z)^2 &= x^2 + 2(y + z)x + (y + z)^2\\ &= x^2 + 2xy + 2xz + y^2 + z^2 + 2yz.\end{aligned}$$

or, rearranging the terms,

$$= x^2 + y^2 + z^2 + 2yz + 2zx + 2xy.$$

Proceeding in the same way, we can obtain a formula for the square of the sum of *any* number of quantities. We may express the result in words, thus,

The square of any multinomial is equal to the sum of the squares of each term of the multinomial, together with twice the product of every pair of terms.

Example **2**. Square $a + 2b - 3c$.

$$(a + 2b - 3c)^2 = a^2 + 4b^2 + 9c^2 - 12bc - 6ca + 4ab \quad \underline{Ans.}$$

Note that, whatever signs the terms of the given expression may have, the "square" terms of the result must, by the rule of signs, always be positive. We do not, therefore, have to trouble about the signs of the result until we come to the part which consists of "twice the product of every pair of terms."

After writing down the square of a multinomial, we must, if there are any like terms, collect them according to the ordinary rules.

Example 3. Find the value of $(x^3 - x^2 + x - 1)^2$.

The required value

$$\begin{aligned}&= x^6 + x^4 + x^2 + 1\\ &\quad - 2x^5 + 2x^4 - 2x^3 - 2x^3 + 2x^2 - 2x\\ &= x^6 - 2x^5 + 3x^4 - 4x^3 + 3x^2 - 2x + 1 \quad \underline{Ans.}\end{aligned}$$

NOTE. To make sure that we take *every* pair of terms, it is best to take "twice the product of every term into *every term which follows it.*"

CUBE OF A BINOMIAL

33. The student should also remember the *cube* of a binomial. We can obtain it from the formula

$(x + a)(x + b)(x + c) = x^3 + (a + b + c)x^2 + (bc + ca + ab)x + abc$ by putting b and c each equal to a. Thus,

$$\begin{aligned}(x + a)^3 &= x^3 + (a + a + a)x^2 + (aa + aa + aa)x + aaa\\ &= x^3 + 3ax^2 + 3a^2x + a^3.\end{aligned}$$

Example. Write down the value of $(2b - 1)^3$.

Here, the x of the formula becomes $2b$, and the a becomes -1. Therefore,

$$\begin{aligned}(2b - 1)^3 &= (2b)^3 + 3(-1)(2b)^2 + 3(-1)^2(2b) + (-1)^3\\ &= 8b^3 - 12b^2 + 6b - 1 \quad \underline{Ans.}\end{aligned}$$

The working should, of course, be performed mentally, nothing but the result being written down.

34. Before leaving multiplication, there is one other important result to be obtained from the formula

$$(x + a)(x + b) = x^2 + (a + b)x + ab.$$

Suppose $b = -a$. Then we get

$$\begin{aligned}(x + a)(x - a) &= x^2 + (a - a)x + a(-a)\\ &= x^2 - a^2.\end{aligned}$$

Hence, *the product of the sum and difference of two quantities is the difference of their squares.*

EXAMPLES 5

Multiply

1. $x^2 - xy + 3y^2$ by $3x^2y$.

2. $x^2 - y^2 + 1$ by $-4xy$.

3. $a^2y^2 - abx^2 + ac^2 - 2bcy^2 + 2c^2xy$ by $-5ab^2xy$.

4. $x^2 - xy + y^2$ by $x + y$.

5. $x^2 + xy + y^2$ by $x - y$.

6. $x^2 + ax - a^2$ by $x^2 - ax + a^2$.

7. $x^2 - 2x + 3$ by $x - 1$.

8. $x^3 + ax^2 - bx + c$ by $x^2 - ax + b$.

9 $3x^2y^2 - x^4 - 2y^4$ by $y^2 - x^2 + xy$.

10. $a^2 - ab - ac + b^2 - bc + c^2$ by $a + b + c$.

Using the result of Art. **34** find the continued product of

11. $1 - x$, $1 + x$, $1 + x^2$.

12. $x^2 + xy + y^2$, $x^2 - xy + y^2$, $x^4 - x^2y^2 + y^4$.

Simplify

13. $(a + b + c)(b + c - a)(c + a - b)(a + b - c)$.

14. $(x - y)^2 + (y - z)^2 + (z - x)^2$.

15. $(x + 2)(x - 3)(x - 4)(x + 5)$.

16. $x^2y^2(p^2 - q^2) + p^2q^2(x^2 - y^2)$
$\quad - p^2y^2(q^2 - x^2) + q^2x^2(y^2 - p^2)$.

17. $9(x - 3)(x + 3) - 2[(x - 2)^2$
$\quad - \{2(x - 4)(x + 5) + 3(x - 1)^2\}]$.

Find the following squares

18. $(x-3y+4z)^2$. **20.** $(a+b-c-d)^2$.
19. $(3a^2-2a+5)^2$. **21.** $(a+b)^2(a-b)^2$.

Find the cube of

22. $3x-y$. **24.** $x+y+z$.
23. $1-4a$. **25.** $x-y-z$.

DIVISION

35. Division is the inverse of multiplication. When we divide 6 by 2, we find the quantity by which 2 must be multiplied in order to produce 6. Similarly, when we divide a by b, we find the quantity by which b must be multiplied to produce a.

Now, in Art. **22**, we saw that successive multiplications can be done in any order. Therefore, successive divisions can be done in any order. Hence, a succession of multiplications and divisions can be done in any order. For example, if we multiply a by b, and divide the product by c, we obtain the same result as if we divide a by c and multiply the quotient by b.

36. In Art. **21** we saw that

(i.) $(-a)\times(+b) = -ab$.

Therefore

$$(-ab)\div(-a) = +b.$$

(ii.) $(+a)\times(-b) = -ab$.

Therefore

$$(-ab)\div(+a) = -b,$$

and

$$(-ab)\div(-b) = +a.$$

(iii.) $(-a)\times(-b) = +ab$.

Therefore

$$(+ab)\div(-a) = -b.$$

On examining these results we see that, just as in the case of multiplication, "like signs give +, unlike signs give −." Thus, *the Law of Signs is the same for division as for multiplication.*

37. In Art. **23** we showed that $a^3\times a^4 = a^7$. If, then, we divide a^7 by a^3, we obtain a^4 for quotient.

That is,

$$a^7\div a^3 = a^4 = a^{7-3}.$$

Therefore, *when one power of a letter is divided by another power of the same letter, the index of the quotient is found by subtracting the index of the divisor from the index of the dividend.*

38. We are now able, by using these results, to divide one simple expression by another.

Example 1. Divide $14x^3y^4$ by $7xy^2$.

$14x^3y^4\div 7xy^2 = (14\div 7)\times(x^3\div x)\times(y^4\div y^2)$ by Art. **35**.

$= 2\times x^{3-1}\times y^{4-2}$, by Art. **37**.

$= \underline{2x^2y^2\ \textit{Ans.}}$

As in multiplication, it is clear that we can write down the result at once, the steps shown above being done mentally. We (i.) write down the sign of the quotient, (ii.) divide the numerical coefficient of the dividend by that of the divisor, (iii.) write down each letter that occurs; the index of its power being found by subtracting the index of that letter in the divisor from the index of the same letter in the dividend.

Example 2. Divide $-15a^7b^4c^3$ by $3a^4b^2c^2$.

$$-15a^7b^4c^3\div 3a^4b^2c^2 = \underline{-5a^3b^2c\ \textit{Ans.}}$$

Here we have "unlike signs give −." Then $15\div 3 = 5$. Next, $a^7\div a^4 = a^3$, and so on.

39. It should be noticed that when a power of a letter is divided by the *same* power of that letter, our rule gives us 0 for the index of the quotient.

Thus,

$$x^4\div x^4 = x^{4-4} = x^0.$$

But it is evident that $x^4\div x^4$ is 1. Hence, a quantity whose index is zero is equal to 1.

Answers to Algebra

EXAMPLES 3

1. $2a-[b-\{a-2b-a\}] = 2a-[b+2b] = 2a-3b$ *Ans.*

2. $3x-[1-\{3x+1-3x+1\}] = 3x-[1-2] = 3x+1$ *Ans.*

3. $a+b-[-c+a+2b-a-c] = a+b+2c-2b = a-b+2c$ *Ans.*

4. $-\{-1+1+2\}-[2+1-2-3] = -2+2 = 0$ *Ans.*

5. $x^4-x+3x^3+x^2+x-1-[-3+x^4+3x^3+x^2+1] = x^4+3x^3+x^2-1+3-x^4-3x^3-x^2-1 = 1$ *Ans.*

6. $\frac{1}{2}x-\frac{3}{2}y-\frac{1}{4}-\frac{1}{2}x-\frac{1}{2}y+\frac{1}{4}+x = x-2y$ *Ans.*

EXAMPLES 4

1. $28a^7$. **7.** ab^2cxy.
2. $12x^4$. **8.** $-20cx$.
3. $-2x^3y^2$. **9.** $-60a^2bc^2$.
4. $-6a^2bc^4$. **10.** $-6a^3bc^2x^2$.
5. $44a^2bc$. **11.** $-xy^4z$.
6. $-2a^4b^2c^4$. **12.** $-48ab^2c^2xy^2$.

13. $2ax^2y = 2.(-1).4.3 = -24$ *Ans.*

14. $5a^2y^3 = 5.1.27 = 135$ *Ans.*

15. $3xy+4y^2-5a = -18+0+5 = -13$ *Ans.*

16. $(2x+3y)^2-3(a^2+z^2) = (-4+9)^2-3(1+0) = 25-3 = 22$ *Ans.*

17. $2ax-\{3x^2y-4xy-a^2\} = 4-\{36-0-1\} = -31$ *Ans.*

18. $\sqrt[3]{6ax^2y^2} = \sqrt[3]{6.(-1).(-32).9} = \sqrt[3]{2^6.3^3} = 2^2.3 = 12$ *Ans.*

19. $\sqrt[3]{\dfrac{a^2+xy}{5x^3}} = \sqrt[3]{\dfrac{1-6}{40}} = \sqrt[3]{\dfrac{-5}{-40}} = \sqrt[3]{\dfrac{1}{8}} = \dfrac{1}{2}$ *Ans.*

20. $\sqrt{6ax^2y}\div\sqrt[4]{12a^2x^2y^2} = \sqrt{144}\div\sqrt[4]{2^4.3^4} = 12\div 6 = 2$ *Ans.*

TRANSIT
1

VARIOUS METHODS OF TRANSIT

Natural and Vehicular Transport. The Bicycle and the Automobile. Relative Speed and Cost of Various Methods of Transit

By F. L. RAWSON

As an ambulatory biped, man from the remotest ages has possessed the power of moving from place to place. In the beginning he relied solely upon the means with which Nature had provided him, and for all ordinary purposes he needed no other. The average man can maintain on foot a speed of four miles an hour for several hours, and can traverse more than 30 miles in a day's march of 10 hours without undue effort. For short distances a walking pace of over nine miles an hour can be attained under racing conditions, and over eight miles has been covered within one hour. On forced march, with the usual impedimenta, British soldiers have traversed a distance of 43 miles in 32 hours.

When running, a man can cover 11½ miles in the hour on a racing track, but the effort is severe; in semi-civilised countries, however, the natives possess remarkable powers of running for prolonged periods. For example, the native letter carriers of India are accustomed to maintain a steady trot for many hours, without apparent effort, over rough country, in a way that would be a physical impossibility to a European under similar conditions.

Animal Service in Transit. In civilised countries the roads are kept in good order, and progress on foot is therefore easy and comparatively speedy; but in unsettled countries, where roads are poor or absent, walking is a poor and inefficient means of transit, and in any case the transport of goods on foot is an arduous process. Hence it came about that at a very early stage of human civilisation the assistance of animals was invoked. Whether camels, oxen, or horses were the first to become the servants of man need not concern us. While even to this day the camel is the only animal capable of crossing long stretches of desert land without ample supplies of food and water, the horse is by far the most generally serviceable beast of burden.

The Horse. A horse walks at about four miles an hour and trots about 10 miles an hour; it can traverse 60 miles in a day without injury. This gives the rider a range twice as great as that of a pedestrian. Moreover, while the horse cannot travel fast over rough and stony ground, it is far less dependent than man upon good roads, and, indeed, is most at home upon rolling grassland. Riding is practically as safe as walking, and twice or thrice as speedy. The first cost of a good riding horse of course varies with local circumstances, but may be put in this country at about £50, while its useful life is at least 12 years. Allowing for interest at 5 per cent., and taking account of the life of the animal, the annual charges on capital account amount to £7 per annum. The keep of a horse costs, in England, about 15s a week, or, inclusive of shoeing, stabling, and attendance, about £1 per week. Thus, it costs at least £59 a year to keep a horse for riding, without reckoning contingencies.

The daily cost is much the same whether the horse is used every day or not; but allowing a distance of 120 to 150 miles as a fair week's work, the cost per mile amounts to from 1·8d. to 2·3d. at least.

Vehicular Transport. A man who undertakes a long journey, for example, in a new or undeveloped country, such as Australia or Rhodesia, must provide himself with means of transporting his household and other goods, and this cannot be conveniently accomplished, except under special circumstances, without the aid of vehicles. Even in civilised countries railways cannot penetrate everywhere, and transport over the common roads must be carried on as economically as possible. Taking the latter case first, the subject naturally falls under two heads: the transport of men at a comparatively rapid pace, and that of goods at a low speed. Two classes of vehicles are therefore necessary, and two kinds of draught animals.

Light Vehicles. A light vehicle, such as a dogcart, drawn by one horse, proceeds at the average rate of 10 to 12 miles an hour, and has a range of 30 or 40 miles a day—much more, if relays of horses are employed. Estimating the cost of the vehicle and harness at £50, and allowing 5 per cent. for interest, 10 per cent. for depreciation, including repairs, the annual expenditure entailed by the possession of a dogcart is £7 10s., and with that of a suitable horse, as before, amounts to a total of £66 10s. If the vehicle were driven for 30 miles daily, the cost of repairs would be greater, but this is not the average condition. Assuming, therefore, that the charges are as stated, the cost per mile of vehicular transit by this means, on the basis of 120 to 150 miles per week, may be estimated at about 2·3d. per mile, and if an attendant is employed this will be at least doubled.

Turning to the transport of goods, this is most economically effected in large waggons, drawn by two or more horses, at a speed of 2½ to 3 miles per hour. The burden constituting a load depends upon the nature of the goods carried, but the weight that can be hauled on ordinary roads under the conditions named is about 2 tons per two-horsed waggon. The cost of such a waggon is £40. Allowing

5 per cent. for interest, and estimating the life of the waggon at, say, 15 years, the annual charges amount to £5. Labour will cost, roughly, £65 per annum. The first cost of the draught horses, which are heavy animals, and require more food than carriage horses, will amount to £100, and their keep, stabling, etc., to £110. The total annual cost of the two-horsed waggon is therefore £194, and, allowing for a total journey of 20 miles a day, six days a week, the cost per ton-mile is 3⅞d. If either the load or the distance be less, the cost will be proportionately increased.

Ox Transit. In countries such as the Transvaal, while riding and driving in light carts are the customary means of travelling in person, goods are conveyed in waggons hauled by oxen at a very slow pace, not more than 1½ miles an hour; the roads are very primitive, and often as many as 20 oxen are harnessed to a single waggon. Bullock carts are also largely used in India and other Eastern countries, and in the latter personal transit is more commonly effected with light hand-carriages, called jinrikshas, or "rickshaws," hauled by native runners, than on horseback.

Town Transit. The means of transit available in towns, especially large ones, with dense populations and often narrow streets, stand in a category of their own. The subject is one of immense importance, and, in such a city as London, is of vital interest to all classes. Naturally the horse has hitherto occupied a prominent position in this connection, and, apart from railways, has remained until recent years practically the only available agency for carrying on the transport of passengers and goods. In addition to innumerable private carts, waggons, carriages, etc., there are in London about 11,500 cabs for hire, and 3,000 omnibuses, besides about 2,000 tramcars. All these ply upon the common roads, and the congestion of traffic is such that, according to the Report of the Royal Commission on London Traffic, the loss of time due to this cause alone amounts to 30 or 40 per cent.

Omnibuses. Omnibuses are public conveyances usually carrying passengers on the roof as well as inside, to the number of about 26, and are hauled by two horses at the rate of six to eight miles an hour on the average. The fares are in the neighbourhood of 1d. per mile. Such vehicles form a most valuable means of transit, though the pace is slow, and in many parts of London they are the only means. They have been accused of being to a great extent the cause of the congestion of the London streets, but this contention is easily refuted. The most fruitful sources of delay are the slow-moving carts and waggons with which the narrow streets are encumbered, and especially the vehicles which are kept standing at the roadside whilst loading or unloading, thus reducing the available width of the roadway often to the extent of 25 or 30 per cent. If the main streets could be rid of these, and reserved solely for the quick-moving traffic, the congestion would be very greatly lessened. In towns which are more fortunate than London in the possession of wide streets, omnibuses have been largely superseded by tramcars, to which we shall refer later.

The Bicycle. Not everyone can afford to keep a horse, and, therefore, the evolution of a cheap and reliable bicycle from the old boneshaker during the last twenty years has resulted in the manufacture and sale of an enormous number of these machines. The invention of the pneumatic tyre was of supreme importance, rendering the motion smooth and agreeable, and greatly increasing the average speed attainable. A well-made and durable machine can now be obtained for £6 or £8, and will last for several years, if kept in good order and repair. The maximum distance traversed in an hour on a racing track is 54 miles 750 yards, and on ordinary roads over 226 miles have been covered in 12 hours, thus leaving horses and men on foot far in the rear. Without forcing the pace, it is easy to maintain a speed of 15 miles an hour, and to cover 100 miles in a day. Bicycles, however, are ill-adapted for carrying weight other than that of the rider. Allowing for a total outlay of £4 per annum, the cost per mile (150 miles a week) is ⅛d., so that the bicycle is one of the cheapest means of transit.

The Motor Bicycle. The introduction of the small, high-speed, internal combustion engine for the propulsion of road vehicles was soon followed by its application to the bicycle, and led to the development of very high speeds on the racing track (one kilometre in 26⅖ seconds, equalling a speed of 84·68 miles an hour, having been reached), but not to any great extent on ordinary roads, owing to the legal restrictions and the necessity of exercising caution in the presence of other users of the highway. Except for individual use, the bicycle obviously cannot form an important factor in locomotion.

The Automobile. The modern automobile, on the other hand, is destined to exercise immense influence on the transit problem, and its meteoric development during the last ten years has resulted in the evolution of various types of automobile cars adapted to every modern requirement. The speeds attainable are equal to, or even greater than, that of the fastest express train (a kilometre having been covered in 21⅖ seconds, or at the rate of 104·52 miles an hour), while the car remains under the most perfect control, as regards both the steering and the ability to stop in a very short space. The high speed is due to the great advances made in recent years in the design and construction of small engines.

Thanks to the accuracy of modern manufacturing methods it has become possible to run these at very high rotative speeds, thereby enabling them to develop large powers with small weight. The use of volatile liquids, such as petroleum spirit (petrol), alcohol, etc., exploded in the cylinders of these engines in the form of vapour mixed with air, and thus dispensing with the complications due to the use of steam, has made them capable of running continuously without attention, a condition essential to success in the case of a car running at considerable speed on the common roads. It is true that some types of automobiles are driven by steam, but this agent is now little used except for heavy goods waggons. Improvements in automobile propulsion may be expected in the application of steam or gas turbines and the use of paraffin instead of petrol as a fuel. Paraffin or petroleum costs only half as much as petrol, and the only obstacle to its use is the difficulty of carburetting properly.

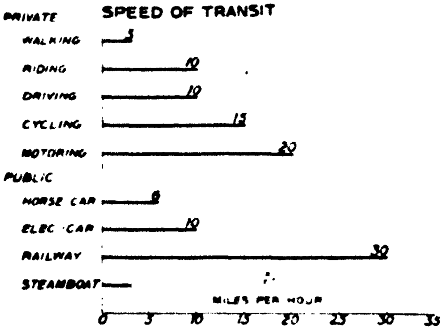
Cost of Automobiles. Although great reductions in the cost of automobiles have taken place during the last few years, they are still very expensive machines, both in first cost and in upkeep. The latter is largely due to the indiarubber tyres, which are indispensable adjuncts to comfort in travelling, but are, unfortunately, subject to very rapid wear. A set of tyres for a motor-car costs from £20 to £60, and lasts for not more than 4,000 to 5,000 miles, so that, for tyres alone, the cost per car-mile amounts to 2d., or, say, per passenger per mile, ½d. Allowing for interest and depreciation on the cost of the car, stabling and attendance, and the cost of petrol, the total cost per passenger per mile may be estimated at 2½d. for a four-seated car, assuming that all four seats are occupied, and that the average distance covered is 150 miles a week.

For the transport of goods the heavy motor waggon has already amply proved its worth, and has quickly come into general use. Such waggons are built to carry from three to six tons, at speeds from 2½ to 5 miles per hour; the driving motors are usually actuated by steam, at very high pressure (220 lb. per square inch), and are rated at from 25 to 45 indicated horse-power. These waggons are not provided with rubber tyres, but with broad and heavy wooden wheels, shod with steel tyres. The cost of transport carried on by their means is about 3½d. per ton-mile. Faster and lighter vans are made for delivering parcels, and motor-vans driven by petrol engines have been adopted by the British Post Office for carrying the mails in and between certain towns.

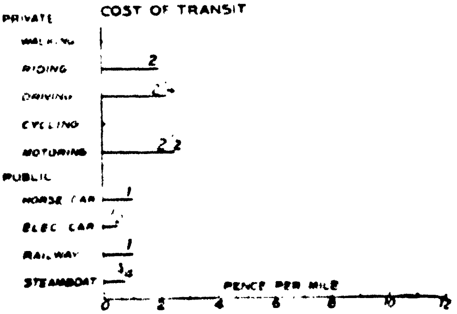
Comparison of Methods of Transit. It may be opportune at this point to summarise the data given in the foregoing and subsequent sections, and this is most conveniently done by means of diagrams. We must here point out the enormous importance of the element of time in comparing rival systems of transit. Time, says the proverb, is money, and certainly to the busy man it has a very real value. Considerations of space compel us to confine ourselves to a single example, and for this purpose we shall take the case of a man whose time is valued at half-a-crown an hour, or ½d. per minute. Our readers can readily work out for themselves any other case in which they may be more directly interested.

These diagrams are very instructive. It will be seen that the time allowance puts an entirely different complexion on the matter. The fastest mode of transit at once becomes the cheapest, and if an express train be used, the railway is by far the cheapest, for then the cost per mile will come down to but little over 1·5d. Walking would at first sight seem the most economical means of transit, costing nothing but shoe-leather; yet it proves to be the most expensive.

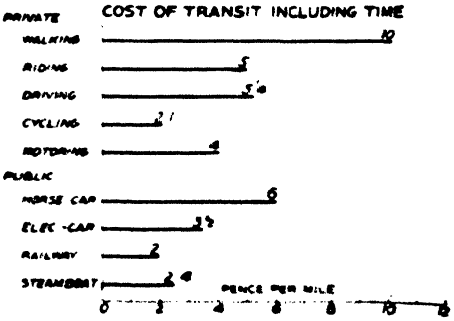
The first diagram gives the relative speeds attainable under practical commercial conditions for personal transit, with which we are mainly concerned:



We take next the actual outlay entailed by various means of transit, without allowing for the cost of time expended:



Lastly, let us see the effect of taking time into consideration, on the aforesaid basis:



The diagrams must be regarded not as absolutely exact under all circumstances, but as only approximately true.

WEAPONS & COLOURS OF MAMMALS

Development of Brains. Horns and Antlers. Skin, Fur, and Scales as Armour. Various uses of Colours. Other Ornamentation

By Professor J. R. AINSWORTH DAVIS

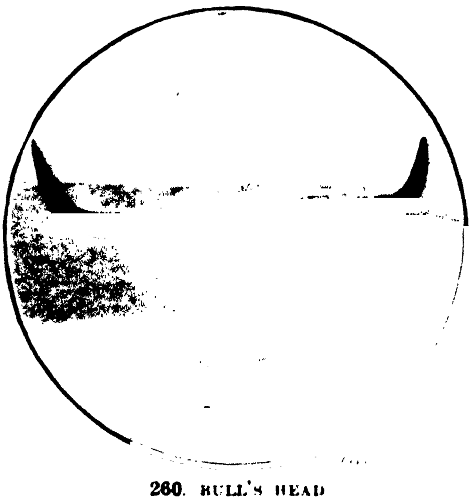
THE backboned animals which first dominated the land were amphibians, now represented by newts, salamanders, frogs and toads. Later these were supplanted by a branch of their own stock—*i.e.*, reptiles—which adapted themselves to all sorts of conditions, and presented a great variety of groups, most of which are now entirely extinct. The members of this class in their turn yielded to mammals and birds, both of which are improvements upon the remote reptilian ancestors from which they have undoubtedly sprung.

The Blood of Reptiles. The success of both birds and mammals in the struggle for existence is primarily due to the fact that their circulatory and breathing organs have become extremely efficient. The latter purify the blood very thoroughly, and in the former there is no mixing of pure and impure blood, as in amphibians and reptiles, which are both greatly handicapped by the circumstance. They have, in fact, only partly succeeded in adapting the fish circulation they have inherited to the conditions which obtain on land. The advantage which birds and mammals have gained in the directions indicated means increased energy, enabling them to cope advantageously with competing lower types.

Mammals, again, have become specially fitted in several ways for both offensive and defensive warfare. All but the spiny ant-eater and duck-billed platypus—now on the way to extinction—have abandoned the primitive device of egg-laying, their young being born "alive." Parental care after birth gives the young animals a good start, and the milk diet provided for them obviates many difficulties as to feeding. Even the primitive mammals just mentioned show great solicitude in the care of their young, and possess milk glands.

The Value of Brains. An even more important advantage gained by mammals in the course of evolution has been the development of a relatively large brain, which is correlated with marked intelligence, a leading factor in the struggle for existence, and a concrete illustration of the principle that "the race is not always to the swift, nor the battle to the strong." Man himself is, of course, the most remarkable example of this, while, on the other hand, there are certain extinct groups of mammals which have become extinct because their brains did not develop to a sufficient extent, and which have perished so to speak from sheer stupidity.

Preservation of the Weaker Orders. Coming now to special methods of defence among mammals, we find that among the weaker orders, such as the GNAWERS (*Rodentia*), great fecundity largely compensates for disabilities in other directions, and prevents many species from becoming extinct. The rabbit has become proverbial in this respect. Many, too, of the ill-defended forms have adopted modes of life which have reduced the pressure of competition. Some of them have taken to burrowing, others have become aquatic, still others are arboreal, and bats have developed organs of flight.



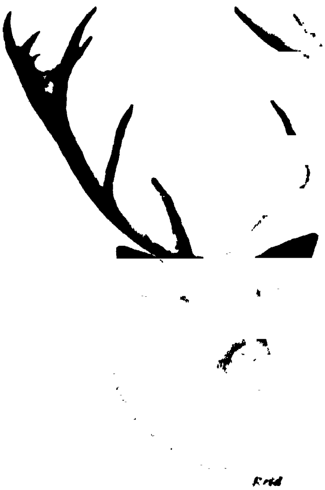
260. BULL'S HEAD

Many mammals are in the possession of more or less efficient weapons, which stand their owners in good stead in the event of attack. Some of these, such as the sharp teeth and claws of the cat-like types, are primarily offensive in character, but serve equally well for the other purpose. And in vegetarian forms we find a great variety of weapons which are primarily of use in what may be termed active defence. A good instance is afforded by the formidable tusks of the elephant and wild boar.

Horns. Actively defensive weapons are also the horns and antlers of many species, of which a great variety are to be found among the HOOFED MAMMALS. One type is that possessed by the Indian buffalo, the American bison, oxen [260], sheep, goats, and antelopes. There are here two bony outgrowths from the top of the skull, covered by horny sheaths of varying shape, the sharp points of which are well calculated to meet attacks. Those of the sable antelope of Africa, for example, sometimes enable their possessors to transfix an aggressive lion. In antelopes these weapons are nearly always limited to the males.

Antlers Indicate Age. The antlers of deer [261], also possessed by the male only, as a general rule are of very different character, being bony outgrowths from the skull, which are shed annually, and in many cases become more complex each year, this serving as an indication of age. Until their full size is attained they are covered with soft, hairy skin, the "velvet," after which a projecting ridge, the "burr," grows out at the base of the antler, and stops the circulation of the blood in the skin-layer, so that it dies and peels away, and the antler itself, being deprived of its nourishment, becomes dead bone, to be cast off later. Being insensitive, it makes a particularly serviceable weapon. Antlers, however, are not merely used in active defence, but also in the annual fights which take place between the polygamous males for the possession and holding of establishments.

The Unicorn. The curious epidermal horn or horns of a rhinoceros are formidable weapons of quite a different kind, which, like the paired horns of oxen, etc., are not periodically shed and renewed. The emblematic "unicorn" was probably founded upon imperfect knowledge of the Indian rhinoceros by someone possessed of a lively imagination. In one of the dolphin-like cetacea living in Arctic seas, the narwhal (*Monodon*), a long ivory spear marked with a spiral groove projects from the snout of the male, and was at one time considered to be a "horn." In reality, it is a much elongated incisor tooth, comparable to the tusk of an elephant; sometimes a pair are present.



261. RED DEER

Armour. Mammals often possess structures which, being used in passive defence, may be grouped under the heading of "armour." The skin may be very tough and thick, as in the elephant and rhinoceros, or the fur may be so dense as to be a protection. The excessive development of hair on the head and neck of a lion very possibly serves to guard the throat during fights with other individuals of the same species.

Spines. In several orders a number of hairs are transformed into spines, which help to ward off attacks. Examples are afforded by the spiny ant-eater (*Echidna*) of Australia, the hedgehog (*Erinaceus*) [231, page 1490], and the porcupine (*Hystrix*) [262]. Almost everyone living in the country has probably observed the way in which this *chevaux-de-frise* is displayed to the best advantage by an alarmed hedgehog, when it rolls itself into a ball, and remains motionless until the danger is past. A powerful layer of muscle in the skin renders this possible.

Among mammals poor in teeth (*Edentata*) we find both scale and plate armour. The former is affected by the pangolins of Africa and Asia, in which the body is defended by horny, overlapping scales. In the armadillos of South America, there are bony plates in the skin [263] which serve a similar purpose. Some of these creatures are able to roll up like hedgehogs. Other special methods of defence are included under the next heading, and we may here note the great powers of speed possessed by many hoofed mammals, their gregarious habits, and their powerful hoofs, all contributing to foil or repel attacks. Some of them set sentinels while the herd grazes, to give notice of approaching danger. The power of ruminating, or "chewing the cud," which some of them have acquired, has already been mentioned as a protective habit.

The Colours of Mammals. As reference will from time to time be made to animal colouration in connection with various groups, it may be well to give a general classification of colours and markings, to be illustrated for the present by reference to mammals only:

1. Protective Colouration. (*a*) General; (*b*) special. 2. Aggressive Colouration. (*a*) General; (*b*) special. 3. Warning Colouration and Mimicry. 4. Courtship Colouration. 5. Signalling Colouration. 6. Recognition Colours and Markings.

Protective colouration is of such a nature that it renders its owner inconspicuous, and therefore more difficult for foes to discover. When it is "general," the result is a harmonising with surroundings of which the animal so protected appears to form a part. This is why the upper side of the body is so often darker than the under, a sort of "reversed shading," which takes away from the appearance of solidity.

Summer and Winter Dresses of Animals. No better example could be taken than that of the wild rabbit. In countries where there is a marked difference of temperature between summer and winter, some mammals change the colour of their fur. The variable hare, for instance, which ranges east from Ireland and Scotland to Japan, has a dark summer and a white winter coat, the difference being most clearly marked in the northern part of its area of distribution.

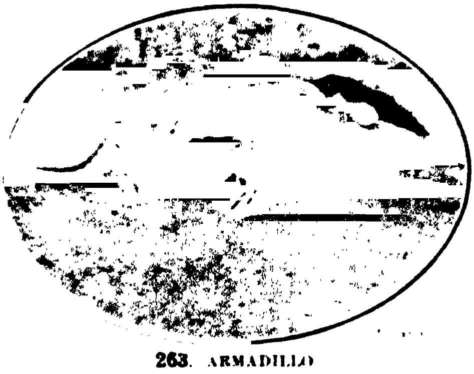
Protective colouration is "special" when it brings about a resemblance to some particular inanimate object. A squatting hare, for example, looks very much like a clod of earth. It is said that the two-toed sloth of South America presents a striking resemblance to a lichen-covered bough, brought about by its dull, rough hair, on which a small green alga grows; and in one species there is an oval brown patch between the shoulders, which suggests the broken-off end of the sham bough.

Ermine a Winter Dress. Aggressive colouration is of much the same character as the preceding, but its purpose is different, for it enables flesh-eating forms to escape the observation of their prey. The tawny hide of the lion, and the spotted coat of the leopard are cases in point, and so is the white fur of the Polar bear. There may also be, as before, summer and winter coats of different colour. Our native stoat (*Putorius erminea*), for instance, has a reddish-brown back in summer, while in winter in north Scotland—it turns white, except that the tip of the tail remains black. This winter dress is the source of the valuable fur called "ermine."

Warning colouration is of such a kind as to make its possessor very conspicuous, and may be taken as an advertisement of unpleasant properties, which only a particularly hungry enemy would care to face. The common badger (*Meles taxus*) belongs to an evil-smelling group, and here the upper side of the body is light-coloured, contrary to the general rule. The American skunk (*Mephitis suffocans*) possesses glands from which it can squirt out an irritating fluid of indescribable odour, and this property is advertised by a white back and a large bushy white tail, which serves as a "danger flag."

The term mimicry is applied to cases where a "mimic," devoid of unpleasant characters, closely resembles a "model" which is defended by warning colouration. Plenty of instances are to be found among insects, as we shall later on have occasion to see.

Moustaches and Courtship. Courtship colouration applies to cases where one sex, usually the male, possesses gay adornments, supposed to facilitate love affairs. We see this in some male baboons which are decorated with vivid red or blue, both fore and aft. It is not improbable that the moustaches and beards of men were evolved for similar reasons, and they are said still to retain their original use to some extent. Some male monkeys possess a similar adornment.



263. ARMADILLO

Signalling colouration is exemplified by some of the gregarious mammals, and serve to announce the approach of danger. The white tail of the wild rabbit, so conspicuous when it runs, probably has this use. It may also be noted here that buck rabbits warn their fellows by stamping on the ground with their hind feet. The sentinels set by some forms have already been mentioned.

262. PORCUPINE

Recognition markings have also been described in some gregarious forms, and are supposed to be a means of keeping individuals of the same species together. Many antelopes, for instance, are marked with alternating light and dark stripes or spots on the upper parts of their bodies, which may, perhaps, serve the purpose indicated. Another means of keeping communities together is afforded by the possession of characteristic odours. In the peccaries or wild pigs of South America, there is a gland on the back which secretes a fluid of unpleasant smell, at least to our way of thinking, and in sheep there are bottle-shaped glands between the hoofs, from which an odorous fluid is squeezed out on the herbage, leaving a track that can easily be followed by the sense of smell.

Descent of Man. By those most competent to judge, it is now universally admitted that the physical structure of man does not separate him more sharply from the highest apes than these, by their anatomical characters, are marked off from ordinary monkeys, and the highest apes are undoubtedly his nearest allies. It is true that man is the animal best adapted to progression in the erect attitude, as seen in the structure of his hind limbs, but this is simply a matter of degree.

It may be added that the body of a human being is quite a museum of "vestiges" handed down as souvenirs of earlier stages in evolution. Such are the troublesome "appendix" of the intestine, and a little red fold in the inner corner of the eye, which represents a "third eyelid," found in some lower mammals—*e.g.*, the rabbit.

The real differences are to be found in the power of articulate speech, and the faculty of reason associated with an exceedingly large brain. But most probably both speech and reason were both gradually evolved, just as physical characteristics have been. A course in natural history is not the place to discuss in detail so thorny a question, especially as experts are not all

THE SERVICE OF THE STATE

The Advantages of the National Service. Its Scope and Departments. Emoluments. Conditions of Entering

By ERNEST A. CARR

READERS of this course will recall that at its inception the ground to be traversed was mapped out into three great provinces—the *municipal*, the *national*, and the *imperial* services. Our consideration of the first of these ended with the section on Poor Law appointments. We now turn to that distinct and very important branch of our general subject which is comprised in the National Service. It corresponds very nearly with that division which is technically known as the home Civil Service, though we have throughout this course employed the word "civil" in a less restricted sense.

The National Civil Service. For a clear understanding of this section it is essential, before reviewing in detail each of its many grades, to consider briefly the national service as a whole, and the general conditions characterising it. We must understand something, for instance, of the average prospects it offers, the nature of the duties involved, and the provisions existing as to the sick pay and the retiring allowances of Government servants. And it is necessary, also, to have a clear comprehension of the methods by which appointments are filled, and the requirements in respect to education, age, and health. The prevalent system of open competitive examinations, in particular, is of supreme importance to prospective candidates.

We may define the national service in a phrase as the sum total of all non-fighting posts—except in India and the Colonies—which are held directly under the State and remunerated from public funds. This definition will be seen to exclude municipal servants, since their offices are held under local authorities of various kinds; but it is wide enough to embrace all other public servants of every degree. The Secretaries of State and their youngest messenger lads, our representative at Berlin or The Hague and the modest Customs officer who searches his baggage for smuggled spirits or tobacco when that dignitary lands at Dover or Harwich—all these, with every Government official of intermediate grade, are equally members of the national service.

Numbers and Constitution. This great army of State servants numbers between 50,000 and 60,000 of all ranks, and is entrusted with the execution of all civil affairs which are of national interest as distinguished from merely local concerns. The importance and varied nature of the duties thus performed cannot readily be estimated. With the giant work of the postal and telegraph services and of our preventive departments we all are more or less familiar; but few of us realise, probably, how much labour is involved in such functions as our prison system and courts of law, or the civil direction of the Army and Navy. To these we must add the great and grave departments of State, controlled for the most part by parliamentary secretaries, which are concerned either with the administration of internal affairs or with the problems of international relations.

Scope of the National Civil Service. In the former category we may place the Home Department and the Treasury, and in the latter the Foreign Office, Colonial Office, and that of the Secretary of State for India. In the course on the municipal service we saw that two further State departments—those of the Local Government Board and the Board of Education—exercise a central and salutary control over the actions of local authorities. Other special functions are exercised by the Board of Trade, the Patent Office, Royal Mint, and a host of offices, great and small, with whose very names the general public is unfamiliar, but whose duties, nevertheless, are of national importance. And, save for certain technical posts in the Admiralty and War Office which are reserved for members of the combatant services, every Government office is staffed entirely by officials of the national service.

In a few exceptional instances—as in the metropolitan police courts, whose officers are paid partly out of the police rate—the salaries of Government servants are derived in part from local funds, but in the great majority of cases the sources of income are wholly national. The cost of each department, including salaries, is estimated annually in advance, and the total amounts thus calculated are submitted to the House of Commons every year and appropriated out of the nation's revenues by a parliamentary Vote on Account.

Salient Features. The national differs from the municipal section in several material respects. In the first place, as befits a Government institution, it is marked by a completeness and uniformity of system almost entirely wanting in the municipal world. Instead of conditions altering in greater or less degree with every change of district, the State affords its employees of each grade, throughout the country, clearly defined and practically unvarying terms of service, including rates of pay, amount and frequency of increment, and so forth. This is not entirely an advantage. Local bodies, in exceptional cases, may mark their sense of official zeal and devotion by a liberality unknown under the rigid rules of Government service. On the whole, however, a fixed and adequate scale of remuneration is preferable to dependence on the uncertain views of a council or board of guardians.

This uniformity of method extends also to the conditions under which the Government service may be entered and left. For admission to each of the main grades of appointment certain regulations are framed which are bindng on all candidates alike, and every permanent official is subject to the same provisions as to pensions and gratuities on retirement.

A Clerical Service. A further distinction may be based on the nature of the duties in this service. The municipal section, as we have seen, comprises engineers, inspectors, chemists, police officers, firemen, nurses, and a great many others whose functions are practical and executive rather than clerical. The national branch, as viewed from the candidates' standpoint, is in the main an assemblage of clerks of various grades. There are many exceptions, it is true, notably in the Excise and Customs and Prisons departments, the inspection of mines and factories, and certain technical posts in the non-combatant staff of the Royal Navy. But, speaking generally, the work of the national service is clerical throughout

The distinction is worth considering. It is evident that such a service, as compared with one which is largely executive, will include fewer posts for which some degree of education is not imperative. On the other hand, it affords less scope for the skilled expert and the able administrator A clerk, however capable he may be, can hardly expect to find in his calling the same opportunities for personal distinction and rapid advancement as may await a clever analyst or architect, or a trained engineer who is willing to incur the grave responsibilities involved in carrying out great public works.

Such considerations lead us to expect in the national service precisely the features which, in fact, it displays. These are moderate but progressive salaries, promotion usually dependent on steady service, light and regular duties, and a small proportion of distinctly subordinate posts.

Lot of the Government Clerk. To a man of reasonable ambitions, who is repelled by the uncertainties and stress of commercial life, the national service, with its assured income and liberal leisure, offers many attractions. The Government clerk enjoys, indeed, a degree of consideration and dignity but rarely attained by his colleague in commerce. He is generally housed in a spacious and comfortably appointed building, as befits a servant of the State. The Foreign Office, Home Office, and other great departments in the West End of London, are among the finest structures in that region of fine buildings. During the seven hours which constitute the average official day, work proceeds at an unhurried and equable pace, with due regard to the sanctity of the luncheon interval. The character of that work naturally varies with the various offices. Usually it includes correspondence or bookkeeping, indexing and docketing documents, compiling statistics, preparing reports, and similar clerkly duties. In the higher ranks the work, while of the same general character, is more responsible, and involves the supervision and control of the subordinate staff.

Such are the conditions normally prevailing in the average Government office. Certain busy, important departments, however, are disagreeable exceptions to the rule. The General Post Office, throughout all its branches, is a notorious instance in point. It employs an enormous staff of clerks and other workers on duties that are generally monotonous, uninteresting, and performed at high pressure. The outdoor officers of the Inland Revenue and Customs offices, again, are required to work under irksome conditions of exposure and irregular and often protracted hours.

Vacation and Sick Leave. In respect of leave and sick leave the State is unquestionably a liberal employer. Higher class officials are entitled to six weeks' holiday yearly, which is extended after ten years' service to eight weeks. For officers of intermediate rank the annual leave varies between three weeks and a month, and only the distinctly subordinate grades are restricted to shorter terms of from ten to eighteen days. The provisions as to sick leave are as follows. Members of the permanent staff receive full pay while absent on account of ill-health, until they have been away for six months continuously. If still unfit for duty, they may then be placed on half pay for another six months. At the end of this latter term their case is specially considered, and they are usually either granted further leave without pay or called upon to resign.

Such considerate treatment is rare indeed outside the Government service. How beneficent the system proves in practice was illustrated by the case of a colleague and friend of the writer's, who, after a few years in a State department, developed somewhat serious lung trouble Dependent as he was upon his salary, he might have fared disastrously in other employment. But the authorities promptly granted him six months' absence on full pay He was thus able to make a voyage round the world, returning to England completely restored to health.

Remuneration. The national service comprises appointments of a great many grades. A special feature of our next article will be a "conspectus," or general table, showing the range of salary and other particulars in respect of each rank. For the present it will serve to group these posts approximately into three broad divisions.

Of these the first includes the highest clerical and administrative offices, relatively few in number and keenly contested. Starting at £150 or £200 a year, they rise rapidly to £700, £800, £1,000, or higher. In the second flight are the mass of ordinary clerical positions, with initial salaries varying from £70 to £100, and advancing by moderate increments to £350, £400, or occasionally £500. Last in rank we must place the post-office telegraphists and sorters, inferior clerks, messengers, and other subordinate officers, whose prospects are bounded by a slowly attained maximum of £150 or £200 a year.

Promotion. Prospects of promotion vary a good deal with the different offices, some of which are conspicuous for the chances they afford while others are as notably wanting in that respect. Generally, the traditions of the Service are opposed to the speedy promotion of juniors. This vexed question was briefly discussed in our opening article [page 79]. As was there pointed out, the authorities, while avowedly solicitous to reward ability, in practice make advancement by seniority a rule from which they are very reluctant to depart. Rarely is a deserving junior specially promoted. He must generally wait until all the men before him on the list have been given their "step" in turn. Hence, though a great many higher posts are filled from the subordinate ranks, and the chances of eventual promotion are consequently good, advancement comes with halting feet. The natural result is a certain degree of discontent among eager, ambitious young officials whose road to promotion is blocked by a line of stolid and not over strenuous elders. For men of the requisite ability and resolution, however, there is a more direct method of advancement than awaiting the special recommendation of a chief or the translation of every senior officer. This short cut consists in competing while in the Service for a post of higher value—a course which is facilitated by the ample leisure left at the close of the official day.

Pensions. Among the attractions of State employment is the prospect of a pension when one's term of duty is ended. The system in force is a liberal one, and is so simple in principle that it may be summarised in a few words. Members of the permanent staff who are invalided before completing ten years' service are not entitled to claim a pension, but may receive a gratuity of one month's pay for each completed year. Officers of ten years' standing and upwards, if certified unfit for further duty, are entitled to a life pension proportionate to their position and length of service. This is calculated upon the scale of one-sixtieth of the officer's salary for every year of service up to a maximum of 40 years. If invalided after 15 years, for example, the superannuation allowance would be $\frac{15}{60}$ths, or a fourth of the salary. After 20 years it would be $\frac{20}{60}$ths, or one-third; after 30 years $\frac{30}{60}$ths, or a half; and after 40 years (or more), $\frac{40}{60}$ths, or two-thirds, which is the *maximum* proportion attainable in any event.

At the age of 60 retirement is optional, and at 65 it is compulsory. Thus, an officer entering when 20 years old and reaching a post with £600 a year, can claim on his sixtieth birthday a pension of £400. Five years later he would be obliged to retire; and since not more than 40 years' service counts towards a pension, his superannuation would not be increased. If, however, he entered at 25, the pension payable at 60 would be only $\frac{35}{60}$ths, or £350 a year, while by continuing at his post until 65 he would complete the 40 years' service requisite for the full allowance of £400. Officers serving abroad in unhealthy districts are entitled to count every two years thus spent as three years for pension purposes; and for those who are injured in the course of their duties special provision is made.

Government servants are not liable, as we saw that Poor Law officers are, to any deduction from salary on account of pension.

In one respect only does the scheme we have outlined lend itself to criticism. This is the absence of any provision for the family of an officer dying "in harness." The question has recently been investigated by a Royal Commission, and there is good reason to hope that as the outcome of its recommendations a year's salary at least will be payable in that event, the general pension scale being slightly reduced to meet this extra expense.

How Vacancies are Filled. From the figures quoted as to the number of Government officials it is evident that vacancies are constantly arising. Estimating the average official term at 20 years, it follows that some 3,000 appointments must be made every year to replenish the losses occasioned by resignations and deaths. For us, as candidates actual or potential, the supreme question is just this: under what conditions are those 3,000 vacancies filled?

In the bad old days of patronage, down to the middle of last century, such posts were in the gift of the Ministers of State, who appear to have bestowed them with less regard for the needs of the Service than for the wants of their importunate friends. It is from this age that the tradition dates which depicts the average civilian as an incompetent and supercilious lounger. If such a portrait be now admittedly libellous and out of date, it is wholly because the patronage system has been gradually replaced, meantime, by one which makes ability, education, and health the passports to the Service. At first nominated candidates were required merely to furnish proofs of their fitness to serve. But in 1870 a radical change was introduced, which, by attracting capable, well trained men to the Service, has done more than anything else to promote its efficiency.

Open Competition. This sweeping reform consisted in throwing open the majority of Government appointments to the unrestricted competition of British subjects of fitting age, health, and character. The system proved instantly successful and is in vigorous operation to-day. Under the direction of a special department—the Civil Service Commission—open contests are held for posts of the various grades as occasion requires, and existing vacancies are filled by appointing the candidates who take the highest places.

From the standpoint of would-be Government employees the importance of the reform thus effected can hardly be overstated. Open competition fulfils Napoleon's boast of opening a career to talent, however lacking in influential friends its possessor might be. The highest positions in the service of the State are placed within reach of any youth of the requisite ability and education, no matter how humble in origin or poor in purse. And this tendency to democratise the Service, already strongly marked, will become still more accentuated in the near future. Hitherto, despite the absence of caste barriers in these contests, the degree of education necessary to compete successfully for the most valuable posts has proved, in practice, almost prohibitive for candidates below the middle classes in position. But with the elaborate system of scholarships recently devised by the County Council, extending from the elementary school to the University [see page 1677] that disability will be minimised, and the labourer's son may meet the scion of nobility in fair and honourable rivalry for the prize of a lucrative career under the State.

Open competitions for the various vacancies are announced from time to time in the "London Gazette" and the leading newspapers. The advertisement of the Examining Body appears in the Thursday issue of most of the London morning papers, and may usually be found below the theatrical announcements on the centre sheet. Detailed particulars of any of the examinations there named, and of the appointments to which they relate, may be obtained on application to the Secretary, Civil Service Commission, Burlington Gardens, W.

Nominations. While public competitions form the principal means by which the national service is recruited, a certain number of posts (some of which are distinctly valuable) are still reserved for the nominees of leading officials. A list of such appointments, and of the persons in whom the right of nomination is vested, will be found in the general table appearing in the next instalment. The usual practice is to name *several candidates to compete among themselves* for each vacancy. Contests of this character are officially styled "limited competitions," and are not advertised. In some instances, nominations for superior posts are given to subordinate officers as a reward for ability and zeal. A few technical and minor positions are filled without competition, the person designated having only to pass a qualifying examination.

Since appointments *as valuable are to be* won by open as by limited contests, it may be supposed that a nomination is of little service to the candidate. This, however, is a gravely mistaken view. In the arena of public competition the fight for success is very keen. There are sometimes ten or fifteen candidates for every vacancy, and occasionally the proportion is as high as 20 to 1. But within the select circle of the nominated, no such stress exists, and the competitors usually number from three to five for each post. Aspirants who can obtain a suitable nomination should therefore on no account neglect to secure it.

Age and Health. Each class of appointment, as we shall see hereafter, has its own age limits as well as its special examination subjects. Except for certain subordinate work in the Post Office, the earliest age at which a permanent footing can be gained is 17, and there are few posts for which a candidate can compete after passing his 25th birthday. By a valuable provision, however, persons who have served in the Army or Navy, or as Volunteers on military duty, may deduct from their actual age any time so spent. And under certain restrictions a similar allowance not exceeding five years may be claimed by members of the national service itself when competing for higher posts.

After succeeding at the educational contest, every candidate is required to pass a medical examination before appointment. As is imperative in a service making such liberal provision in case of illness, this is a fairly severe test, and is particularly stringent in the case of foreign service. In the Customs good eyesight is insisted upon, but for other departments a moderate degree of short sight is not a disqualification. The Civil Service Commissioners mention the following as among the commonest causes of rejection on medical grounds: poor physique, delicacy of constitution, diseases of the heart, lung, eye and ear, paralysis, epilepsy, nervous complaints, and diseases of the liver and kidneys, especially persistent *albuminuria*.

No aspirant who is dubious of his health can afford to disregard this question. The Commission absolutely declines to sanction an official *examination of the health of any save successful* candidates. On the other hand, rejection on medical grounds at the eleventh hour is a cruel possibility in such a case. Any competitor having reason to fear such a contingency would therefore do well to apply to the Secretary of the Civil Service Commissioners for their "Memorandum respecting Medical Examinations," which is explicit enough to enable any competent doctor *to pronounce on the candidate's ability to pass* the medical test.

Fees. The examination charges made to competitors vary from 1s. up to £6, according to the salary ordinarily obtainable in the appointment sought. A £100 maximum, for example, involves a fee of 7s. 6d.; for £200 it is 12s. 6d.; and for posts rising severally to £300, £350, and £450, the corresponding fees are £1, £2, and £4

AUSTRIA-HUNGARY & BALKAN PENINSULA

States of Austria-Hungary. Danubian Plain. Alpine and Carpathian Provinces. Climate, Products, and Physical Features of the Balkan States

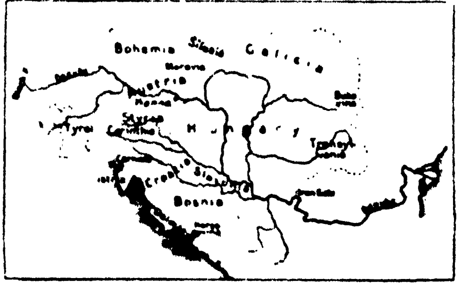
By Dr. A. J. HERBERTSON and F. D. HERBERTSON, B.A.

The Danube Basin. All the regions hitherto described are crossed by rivers flowing to North European seas. The only remaining region, the Danube basin, is cut off from the rest of Germany by the Central Highlands and is drained to the Black Sea.

The sources of the Danube in the Black Forest are quite near the Rhine, but the two rivers immediately diverge. The Danube flows east along the base of the Swabian Jura, receiving, among other tributaries from the Alps, the Iller, with Ulm at its confluence, the Lech, on which is the old trading town of Augsburg, the Isar, on which is Munich (München), the capital of Bavaria, and the Inn from the Tyrol. The Inn enters the Danube among magnificent scenery, and at its confluence is Passau, the frontier town of Austria. Into that country we shall next follow it.

What Austria-Hungary Is. Austria-Hungary is a dual monarchy, consisting of the empire of Austria and the kingdom of Hungary, governed by an Emperor-King.

The Austrian Empire (116,000 sq. miles) consists of (1) Bohemia, Moravia, and Austrian Silesia, all in the Central Highlands; (2) the Danube archduchies of Upper and Lower Austria; (3) the Alpine duchies of Tyrol, Salzburg, Styria, Carinthia and Carniola; (4) the Dinaric lands of Istria and Dalmatia, on the Adriatic; (5) the Carpathian lands of Galicia and Bukovina, on the northern foreland of the Carpathians; and (6) the protected Balkan States Bosnia and Herzegovina, north of the Balkan peninsula, technically part of the Turkish Empire, but administered by Austria [95].



95. THE STATES OF THE AUSTRIAN EMPIRE

In the midst of these is Hungary (126,000 sq. miles), the plain of the Danube, surrounded in the north and east by the Carpathians and the Transylvanian Alps, the latter forming Transylvania, and in the west by the bare limestone mountains of Croatia-Slavonia.

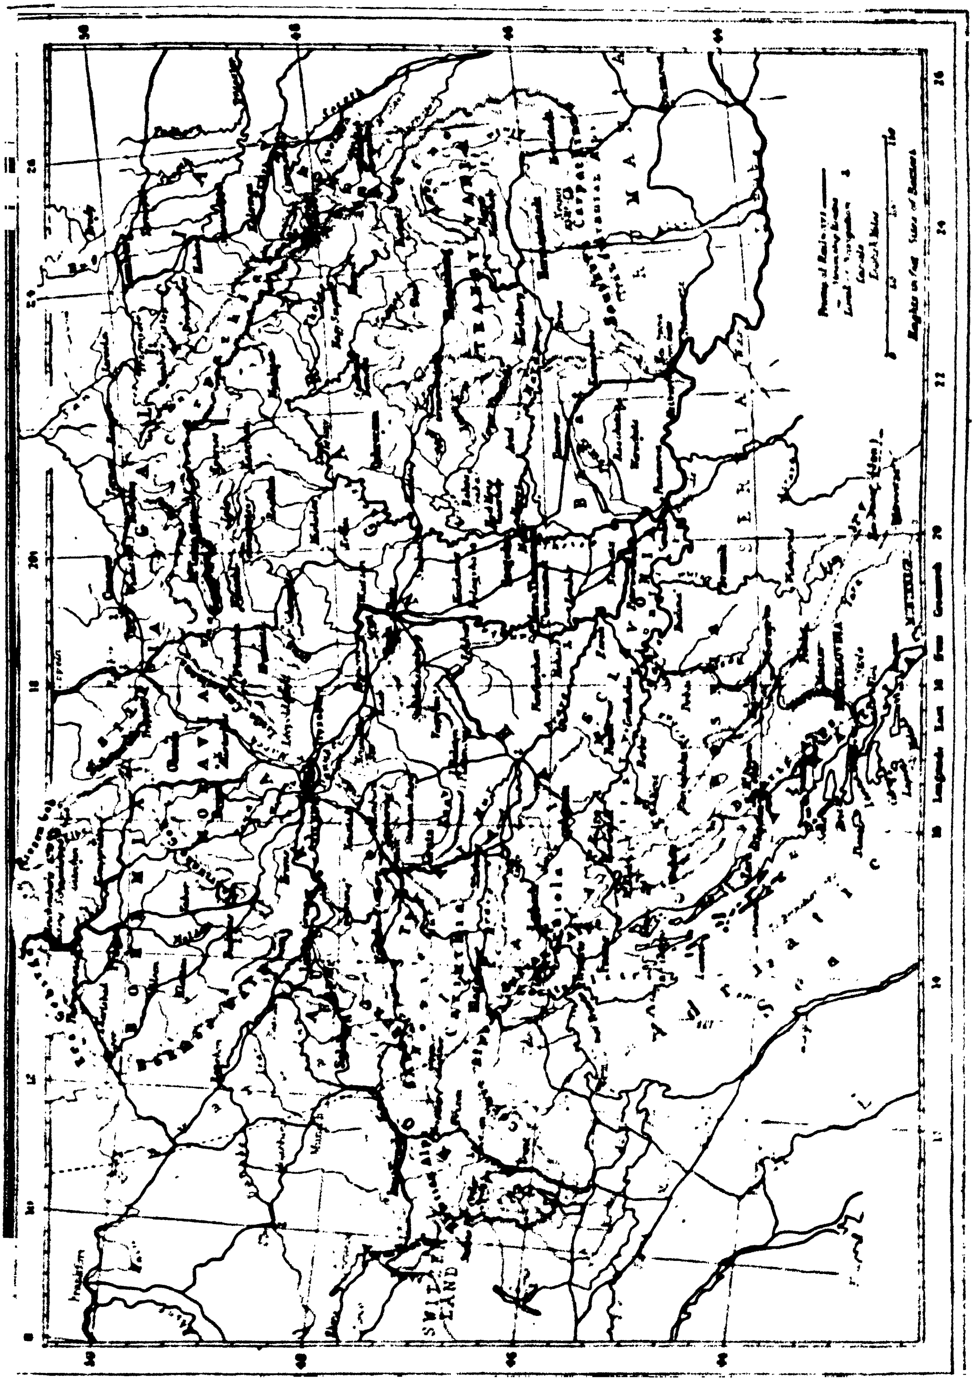
The Lack of Unity. Many different regions are thus united, occasionally, as in the case of Hungary and Bohemia, corresponding with geographical conditions, but often determined by merely political considerations. Austria-Hungary is, therefore, geographically unstable. It is also racially unstable. The different elements in the population—German and Slavonic in Austria; Magyar, Romanian, and Slavonic in Hungary—contend for mastery, and their political union is attended by constant friction.

The Danube in Austria. A region so vast and diverse has too many varieties of climate, products and occupations to be described as a whole. What unity it has comes from the great Danube, which enters Austria at Passau, where it receives the Inn, its only tributary from the Swiss Alps. Below Passau it flows between the Alps and the Bohemian Mountains, forming the Austrian Gate, at the eastern end of which Vienna is built. A traveller thus describes the scenery of the Austrian Gate.

"The river spreads out into a lake, completely closed in by the forest-clad amphitheatre of mountains. On and on for many long miles through scenes of the most romantic beauty, past mountains clothed from top to bottom with dark pines, and ruined castles peering out from amidst the fir forests on the summits of precipices, and sequestered ravines where nestle small villages with overhanging roofs and wooden balconies, and side valleys, up which you see waterfalls and hanging bridges. Scene succeeds to scene of romantic and even awful beauty."

At Vienna the Danube is a magnificent river, rolling across a plain shut in to the south by spurs of the Styrian Alps projecting towards the little Carpathians, offshoots from the main range. Between these the river flows in a gorge known as the Hungarian Gate, where the Hungarian town of Pressburg is built.

A Magnificent View. All this is easily made out on the map, but it is thus a traveller translates the map's abstractions into realities: "To the east downwards the plain sinks into the horizon, and the towers of Pressburg, and even the foremost heights of the distant Carpathians, are discernible. To the south-west are offsets from the ridges of the Styrian Alps which form the rapids of the Danube. To the west the country rises from vineyards and orchards to precipices, forests, and mountains, the commencement of the Alps. To the south the lofty snow-clad summits of the Styrian Alps, embracing one side of the plain on which Vienna stands, and sending out promontories abruptly to the Danube, close



96 AUSTRO-HUNGARIAN EMPIRE

the circle. In the midst of this vast panorama lies in full view the city of Vienna, with its cathedral and lofty spire rising against the sky; and far the most striking part of every view of which it forms part, the Danube, the monarch of European rivers, rolling its rapid and mighty stream." Just above Pressburg comes in the March from the Moravian Gate, flowing between the Bohemian Mountains and the Carpathians.

The Hungarian Danube. We are now in Hungary, with the Alps and Central Europe receding behind us. Pressburg is the gate of Eastern Europe, the direct road to that sea whose waters wash the shores of Asia. In the fertile plain which the Danube next crosses, the Raab comes in on the west from the Alps, and on the east tributaries descend from the Carpathians, which are broadest in the Hungarian Ore Mountains. Between these and the Bakony Forest on the west, at whose southern base is Balaton, the largest lake in Austria-Hungary, the river flows, and is turned south by the eastern spurs of the Bakony Forest. On these, the last heights in the Hungarian plain, is Budapest, the capital, a double city, Buda on the high west and Pest on the low east bank, together forming a city magnificent in natural beauty and architectural splendour.

The Plain of Hungary. Before us stretches the lake-like river, studded with wooded islands, and a vast plain loses itself on the distant horizon. Hundreds of rivers water it, spreading their rich sediment over it in every flood. On its illimitable pastures are bred famous horses, and tens of thousands of cattle, sheep, and swine. It is, in fact, part of the great Eurasian steppe, and its Magyar inhabitants are true to the blood and the pastoral occupations of their Asiatic ancestors who centuries ago conquered a country so well suited to them. Elsewhere, ploughed fields, golden in summer, stretch far as eye can reach. The villages, with their orchards of plum and pear, and their shady acacias, are dotted about the plain, far apart, but large and prosperous. Through this land of green and gold the Danube flows south to meet the Drave, which has come down from the Tyrol and along the eastern margin of the Croatian Mountains, behind which are the blue Adriatic and the Hungarian wheat and flour port of Fiume. The united river keeps the direction of the Drave, receiving the Tisza, or Theiss, flowing from the Carpathians through corn lands and the famous vineyards of Tokay. Its last great tributary is the Save, which has come 700 miles from the Alps of Carniola and along the north-west margin of the Balkans; it receives the Drin from the south, the boundary between Bosnia and Servia, the latter of which fronts Hungary across the Danube. The Servian capital, Belgrade, is built at the confluence of the Save, and 50 or 60 miles lower the Danube forces its way between the Transylvanian Alps and the Balkans, in a series of grand defiles called the Klisura, terminating in the rapids of the Iron Gate, now made navigable by blasting and canalising. Here, at Orsova, it leaves Hungary.

The Climate of Hungary. In Hungary we begin to experience the continental climate of Eastern Europe. The summers are hot, the winters very severe, except along the Adriatic coast. The products have already been described. Wheat, and timber from the forests of the highlands are the chief exports.

The Mountains of Hungary. So vast and rich are the plains that we often forget the mountains of Hungary. For 600 miles on the north and east the country is enclosed by the Carpathians, 150 miles broad at their broadest. The finest scenery is in the Tatra, where granite peaks, 8,000 feet high, rise above lovely lakes. Oak, beech, and pine forests clothe the mountain side, with bear and wolf lurking in their unknown depths. Below are jewelled meadows and terraced vineyards. Minerals, such as gold, salt and petroleum, are abundant. The occupations are mining, forest industries, cattle-rearing, and agriculture.

The mountain-girt Transylvania is watered by tributaries of the Maros, which breaks west through the mountains to the Danube. The capital is Kolosvar, or Klausenburg, a university and manufacturing town.

Croatia consists of bare limestone mountains, rising above the Adriatic, and of the fertile but marshy land between the Drave and Save. The bare, treeless mountains are "furrowed, pierced, and riddled into caverns, clefts, and gullies, valleys that have no outlets, and rivers without perceptible sources." This region is called the Karst. Agriculture and cattle-rearing are both backward. The capital is Agram.

To the north-east of Croatia is the Istrian peninsula at the base of the Alps, with the Austrian port of Trieste, behind which rise the bare mountains of the Karst.

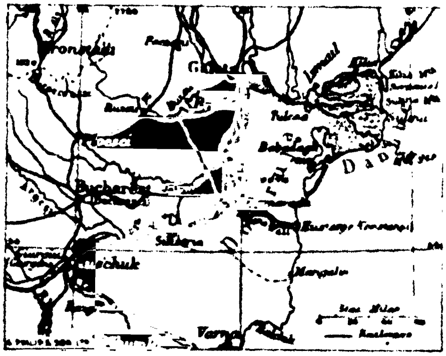
Dalmatia. To the south the Karst scenery continues in the wild Dinaric Alps, which descend 5,000 ft. or 6,000 ft. to the white towns, Ragusa, Cattaro, and others, of the Dalmatian coast. The summers are hot and dry, the winters mild and wet. Some evergreen forests remain, and on the lower Adriatic slopes the vine, olive, and orange are grown.

The Alpine Provinces of Austria. The scenery is of the Alpine type already described. The climate varies with elevation and situation. Valleys opening north and east have warm summers, but cold winters; the Adige and other valleys opening south have a climate which suits the vine and mulberry. In the higher Alps cattle-rearing is the chief occupation. Agriculture becomes important in the lower valleys and towards the Danube. Salt is abundant in the Salzkammergut, the picturesque district round Salzburg. Iron and lead are widely distributed in Styria, Carinthia, and Carniola. Besides Salzburg, the chief towns are Innsbruck, on the Inn, the capital of Tyrol, giving access to the fine rock scenery of the Dolomites; Gratz, the capital of Styria, on the Mur, a tributary of the Drave; Klagenfurt, the capital of Carinthia, on the Drave; and Laibach, the capital of Carniola, on the Save. All these rivers and towns are connected with important routes across the Eastern Alps.

Upper and Lower Austria. These lie between the Alps and the Central Highlands, forming a transition between Germany and Hungary. They are mountainous, and thinly peopled. The chief towns are Linz and Vienna, at opposite ends of the Austrian Gate.

Bohemia. Bohemia consists mainly of the basin of the upper Elbe. It possesses many natural advantages which a prosperous people are quick to utilise. The climate of the surrounding mountains is severe in winter, but in the lowlands the vine can be grown as well as cereals; also sugar-beet, for making sugar; potatoes, for food and distilling; and hops, used in brewing famous beers, especially round Pilsen. The mountains yield valuable forests, leading to paper-making and other forest industries, and cheap water-power to carry them on. Coal and iron are widely distributed, and kaolin, clay and quartz in the northern mountains make Bohemian glass and porcelain famous. Wool from the highlands, and cotton and flax brought by the Elbe are largely manufactured. Engines and railway plant are made at Prague, the capital, a city of palaces and factory chimneys, situated on heights above the Moldau. The majority of the inhabitants are Czechs, but Germans are numerous in the towns.

Moravia and Austrian Silesia. Moravia lies east of Bohemia, between the Moravian Highlands and the Carpathians. The mountains have a severe climate, but the vine can still be grown in the lowlands, as well as barley and sugar-beet. Linen and woollen manufactures are important round Brünn, the capital. Silesia carries on manufactures on the Austrian portion of the Silesian coalfield. The capital is Troppau.



97. THE DELTA OF THE DANUBE

The Carpathian Provinces. Galicia and Bukovina are mountainous in the south, where the Carpathians rise to 5,000 ft., but fertile in the north, where they sink to the plain. The climate is severe, the country being exposed to the snowstorms which sweep over Russia. Forests cover hundreds of square miles. In the lowlands cereals and potatoes are grown, and much spirit is distilled. Petroleum and rock salt are abundant, and a miniature underground town exists in the rock-salt mines of Wieliczka, near Cracow. This, the old Polish capital, in the narrow valley of the Vistula, commanding the route to the Moravian Gate, is a handsome city, manufacturing cloth and leather.

Bosnia and Herzegovina (20,000 sq. miles). Bosnia is a land of mountains and valleys, the former clad in magnificent but unproductive forests. Much of the surface has a mere film of soil, and is only fit for pasture. In the valleys, cereals, the vine and immense quantities of plums are grown. Manufactures are in their infancy. The capital is Sarajevo. Herzegovina has the barren Karst scenery, but fertile valleys. The capital is Mostar, in the fine gorge of the Narenta.

THE BALKAN PENINSULA

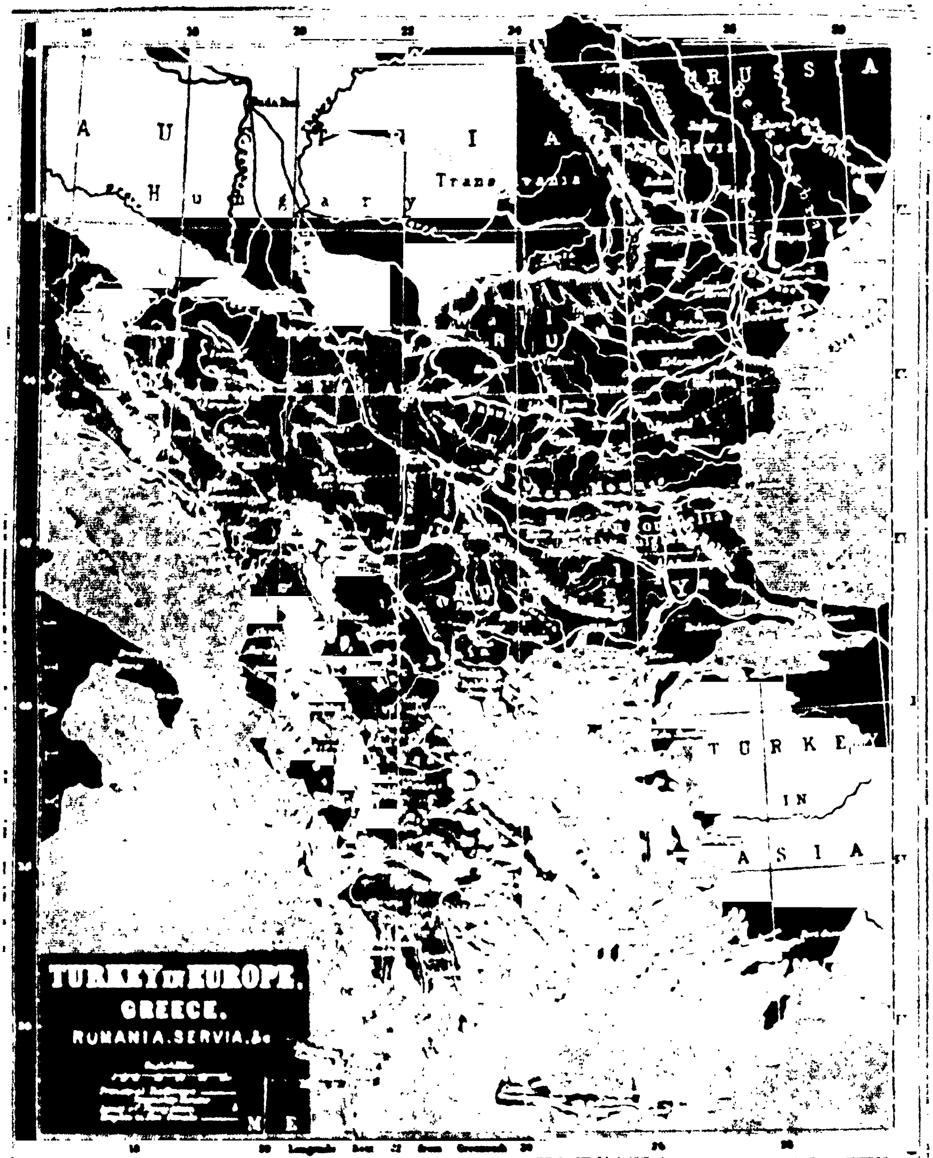
The Balkan States. East of Bosnia and south of the Danube are the kingdom of Servia and the principality of Bulgaria, the latter including Eastern Roumelia. The little principality of Montenegro is south of Herzegovina. Except Rumania, and the small kingdom of Greece in the extreme south, the rest of the peninsula belongs to the Turkish Empire [95].

Rumania. At Orsova the Danube enters the fertile plains of Rumania, lying between the Transylvanian Alps and the Danube. These are crossed by innumerable rivers, flowing south to the Danube, the Rumanian bank of which is low and marshy. The largest are the Sereth and the Pruth. The summers are hot but the winters very severe, the temperature falling many degrees below the freezing point. Rumania (50,000 sq. miles) is an agricultural land, growing immense quantities of wheat, shipped from Galatz and Braila, near the confluence of the Sereth; also hemp, flax and tobacco. Petroleum is abundant and refineries numerous. Flour mills, saw mills, distilleries, cloth mills and tanneries tell their own tale.

The capital is Bucharest. The Danube reaches the sea by a great delta [97], the branch most used for navigation being the Sulina. The total length of the river is 1,800 miles.

A Transition Region. In the north of the Balkan peninsula we have the Central European climate and vegetation. The summers are warm and the winters severe. Oak and beech are the forest trees, the plum is the commonest orchard tree, and wheat the typical cereal. South of the Balkans, which curve round from the Transylvanian Alps, separating Bulgaria from Eastern Roumelia, we pass into a different region. The summers are hot, and also dry. The winters are mild, and most of the rain falls at that season.

The rainfall is often so scanty that irrigation is necessary for agriculture. To suit this climate plants develop various peculiarities. The aloe has thick, fleshy leaves, which store up moisture; the cypresses, evergreen oaks, and the bushy stone-pines have small, hard leaves, which lose little moisture by evaporation. This type of climate and vegetation is characteristic of the Mediterranean region, to which we are now passing. The fruits are the vine, olive, orange,



98. THE BALKAN PENINSULA

fig, pomegranate, peach and apricot. The mulberry is largely cultivated to feed silkworms. Wheat is grown under irrigation, but millet and maize are better suited to the hotter, drier parts. Pulses, principally varieties of beans and lentils, are as important as root crops in Central Europe. One of them, lucerne, replaces grass as fodder. Cattle and horses, which need rich, moist pastures, give place to the hardier sheep, goats, mules and asses.

Mountains and Rivers of the Balkan Peninsula. Almost the whole peninsula is mountainous, though the mountains do not rise above the snow line. They form part of the great Eurasian mountain system already described, and are known under various names in different parts, as the Balkans between Bulgaria and Eastern Roumelia, the Rhodope Mountains or Despoto Dagh between Bulgarian and Turkish Roumelia, the Pindus Mountains in Greece, etc. In the north they are densely forested, but the forests have been destroyed in the south. Small plains, surrounded by mountains and difficult of access, are very characteristic of the whole peninsula. Roads are bad, and communication backward.

Four important river valleys must be noticed: (1) The Morava, flowing north, across Servia, to the Danube; (2) the Isker, rising south of the Balkans, and breaking through them to the Danube; (3) the Maritsa, flowing round the northern and eastern base of the mountains of Thrace to the Ægean; and (4) the Vardar, flowing south to the Gulf of Saloniki. Notice that (1) the Morava and the Vardar, and (2) the Morava, Isker, and Maritsa give through routes from north to south, and that the railways follow them.

Montenegro. Montenegro (3,600 sq. miles) is a wild land of bare limestone mountains, with a small, hardy shepherd population. The mountain scenery is of the Karst type, and agriculture is possible only in the wider valleys. The peasants' houses are often festooned with tobacco, which is of excellent quality. There are few roads, no industries, and little trade. The capital is Cettinye (Cetigne), a small, red-roofed village town in a mountain-girt plain, with a population considerably under 5,000.

Servia. Servia (19,000 sq. miles) consists of a lowland along the Danube, rising to wild mountains on the west, on the east (where the Danube breaks through spurs of the Carpathians at the Iron Gate), and on the south, where the mountains are part of the Balkan system. The valleys are generally fertile. Vast beech and oak forests feed countless herds of swine. In the clearings sheep and cattle are kept. The agriculture is often primitive, the fertile soil producing excellent wheat, tobacco, vine, and fruits. Dried and preserved plums are an important export. Much plum brandy is also distilled. The capital, Belgrade, is finely situated. "Perched on a hill, at the foot of which the Save joins the Danube, it commands westwards a wonderful expanse of sky and stream and willows, with a pale mauve distance of Servian mountains, while opposite lie the rich plains of Hungary and the little town of Semlin."

Bulgaria. Bulgaria (37,000 sq. miles) rises from the southern bank of the Danube to the crest of the densely-forested Balkans, beyond which lie Eastern Roumelia or Southern Bulgaria. In the Danube area maize and wheat are grown, but south of the Balkans we find the products of a hotter region, rice and cotton, as well as the vine and the ever-present plum. Mulberries and the silkworm are very important. In the Maritsa valley, the most fertile part contains many square miles of rose gardens, from which is distilled the famous Oriental perfume, attar of roses. Bulgaria is on the way to prosperity, and roads and railways are fairly well developed. Sofia, the capital, is a handsome modern city in a mountain-girt plain, commanding the Isker route. Philippopolis, built on isolated heights in a wide plain, is the second city. The ports are Ruschuk, a river port of the Danube, and Varna, on the Black Sea.

The Turkish Provinces. Wild and mountainous in structure, torn by racial and religious feuds, undeveloped and ill-governed, the Turkish provinces (62,000 sq. miles) are a waste instead of a garden. Both agriculture and cattle-rearing are backward, and the peasantry are poor, ignorant, and oppressed. The capital is Constantinople, built in one of the finest situations in the world, where "the Sea of Marmora, the Bosphorus, and the wide and winding harbour of the Golden Horn meet, forming, as it were, a great lake round which the city extends, rising stage by stage along the slopes of the hills, minaret and dome lifting themselves one above another against the azure sky." Commanding the entrance to the Black Sea, where Europe and Asia all but touch, this is one of the finest strategic points in the world. Another key to the Black Sea and the lands beyond is Gallipoli, on the Dardanelles. Saloniki, on the gulf of the same name, is the port of the Vardar Valley. Adrianople, on the Maritsa, strongly fortified, commands the route to Constantinople.

Greece. Greece (25,000 sq. miles), consisting of the southern and deeply indented portion of the peninsula, with many adjacent islands, is a land of mountains and small, isolated mountain-girt plains. The climate is typically Mediterranean, and irrigation is necessary in the drier parts. All Mediterranean plants are grown, but the chief export is the currant, a small dried grape. The sponge fisheries of the Ægean Sea are important. The capital is Athens, built much like Edinburgh, round a height between the mountains and the sea, with Piræus as its Leith. From Corinth a ship canal has been cut across the narrow isthmus of the same name between the mainland and the mulberry-leaf shaped peninsula of the Morea. Patras exports currants.

Off the west coast are the Ionian Islands, all mountainous, with fertile valleys. Corfu is the most important. The islands of the Ægean are less fertile, and produce little but wine. Syra (Hermopolis), on a small island of the same name, is the centre of the Ægean trade.

Continued from page 1865

THE BONDING OF BRICKWORK

Various Forms of Bonds. The Formation of Brick Walls. Bonding with Mixed Materials. Building and Bonding Curved Walls

By Professor R. ELSEY SMITH

IN any wall or structure not cut out of solid material, but formed of a multiplicity of parts, each of which is small in bulk compared with the wall into which it is built, it is inevitable that there must be many joints. Some of these are approximately or accurately horizontal, and some are approximately or accurately vertical. The horizontal joint may extend through the whole thickness and length of the structure, if the portions of which it is built be of uniform size and have horizontal surfaces, and this condition is met with in all brick walls. The layer of materials placed between two such level surfaces is termed a *course*. Where the size of the block is not regular, even when the beds are horizontal, the horizontal joints may not be found continuously at the same level, and this condition is met with in some forms of stone walling. [See MASONRY.] Unless some provision is made to prevent it, there is a danger that the vertical joints, like the horizontal ones, may continue throughout the wall from base to top, and while a level horizontal course is an advantage in constructing walls, a vertical joint extending through more than a single course is termed a *straight joint*, and is a source of weakness.

Effect of Straight Joints. If such straight joints extend from top to bottom of a wall, we should have, in fact, a series of small piers placed side by side having no connection with the pier on either side, except the mortar joint [41 and 42]. If such a pier is subjected to a load that is different from the load on the pier on either side, it may be thrust out of the line of the wall, or it may be crushed if not strong enough by itself to carry such load, or it may be caused to subside.

It is of equal importance that there should not be a straight joint in the cross-section of the wall, for if no alteration be made in planning the successive courses, a thick wall, such as that shown in 45, would be, in fact, formed of two thin walls placed side by side, and a load that was borne on the inner half of the wall would convey none of its pressure to the outer half, and might settle down under the burden by itself, whereas a wall that is properly bonded in cross-section [44] will have any load that bears on a given point distributed throughout its thickness as well as along its length.

Bonding, which is used to prevent such a form of construction, is the placing of the vertical joints in every course so that they shall not, except where it is inevitable, coincide with the vertical joints in the courses immediately below it. The result of such an arrangement is that the materials in one course interlock with those in the courses above and below it. A wall is thus formed which no longer consists of independent piers, but is homogeneous in character, and the burden of a load supported at any one part of it is distributed by successive courses over an ever widening area [43].

Brick Bond. It is necessary to bear in mind that the bricks of any one class of manufacture are practically identical in size and shape, and that any trifling irregularities can be corrected by an adjustment of the thickness of the mortar joint. In building, therefore, with materials that are uniform in size and of such a shape that two of them, laid flat and side by side, form a nearly exact square, straight joints are very liable to occur if the work is carelessly put together; but, on the other hand, a comparatively simple adjustment, if properly carried out, suffices to obviate the danger entirely.

There are various methods of making the necessary adjustments, and various methods of arranging the bricks in a wall, and in particular on the face of the wall. Where differences in arrangements of the bricks affect the appearance of the wall, the terms applied to different varieties of walling depend on the style of bond in which they are built.

Forms of Brick for Bonding. Before describing the various forms and methods of bonding, a few general terms must be made clear. A *bat* is half of a brick broken across its length. Usually, bricks are broken so as to be one quarter and three quarters in length, or each one half, and are described as quarter bats, half bats, or three-quarter bats [10 and 11, page 1948]. They may be cut with the trowel from a whole brick, but in the process of carting, unloading, and stacking bricks, some always get broken, and these are utilised for such purposes, and can be cut if required to any requisite length. A *closer* is a brick cut in half in a direction parallel to its length, called a *queen closer* [6, page 1948], or so as to show a width of 2¼ in. on the face of the wall, and the full width of 4½ in. at the back, called a *king closer* [5 and 9, page 1948]. In practice, a queen closer is difficult to cut, and is not often specially moulded; two quarter bats are generally used in place of it. [See dotted lines 6, page 1948.] A brick placed in a wall so that one of its long sides shows on the face of the wall is called a *stretcher* [38]; and a course consisting entirely of bricks so placed is called a *stretcher course* [38, course 1]. A brick placed so that one of its ends shows on the face is called a *header*, and a course consisting entirely of such bricks is called a *header course* [38, course 2].

Describing Thicknesses of Walls. The thicknesses of a wall may be described by the number of headers contained in it [illegible]

EXAMPLES OF BRICK BOND FOR WALLS

thickness—thus, a one-brick, two-brick, three-brick wall, etc.; if the wall be only a half-brick thick, or is a multiple of a half-brick in thickness, it may be described as a one-and-a-half brick, two-and-a-half brick wall, etc. The convenience of this description is that it satisfactorily describes the wall for all types of bricks, not only for the ordinary sized brick [1, page 1948], but for bricks that may run a little larger or smaller. The thickness of a wall may also be described by the number of inches in its thickness—thus, a 4½ in. wall = a half-brick wall; a 9 in. wall = a one-brick wall. A brick-and-a-half wall is sometimes spoken of as a 13½ in., and sometimes as a 14 in. wall, for by using a thick mortar joint in the thickness of the wall it may be brought up to this larger dimension. An 18 in. wall = a two-brick, and so on; but this description is only accurate when bricks of the ordinary standard size are being employed.

English Bond. English bond, which, from a structural point of view, is the best for all ordinary walling when the thickness is one brick or upwards, is formed when in elevation; every course is either a complete header course or a complete stretcher course [38]. Stretchers are never used in the interior of a thick wall, but only on the inner or outer face of such a wall. When the thickness of the wall is the exact multiple of a brick, each course will show alike on the inner and outer face of the wall—*i.e.*, either both sides will show headers or both stretchers. [See examples of one-brick and two-brick walls in **38**]. If there be an odd half brick in the thickness of the wall, the course that shows stretchers on the outer face will show headers on the inner face, and vice versâ. [See one-and-a-half and two-and-a-half brick wall in **38**.] When a wall is returned at the end—that is to say, is continued in a direction at right angles to its former direction—the course that shows stretchers on the main front will show headers on the return front, and vice versâ.

Finishing Ends of Walls. All the plans on the general sheet of bonding show walls which on the left-hand side have returned ends, and it will be noticed that in every case course 1 has closers inserted next the angle brick to bond the return wall, and in course 2 has closers inserted next the angle brick in that course to bond the front wall. It will, of course, be understood that the angle brick in course 1 ranks as a stretcher so far as the front wall is concerned, but is a header if considered in relation to the return wall.

On the right-hand side of each plan the wall is shown to have a *stopped end*—that is, the wall is finished there without any return or reveal. All such ends require special attention to secure a satisfactory finish and perfect bonding.

Laying the Stretcher Course. We shall now consider the bonding of a wall which is an exact multiple of a brick in thickness, and commence with the stretcher course [**38**, course 1]. Such a course, whether the wall be one, two, three, or any other multiple of a brick thick, will have a row of stretchers extending from end to end on the outer face, and a similar row on the inner face. If the wall be one brick thick these two rows will complete the course, and the bricks in them should lie exactly side by side, so that the joints which run from back to front of the wall run straight through from face to face without any break in their length. If the wall be a two-brick wall there will be one row of headers in the interior of the wall separating the stretchers; if it be a three-brick wall there will be two such rows of headers, and so on. But note that in all cases the headers are laid so that two are placed exactly behind a stretcher, and, whatever the thickness of the wall, the joints that run from front to back do so without any break. We shall assume for the moment that the length of our wall is an exact multiple of 9 in., and that it will therefore contain an exact number of header bricks. But, of course, this is not always the case. If our wall be not an exact multiple of a brick in thickness, but contain an odd half brick, the only difference will be that the row of stretchers on the inner face will be omitted, and a brick-and-a-half wall will have one row of stretchers on the face and one row of headers behind; a two-and-a-half brick wall, one row of stretchers and two rows of headers, and so on.

Laying the Header Course. If this course [**38**, course 2] consisted literally of nothing but headers, we should have a wall without bond [**41**]. It is in this course that the closers are introduced; but whatever the length of the wall, so long as there is no opening or return in it, there will never be more than two closers, one of which occurs at each end of the course. For the purpose of bonding, any interruption in the continuity of the brickwork, such as that due to the opening for a door or window, may be considered to divide a long wall up into a series of short lengths, each of which must be provided with the closers for bonding. In laying this course recollect that a header always forms the end brick.

The whole thickness of the wall in this course, if it be an exact multiple of a brick, is formed with headers, and for every brick in the thickness of the wall there will be a header in the plan. In this course, as in the stretcher course, the joints at right angles to the face will run straight through from back to front in an unbroken line. If there be an odd half brick in the thickness of the wall a stretcher course is employed on the inner face.

Position of the Closer. The closer should never form the angle brick, for as it is only 2¼ in. wide, it would be very liable to become dislodged, but it must always form the next brick to the angle header. It should extend right through the thickness of the wall to be bonded from the front to the back. Theoretically, a queen closer should be used for every header in the thickness of the wall, but in practice, except for work of quite an exceptional character, two quarter-bats are used to form the closer for each brick in thickness. It will be seen [**43**] that the width of the angle header (4½ in.) plus the width of the closer (2¼ in.) make together 6¾ in., which leaves 2¼ in. between this vertical joint and the first joint in the course below, and that as the face of the next header

EXAMPLES OF UNBONDED WALLS AND SPECIAL FORMS OF BOND is 4½ in., the vertical joint beyond it will also be 2¼ in. beyond the first vertical joint in the stretcher course. This horizontal distance is termed *lap*. Beyond this point, as two headers together equal in width one stretcher, the same distance between the vertical joints in the header and stretcher course will be maintained till the other end of the wall is reached, and the closer at that end is inserted to give a corresponding break and finish to the wall. A wall, whatever its height, will consist entirely of successive courses, in which the two above described will alternate regularly.

Adjusting Bond to Walls of Various Lengths. We assumed for the moment that the length of our wall was an exact multiple of a brick in length; but this may not always be the case. Suppose there be an odd half brick in the length, the only adjustment required will be that at or near the centre of every stretcher course a half-bat be inserted [46]. In building with such a material as brick, if good and economical work be required, the limitations it imposes must be considered, and no short length of brick wall should be set out except as a multiple of a half-brick in length as well as thickness. In the case of a long wall this point is not of importance; in such a wall there will be so many vertical joints that by a little *fulness*—*i.e.*, an extra amount of mortar—in the joint, or a little *tightness*—*i.e.*, a reduced amount of mortar—in the joint, some definite number of headers may be worked into its length.

Absence of Straight Joints in English Bond. In the case of a wall constructed in English bond [38], if the plans of the two courses of any wall be traced and placed one above another, it will be noticed that if queen closers are used there will be no position either on the face or in the heart or thickness of the wall in which the vertical joints in one course coincide with the vertical joints in the course below. If quarter-bats be used in place of queen closers such coincidence will exist only where the extra joints thus introduced occur. Such a coincidence, as already explained, forms a straight joint, and if it occurs in two successive joints, note that it will run throughout the whole height of the wall inevitably. It is the absence of these straight joints that renders English bond of such great structural utility as a more homogeneous wall is obtained when it is used than in the case of other bonds.

Other Styles of Bonding. On the other hand, in elevation the appearance of successive rows of headers and stretchers is considered less attractive than some other forms of bond, and where, as in the case of much domestic work, the utmost possible strength is not essential, and something may be sacrificed to appearance, a style of bond which is not quite so satisfactory structurally, but gives a different character to the face of the wall, is adopted. With a view to improving the elevation, a variation of this style of bond, known as *English cross-bond*, is sometimes adopted [47]. As will be seen, the only variation consists in breaking the bond between successive stretcher courses by introducing next the angle stretcher (in course 3) a single header, or bat, so that beyond this point the stretchers in this course are shifted 4½ in. to the right, and come over the centre of the stretchers in course 1. This must, of course, be provided at each end of the wall. Course 5 repeats course 1, and course 7 repeats course 3, and so on. No change is made in the header courses, and this particular bond is not inferior to English bond in strength.

Flemish Bond. Flemish bond is made use of as a further improvement to the elevation of the wall; it differs from English in elevation in that each course consists of a header and a stretcher alternating, and at the end of a wall we find in one course a stretcher forming the end brick, and in the succeeding course a header at the end. There is not the same simplicity as to the placing of the bricks in the wall as occurs in English bond, and the number of straight joints are considerable, especially when there is an odd half-brick in the thickness of the wall. In the case of a one-brick wall the same bond must show in both faces; in the case of thicker walls it may do so; but, on the other hand, the use of Flemish bond may be confined to the outer face of the wall and the inner face, and the heart of the wall may be formed in English bond, to which there can be no objection if, as often happens, the inner face is to be plastered. When this form of bond is used throughout the thickness of the wall, and shows on both faces [40], it is termed *Double Flemish Bond*; when used on one face only [39], it is termed *Single Flemish Bond*.

In this bond, as in the English bond, the closer is placed in the course which begins with a header at the end angle. This closer is carried right through the thickness of the wall; but where a header shows in the return end, or face, to avoid using a half-bat and quarter-bat, a three-quarter bat is used, by which the same result is achieved with the saving of one joint. The sources of weakness in this form of bond are the large proportion of bats that are inevitable wherever the thickness of the wall has an odd half-brick in it when double Flemish bond is used [see one-and-a-half and two-and-a-half brick walls, 40], and where the thickness is the multiple of a whole brick where single Flemish bond is used. [See two-brick and three-brick walls, 39.] This is partly due to this use of bats, but mainly to the use of stretchers in every course; if tracings of the plans of two successive courses of Flemish bond be overlaid, it will be found that, to a very appreciable extent, they coincide throughout the whole length of the wall, and that straight joints result. It is on this ground that, where possible, single Flemish bond is adopted, as this confines the use of bats and straight joints to the outer face of the wall.

One of these two forms of bond is used for most ordinary walling. There are other varieties of bond, but they are mainly required to meet difficulties that arise under certain exceptional conditions.

Stretcher Bond. Stretcher bond [48] is used for walls that are only half a brick in

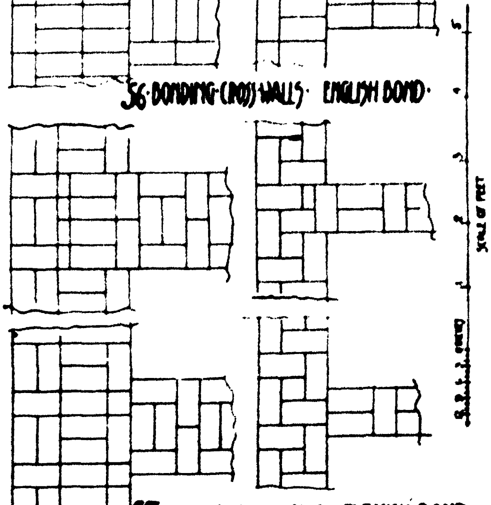
56 BONDING CROSS WALLS. ENGLISH BOND.



57 BONDING CROSS WALLS. FLEMISH BOND.

BONDING OF OPENINGS AND OF CURVED AND CROSS WALLS thickness. It is obvious that headers, which are 9 in. long, cannot be used in such a wall, and if any appear in the wall, they are only bats. This bond, it will be seen, consists of building entirely with stretchers; it is usually built of only two varieties of courses—*viz.*, 1 and 4 [**48**]; but more complete bonding is produced by using the four varieties shown.

This wall, by using a large proportion of bats, might be made to resemble Flemish bond; but the only occasion in which the appearance of the wall would be of sufficient importance to warrant this would be in the case of a half-brick wall formed of glazed bricks.

Garden-wall Bond. Garden-wall bond is used for 9 in. or one-brick walls, in which both faces are exposed to view. These are commonly used for separating the gardens of adjoining houses, hence the name. The difficulty met with in such walls is that though the length of an ordinary brick is given as 9 in., there is a considerable variation in practice in this length, not, perhaps, more than ¼ of an inch, more or less, but enough to make it impossible to set such bricks side by side in a wall so that both faces will be true. If one face is to be plastered, this is not important; the outer face is built even, or "fair," and if the inner is rough the plaster covers it. Adjustment can be made between stretchers, because there is a mortar joint between them, which may be made "full" or tight, as the case requires.

It is therefore necessary to pick over the bricks to be used as headers in such a wall, and to measure them against a standard length of brick, and this process means additional handling and cost. This form of bond is used in this case because it reduces the number of headers by 50 per cent. It may be employed both with English and Flemish bond. *English garden-wall bond* consists in using three stretcher courses to one course of headers [**49**]. This involves a straight joint in the centre of the wall through the stretcher courses, and this is undoubtedly a source of weakness, but such walls rarely support a heavy load. *Flemish garden-wall bond* consists in using three stretchers to one header in every course [**50**], and has the same advantages and drawbacks as English bond. Such work requires careful supervision, for even with selected headers there is often slight irregularity or distortion, and to give a good finish to the face the bricklayer is apt to cut the header into two, making it easier to set fair, but still further reducing the strength.

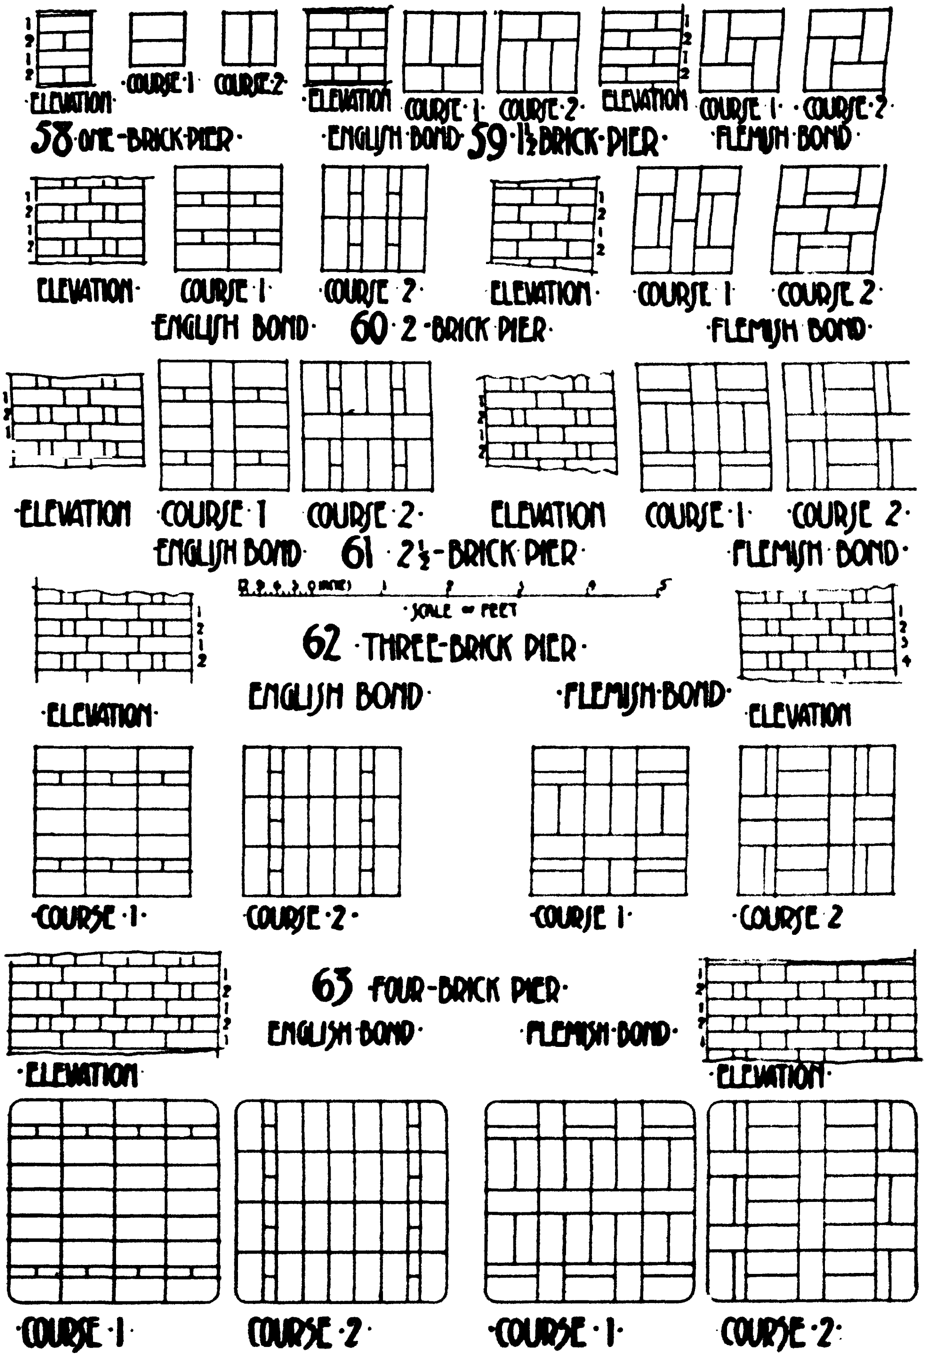
Diagonal Bond. Diagonal bond is used principally in thick walls to give a longitudinal bond at intervals. It does not show on the face of the wall; it is most satisfactorily used in the stretcher course of English bond, and is not employed in every such course, but at intervals of, say, six or eight courses. It consists in filling in the heart of the wall with bricks laid diagonally, as shown in **51**. The small triangular spaces between the facing and the diagonal work are filled with pieces of brick, roughly cut, and mortar. The bricks shown here are inclined from left to right. The next time that such a course was used they should be laid with an inclination from right to left, so as to vary the bond as much as possible.

Herringbone Bond. Herringbone bond is used in the same way as diagonal bond, and with the same object, the only difference being that the filling in is arranged on plan in the form known as *herringbone* work [**52**].

Walls Built Circular on Plan. The work hitherto described is adapted to walls that are built in straight lines, but sometimes walls must be laid on a plan that is not straight but curved. If the radius be large, and the curvature in consequence flat, the wall may possibly be built with one of the bonds already dealt with; but if the radius be short, and the curve rapid, this will be impossible.

In such a case the ideal plan is, of course, to have bricks that are purposely made with the faces formed to the required curve and the sides of the bricks converging so as to form what in an arch would be called a *voussoir-shaped brick*. This is costly; and for most work a sufficiently good appearance may be given by using ordinary bricks, provided only *headers* are employed. Such bricks will not form a true circle; but unless the radius of the curve is very small, the form will approach closely to a curve. It is essential that no stretchers be used and every course consist solely of headers; and the term *Header Bond* is applied to it. Such a piece of curved work rarely stands alone, and is used to connect two straight pieces of walling, and the bonding of the two courses is formed by continuing the bond already existing in the walls. Fig. **54** shows a wall quadrant on plan with a rather short radius, and 9 in. thick. It will be observed that the distance from A to B on the concave face of the wall is appreciably less than that from C to D at the back, and if ordinary parallel-sided bricks are used, the mortar joint must be kept fine on the face and full at the back to adjust this difference. Better work is produced by rough-cutting the brick to a *voussoir* shape, or by rubbing it accurately to such a shape, as shown on half the illustration; but this increases the cost. With the small radius illustrated the use of headers would require very wide joints at the back, and two courses of half-bats are shown. Bonding irons may be used to tie the inner and outer face together. Fig. **53** shows a wall one-and-a-half bricks thick, with a curve of a larger radius. In this case it will be noticed that either on the inner or outer face of this wall a row of bats is inevitable—with a curve of such large radius, very good work may be produced without cutting or rubbing the bricks—but the joints from front to back of the wall will not in this case be in a straight line. In this illustration the wall is shown formed on the right hand side with parallel-sided bricks, and on the left with cut or rubbed bricks.

Forming Reveals. The method of forming stopped ends has been indicated, and we must now consider those cases in which a wall has to be finished with a *reveal*. This is a short return usually 4½ in. on the face, but sometimes 9 in. or more, which projects beyond the



BONDING OF BRICK PIERS

end of the wall so as to form a rebated jamb, to allow of a door or window-frame being inserted behind it. Special attention must be paid to its bond, and it is in connection with this work that the king closer comes into service. The half-bat at the end of the header course is a source of weakness, and the use of the king closer next to it is some compensation. The methods of bonding reveals in ordinary walls of various thicknesses are shown [**55**] for both English and Flemish bond.

Bonding of Cross Walls. In addition to return walls, which have been already described, *cross walls* are frequently employed. These are walls starting from the internal face of the main wall at right angles, and they must be bonded to the main wall equally with a return wall. This is usually arranged for by building in the whole thickness of the cross wall at every alternate course to an extent of 2¼ in. into the main wall, the intermediate course of the cross wall merely abutting against the main wall [**56 and 57**].

Bonding of Piers. Piers intended to carry concentrated loads may be either attached to a wall or may stand alone and detached. In the former case the bond used in the wall will apply to the pier, and it will be treated as a short length of a thicker wall. So, also, in the case of a rectangular detached pier, it may be considered as a short length of wall with two stopped ends; but in the case of square piers a special treatment is usual, to secure proper bonding. Such piers may be constructed either in English or Flemish bond; the former is preferable where great strength is required. In all square piers the extent of closers required for bonding bears a larger proportion to the total area of the pier than in the case of a wall of the same actual area; in piers of less than three bricks this proportion becomes very extensive. It is an element of weakness in them, and all piers require very special care in construction to ensure that the joints are all well filled, and where Flemish bond is used queen closers should be employed and not quarter-bats. A pier one brick square can be formed only of two stretchers in one course and two headers in the next [**58**]. A pier one and a half brick square may be formed in English bond with two three-quarter bats alternating with three headers, but some extent of straight joint is unavoidable [**59**]. With Flemish bond it is necessary to use a bat as a core or centre for all courses, and a straight joint occurs all around it. With piers two bricks square and upwards the bonding is more satisfactory. Examples are shown of piers in both styles of bond up to four bricks square; one pier [**63**] is shown formed with bull-nosed bricks at all four angles. Various examples are given of the method of bonding various small and irregular shaped piers such as occur in the angles of bay windows [**64**] and similar situations; they should be constructed in cement mortar, to secure the utmost possible strength. As in the case of small piers, they involve the use of a large proportion of bats and of irregular pieces of brick. Such piers, as a rule, are of no great height, and cannot be expected to carry anything but quite a light load.

There are many situations in which a return wall is not at right angles to the front wall. When this is the case it is termed a *squint* angle, which may be either acute or obtuse. Here, also, special attention must be paid to the bonding, and no regular rules can be given for the construction of such angles, as the methods vary with the inclination between the two walls. Examples of such angles are given [**65**], and it is important to bear in mind that as few small pieces of brick as possible should be used. Whole bricks, wherever possible, or bricks with only the angles cut off, are the best. In the case of obtuse angle walls squint bricks [**7**, page 1948], of which the longer side is 6¾ in., may often be used in place of using closers, and, when possible, this is advantageous. A bird's mouth [**8**, page 1948] is often also useful for the inner face of an obtuse angle, but such bricks are not easy to cut, as the small angles may be split off. It is advisable, when possible, to dispense with their use.

Hoop-iron Bond. Hoop-iron bond is sometimes introduced into walls to give a bond or tie in the direction of the length. But in walls built with cement mortar it is doubtful if it adds to the strength of the wall materially. It consists of strips of hoop iron about 1½ in. broad and $\frac{1}{20}$ in. thick, which, unless they are laid in cement mortar, should be tarred and sanded to protect them, and in order that the mortar may grip them. It is usual to insert the hoop iron in the mortar joints at certain definite intervals throughout the height of a wall varying from, say, four courses apart to 4 ft. or 5 ft. Each course in which they are used may have several strips of iron. If a joint has to be made in the length of the iron strip a lapped joint is used, and a similar joint is made at the angle of a wall, the two pieces being crossed and the end folded down [**66**]. Hoop iron bond is used in the construction of burglar-proof vaults, and for this purpose hoop iron is laid in every joint, and one strip is used for each half brick in the thickness of the wall, which is built of hard bricks in cement. It is claimed that a structure thus formed will resist even a determined attempt to penetrate it.

Bonding of Facings. It frequently happens, when the appearance of the exterior of a building is a matter of importance, that the bricks used for the face are required to be of a different quality and appearance from those used in the thickness of the wall, and in consequence may be more costly. In bonding such facings with the heart of the wall, if the bricks correspond in size with those used in the general body of the work, the bonding should be carried out exactly as already described for a wall of a uniform quality. The great danger to be feared is that, with a view to economy, half-bats may be employed where headers should be used; for as a true header can be broken into two bats, fewer of the more expensive bricks will be required when this is done; but if this plan is

EXAMPLES OF IRREGULAR BONDING

largely adopted the facing becomes a mere skin of brickwork a half brick in thickness, instead of being, as it should be, an integral part of the wall. It may sometimes happen that the size of the facing bricks differs from that of the bulk of the bricks. When this is the case really satisfactory bonding cannot occur, and such a condition must always be avoided if possible. For example, seven courses of facing bricks may be equal in height to six courses of the general work [71]. If this be so the joints will only correspond so as to form a true horizontal bed at every seventh course of the facings, and all that can be done is to introduce a course of headers at this point, and to build the courses up to the next level bed in stretcher bond.

Bonding Brick with Other Materials. The bonding described hitherto has referred to walls constructed wholly of brick. It frequently happens that for architectural effect or for some other reason part of the wall may be formed of other material, as, for example, terra-cotta or stonework. These materials may be introduced merely in the form of plinths, strings and cornices [67, 70], at quoins [69], and round door and window openings – such work is described under the general term of *dressings*— or it may be used throughout the face of the wall [68]. In the latter case it may form merely a facing, the bulk of the wall being of brick, or the facing material may form the bulk of the wall, with merely an inner lining of brick to take the plastering. This last case, however, arises, as a rule, only when the material employed is of a rough character, such as that from which rubble walls or flint walls are formed. [See Masonry.]

Brickwork and Terra-cotta. The bonding of brick with other materials may be a comparatively simple or a troublesome and costly process. Which it is to be will depend on the care given in preparing the material to be bonded with the bricks. The bricks are of a stock size, and if the work is to be easy in character this must be borne in mind, so that they can be utilised without cutting to any great extent. If terra-cotta be used, it must be specially manufactured for each building in which it is employed; if in moulding it care be taken to see that the height of each course with its mortar joint corresponds exactly with one or more brick courses with their mortar joints, and if the beds are also exact multiples in length and breadth of a half brick, the whole will bond together with ease. But if this be neglected, the terra-cotta, after it is burnt, must not be cut, and if the bricks have to be cut to fit it, this often involves much labour.

Brickwork and Stone. In the case of stone it is usual, except for rubble walls [see Masonry] to dress the stone—*i.e.*, to reduce it to a fair face and to exact dimensions, and such stones can, therefore, usually be made of a size to bond with brickwork without any increase in the cost of working.

In the case of dressings, a string, of which the mouldings have only a slight projection, may be, for example, so designed as to correspond in height with two courses, and on bed to equal a half brick in width from front to back, with here and there a block of material equal to a whole brick [67]. In the case of quoins, whether plain or moulded, these may vary in height from one up to five or six courses [69], or even more, and they are usually arranged so that the widths of successive courses vary by the multiple of a quarter brick to assist in bonding. This is, however, not of such importance as the correspondence in height and width of bed, for it is an easy matter to cut the end off a brick to fit any quoin, even if irregular in form, but if the thickness or breadth of a course will not bond it may involve the reduction, by cutting, of a whole course of bricks.

Stone-faced Walls. Where a wall is to be faced with stone or terra-cotta the work is usually described as *ashlar* [see Masonry], which implies that the stones or blocks are of regular height, length, and breadth, with a regularly dressed face. Such a facing may, of course, be made of any desired thickness, but, on the ground of expense, is often kept thin. The majority of the stones will be of the minimum thickness, but a certain proportion, equal to, say, one-third or one-fourth the area of the face of the wall, will be made thicker, so as to penetrate into the brick backing, and tie the backing and facing together: the difference between this thin and the thick courses should be half a brick or a multiple of half a brick.

In roughly-built stone walls, such as rubble walls, the bulk of the wall is of stone, and if brick is used it will generally be in the main a half-brick thick, with a certain proportion of headers built into the wall either in regular courses or as found convenient, but these should not be less than about one-fourth of the bricks.

Sometimes a flint-faced wall, if of knapped flints [see Masonry], may be built as a facing to a brick wall, and in such a case the bond is usually secured by building in a proportion of extra long flints, so that they penetrate into the brickwork, but sometimes a small proportion of black, vitrified bricks may be used as headers, extending to the outer face of the flint to assist the bond.

Asphalt. Although mineral rock asphalt was first discovered in 1712, it was not commercially adopted as a paving in Paris until 1854, when the first *comprimé* street—*i.e.*, on a concrete foundation—was laid down in the Rue Bergère, in the front of the Conservatoire de Musique, and in London until about ten years later, and it is only in comparatively recent years that its wider uses have been appreciated.

Mineral rock asphalt is a natural product, a pure limestone naturally impregnated with mineral bitumen. The rock when mined or quarried is of a chocolate colour, fine in grain, evenly impregnated with bitumen, which varies from about 6 to 20 per cent. It is usually found in seams or layers from 6 ft. to 30 ft. in thickness, like coal, and is mined in a similar manner. The principal supplies are taken from the Bassin de Seyssel, Haute Savoie, Switzerland; France; Limmer, in Hanover; and Ragusa, in Sicily. The weight of a cubic yard of natural asphalt is about 34½ cwt.

Use of Asphalt. During the last fifty years compressed mineral rock asphalt has stood the severe test of enormously increasing traffic in the principal streets of the City of London, the metropolitan districts, and the provincial cities and towns of the United Kingdom, and has proved to be the most satisfactory sanitary paving that can be laid. It is impervious to moisture, and non-absorbent, and, being jointless, nothing can get into crevices and decay. It has a smooth and even surface, is durable, economical, and quickly laid; and the preparation of compressed rock asphalt is similar to that of mastic asphalt for footpaths, except that the powder is placed in specially designed roasters with revolving cylinders and heated to a temperature of about 280° F. without any admixture whatever of bitumen.

As soon as the superfluous moisture has evaporated, the heated powder is placed in iron-sheathed vans, covered with thick cloths (to retain the heat), and taken to the site where it is to be laid. The asphalt powder is then laid on a Portland cement concrete foundation 6 in. to 9 in. thick, according to the nature of the traffic, well raked over the cement concrete foundation and rammed with hot rammers to the thickness required, then smoothed over with a hot smoothing iron so as to bring sufficient bitumen to the surface, after which a heavy roller is passed over it, while the asphalt is still warm, to straighten and consolidate the surface. When opened to the traffic the asphalt gradually begins to be compressed into solid rock again. In main traffic streets 2½ in. of compressed asphalt are laid on about 9 in. of concrete. In streets of lighter traffic, the practice is 2 in. of compressed asphalt on 6 in. of concrete.

The Asphalt Road. An asphalt road can be constructed exceedingly flat, because a slight gradient is sufficient for rapidly removing the surface water; moreover, the vehicular traffic distributes itself without risk over the entire width of the road, even close up to the gutters, which is not the case, to the same extent, on a stone road. It suffices if, from the apex, which is simply rounded off slightly, two straight lines are drawn as cross or lateral gradients, an extra fall being given to the gutters for a width of about 18 in. As a rule, a lateral fall of 1 in 70 will suffice for the roadway, increased to 1 in 50 at the gutters. For the longitudinal fall 1 in 60 is considered the limit up to which the slipping of horses need not be feared.

The following well-known formula for calculating the camber of asphalt roads has been employed for many years:

$$f \quad c\,\frac{S^2}{S \cdot 7}$$

where f camber (versed sine of arc),
s width of roadway between kerbs,
c coefficient (0·012).

Therefore, the normal camber of a roadway 30 ft. wide would be $0{\cdot}012\,\frac{30^2}{30 \quad 1}$ $0{\cdot}372$ ft. in the centre.

Foundation for Asphalt. The concrete for the foundation should be gauged, six of aggregate to one of Portland cement. On no account must lime concrete be used. The thickness should be regulated according to the weight it has to bear. Cheapside, London, had in 1870, with a then traffic of 400,000 tons per annum per yard of width, a foundation of 9 in. in thickness, and after seven years it was reported to be in good condition. Gracechurch Street, in the same city, with 603,000 tons per yard of width per annum had also 9 in.; while other streets with less traffic had 6 in. Moorgate Street, with upwards of 6,000 vehicles per diem 264,000 tons per annum per yard of width, had a foundation of 6 in.; all these latter streets maintained their surface in good condition. This would go to prove that under the heaviest traffic 9 in. is a sufficient depth, while 6 in. is sufficient for 250,000 tons per annum per yard of width.

It has also been ascertained from cutting into a piece of the already-mentioned roadway in Paris which had been subjected to heavy traffic for 16 years, that it had been reduced in thickness by only three-quarters of an inch.

Bricks for Paving. Bricks as a material for street paving have received very little attention in England, although this country is justly celebrated for the quality of its bricks.

In Holland this class of paving has been in use for about 150 years, and in America about 13 or 14 years, where hundreds of miles have been laid in all sorts of ways and under varying conditions. Bricks obtained from Middlesbrough were laid in Liverpool as a trial in 1881, and a small piece of brick paving to form a carriageway was laid at Cheltenham in 1900. This paving was laid on a sand cushion with a foundation of 6 in. of cement concrete, the bricks being grouted in with pitch. The standard specification for the construction of brick carriageways adopted in the United States of America is as follows:

SUBSTRUCTURE, OR GRADING. Earth in excavation to be removed with plough and scraper or other device to within 2 in. of subgrade, then brought to true grade with the roller, the weight of which should be not less than 5 tons, or more than 8 tons. If the earth is too hard to receive compression through the weight of the roller, then loosen the remaining 2 in. with a pick and cart away. Earth in embankment must be applied in layers of 8 in. in thickness, and each layer thoroughly rolled; and in both excavation and embankment the subgrade must have a uniform density. If the ground is a spouty clay, tile drainage should be provided, to carry off the accumulation of wet.

CURBING. If cement is used, it should be completed; if stone, all should be hauled and distributed and set before the grading is finished, and it may then be used as a guide to finish the subgrade.

It should range in thickness from 4 in. to 6 in., and from 20 in. to 24 in. wide, the business and street traffic governing the same, and the lengths should not be shorter than 5 ft., except at closures. The top to be neatly dressed with a square or rounded outer edge, and 4 in. down on the inside. The outer surface to be tool-dressed to the depth of the face exposed, and to the depth of the thickness of the brick and sand cushion.

The intersection at street corners and alleys should be circular, with radius of 4 ft. and 3 ft. respectively.

MARGINAL CURB. These should always be of a hard and durable character of stone, and from 14 in. to 18 in. deep, dressed on top and 5 in. down on the face next to the brick, and should be set accurately, to fit the curvature of the cross section of the street on 6 in. concrete, and backed up with the same within 6 in. of the top.

CONCRETE FOUNDATION. Crushed stone should be of approved quality of hard rock, with no fragment larger than will pass through a 2 in. ring, and none smaller than will pass through a 1 in. ring in their longest dimensions, free from all refuse and foreign matter.

SAND. Sand must be clean, sharp, and dry, and thoroughly mixed in its dry state until the whole mass shows an even shade, with an approved brand of either hydraulic or Portland cement. If of hydraulic, the proportion of mixture should be one part of cement and two parts of sand. If of Portland cement, one part of cement and three parts of sand. To the above mixture should be added sufficient clean water to mix to a plastic mass, fluid enough to subside rapidly when attempting to heap to a cone shape. To this mixture add four and five parts respectively of damp crushed stone or clean screened gravel, and turn the whole mass over not less than three times, or until every fragment is thoroughly coated with the cement mixture. For the reception of this mixture the grade should be set off in 5 ft. squares, with a stake at each corner. Tops of each should be at the surface of concrete, which must be tamped until free mortar appears on the surface. Occasional sprinkling in extreme hot, dry weather is beneficial. After 36 hours the cushion sand may be spread.

SAND CUSHION. Sand should be clean, and free from foreign or loamy matter. It need not necessarily be sharp. It should be 2 in. thick before the compression of the brick by rolling. The sand should be spread by the aid of a template the whole or one-half the width of the street, and made to conform with the true curvature of the street cross section.

BRICK. The brick should all be hauled and neatly piled inside the kerb line before grading is finished, or, if allowed by the engineer, delivered on the street in waggons and carried from the pile or waggon on pallets or with clamps, and not wheeled with barrows. They should be first class and thoroughly vitrified, showing at least one fairly straight face, with rounded edges, with no greater radius than $\frac{3}{16}$ in. They should not be less than 2½ in. by 4 in. by 8 in., or more than 3½ in. by 4 in. by 9 in., free from cracks, with but slight lamination, and at least one edge with but slight kiln marks allowed. Such bricks or blocks shall be submitted to a test of one hour in the National Brick Manufacturers' Association standard rattler and under the conditions prescribed by that association; and if the loss by abrasion during such test exceeds 20 per cent. of the original weight of the brick tested, then bricks or blocks shall be rejected.

BRICKLAYING. Bricks should be laid perpendicular to the kerb. Broken brick or block can only be used to break joint in starting courses or in making closures. The bricks shall be laid on edge, close together, in straight lines across the roadway between gutters. Gutters shall be constructed as directed by the engineer. After the bricks are laid they shall be thoroughly inspected, and all warped, spalled, and soft bricks removed and replaced by more perfect ones, and those found with the bad face up should be turned down.

TAMPING and ROLLING. After the inspection is thus completed the edge of the pavement shall be tamped to grade next to the kerb, to the width of 6 in. or 8 in. out from the kerb, with a hand tamper. The entire pavement shall then be rolled with a 5-ton steam roller until all bricks are thoroughly bedded, and the whole surface assumes a practical plane.

EXPANSION CUSHION. An expansion cushion must be provided for of 1 in. thickness next to the kerb, filled to two-thirds of its depth with pitch, the top one-third being filled with sand; and a like cushion at right angles with the street at intervals of 50 ft.

THE FILLER. The filler shall be composed of one part each of clean, sharp sand and Portland cement. The sand should be dry. The mixture, not exceeding one-third bushel of the sand, together with a like amount of cement, shall be placed in the box and mixed dry until the mass assumes an even and unbroken shade. Then water shall be added, forming a liquid mixture of the consistency of thin cream. From the time the water is applied until the last drop is removed and floated into the joints of the brick pavement, the same must be kept in constant motion. The mixture shall be removed from the box to the street surface with a scoop shovel, all the while being stirred in the box while it is being emptied. The box for this purpose shall be 3 ft. 6 in. to 4 ft. long, 27 in. to 30 in. wide, and 14 in. deep, resting on legs of different lengths, so that the mixture will readily float to the lower corner of the box, which should be from 8 in. to 10 in. above the pavement. This mixture, from the moment it touches the brick, shall be thoroughly swept into all the joints. Two such boxes shall be provided, in case the street is 20 ft. or less in width; exceeding 20 ft. in width, three boxes should be used. The work of filling should be thus carried forward in line until an advance of from 15 yd. to 20 yd. has been made, when the same force and appliances shall be turned back, and cover the same space again in like manner, except that the mixture for the second coating may be slightly thicker than the first. To avoid a possibility of the grout thickening at any point, there should be a man with a large sprinkling can, having the head perforated with small holes, sprinkling gently the surface ahead of the sweepers. This should be done in the application of each course specified. After the joints are thus filled flush with the top of the bricks, and sufficient time for evaporation has taken place, so that the coating of sand will not absorb any of the mixture, one half of sand shall be spread over the whole surface, and, in case the work is subjected to a hot summer sun, an occasional sprinkling, sufficient to dampen the sand, should be followed for two days or three days. The grouting thus finished must remain absolutely free from disturbance or traffic of any kind for a period of ten days.

Cork Asphalt. Cork asphalt is a compound consisting of bitumen and certain other materials, including cork. It has been used in different parts of the world for a number of years, and possesses all the necessary features which constitute a good paving material. It is durable and elastic, and being non-absorbent to moisture, is therefore hygienic and sanitary. It is comparatively noiseless, and also non-slippery; and, therefore, it is unnecessary in wet weather to sprinkle the surface with sand or fine gravel as is requisite with other pavements. The result of this is that there is a marked absence of mud, and, in dry weather, of dust. These properties make it invaluable for public roadways, especially as freedom from noise, dust and such discomforts is an object. It is claimed that no other pavement possesses such valuable characteristics, and cork asphalt is thus pre-eminently suitable for all classes of traffic, horse, motor, or otherwise. It is manufactured in the form of homogeneous blocks of uniform size, and the surface, when laid, is regular and even. Frost does not so readily act on it as on other classes of pavement.

The first cost of cork asphalt compares favourably with that of other pavements, and the cost of upkeep is much less, owing to its durable nature.

This class of road pavement has been largely used by H.M. Office of Works, at Buckingham Palace and Windsor Castle. The Paddington Vestry and the St. George's (Hanover Square) Vestry have applied cork asphalt with great success, and it has also been used by numerous provincial boroughs and corporations, such as Bournemouth, Eastbourne, and Newmarket.

Cork Asphalt in Railway Stations. Most of the principal railway companies have employed cork asphalt with satisfactory results, and among them may be mentioned the Great Eastern, the Great Northern, the North Eastern, the London and South Western, the Caledonian, and the North British railway companies. It is in use at Liverpool Street, King's Cross, Waverley (Edinburgh), and other stations.

This pavement is manufactured in blocks similar to wood blocks in sizes from 9 in. by 4½ in. by 1 in. thick to 9 in. by 4½ in. by 2 in. thick. It is laid on a concrete foundation, its cost compares favourably with that of wood, and its average life is longer.

Gutta-percha Paving. Gutta-percha, like cork, is the ideal of noiselessness, but is in a very experimental stage as yet, and has hardly come within the scope of practical consideration. A small piece is laid at the entrance to Euston Station, London, and in small, short sections at Glasgow. The sheets are laid down at their sides upon a concrete foundation by strips of iron, which clasp the edges tight on each other. Indiarubber in large sheets about 1 in. in thickness has been introduced in Hanover as a material with which to pave roads.

Granite Setts. A street pavement composed of this material has been in use for many years. This system was introduced into the country by the Romans. The size of the paving stones was, however, much larger than modern science finds necessary. One of the first granite pavements laid was that known as the "Euston pavement." This class of pavement consists of squared setts (the most general size being 6½ in. by 3½ in. by 5 in. to 7 in. long), laid on a concrete foundation consisting of cement concrete, the only reliable material. It should never be laid less than 6 in., while 9 in. will carry the heaviest traffic. The concrete should be composed as follows:

Six parts of screened ballast or gravel — all of which will pass through a screen of 2½ in. mesh — and one part of Portland cement, all thoroughly mixed upon a platform and used while in a semi-liquid state. The resultant mixture of one ton of cement when mixed in the proportion of six to one is about seven cubic yards of concrete. This will cover an area of 42 super. yd. 6 in. deep, and will take four labourers one day for mixing and laying.

Laying Granite Setts. As the concrete is laid in the trench the top surface should be brought to the proper camber with the shovel. For ordinary traffic, Aberdeen or Norway granites are largely used; these are bedded on a sand packing free from small stones or pebbles, and average 1 in. in thickness, and laid touching one another, each stone being so firmly bedded on the packing that it has not to rely on the next one for support, and the setts laid to break joint. The ramming requires careful supervision, as, in order to avoid the trouble of lifting badly-laid setts, the men often try to get an even surface by ramming the high stones extra hard, and omitting to ram the low-lying stones, or stones inclined to give too much.

Local Practice. In the North of England and other places the joints are first filled with clean pebbles, after which the surface is well rammed, and then run with an asphaltic mixture, and covered with a layer of fine gravel, while in the South of England, the finished surface is usually grouted over with a liquid prepared from sand and lias lime, or Portland cement, and well washed into the joints. No traffic should be permitted on a newly-laid pavement of this class for 14 days. One ton of setts of the size mentioned will cover 3·6 superficial yards, and a pavior will lay an average of 30 superficial yards per day of 10 hours.

Macadam. The word "Macadam" is derived from Mr. John Loudon Macadam, the originator of macadam roads [1]. For this class of road, the ground is excavated in the usual manner to an approximate circular segment, and the foundation formed of "hard core," a term applied to a heterogeneous mixture consisting of chalk, broken stone, bricks, dry rubble, clinkers, and other dry and hard materials.

The thickness of the hard core depends on the nature of the subsoil, but 6 in. may be regarded as the minimum thickness, and this should be consolidated by rolling, all hollow places being filled in and made level. Upon this, a thin layer of dug flints or gravel should be uniformly spread and consolidated.

Then, to receive and withstand the wear and tear of the traffic, a 6 in. coating of stones or granite, broken to pass all ways through a ring of 2½ in. internal diameter, should be laid down, and well consolidated by watering and rolling, a little binding material being lightly scattered and swept in over the surface on completion.

Material for Macadamising. It is almost impossible to lay down any hard and fast line as to the material to be used over the whole kingdom for this description of road, as nearly every English county produces descriptions of stones, all suitable in a greater or less degree as a road-making material; but where the material is soft, it will be found economical to obtain a harder stone or granite from a distance, as the hardest description of stone should always be prepared. Those now commonly in use are basalt, Aberdeen, Guernsey, and other granites, Mountsorrel and Hartshill and Leicestershire stone. Picked slag, hill picked surface and land-dug flints, and gravel, are also largely used for suburban side streets and rural roads where the traffic is not heavy. The relative cost of granite as a road metal and flints or gravel is roughly as 1 to 3.

Cherbourg Quartzite in England. Until 1885, this material was little known in England. At that date, the first cargo was imported and laid upon a length of road situated close to Gravesend, and remained eight years without needing repairs.

The natural cautiousness of the English engineer when dealing with something which has not been proved, has prevented this material from being classed with other granite as a road material.

Rules for Laying Macadam. A rule to find the area of surface that can be covered by 1 cubic yard of broken material is as follows:
